In situ Synchrotron IR Microspectroscopy of CO₂ Adsorption on Single Crystals of the Functionalized MOF Sc₂(BDC-NH₂)₃**

Alex Greenaway, Berenice Gonzalez-Santiago, Paul M. Donaldson, Mark D. Frogley, Gianfelice Cinque, Jorge Sotelo, Stephen Moggach, Elenica Shiko, Stefano Brandani, Russell F. Howe,* and Paul A. Wright*

Abstract: Synchrotron radiation (SR) IR microspectroscopy has enabled determination of the thermodynamics, kinetics, and molecular orientation of CO₂ adsorbed in single microcrystals of a functionalized metal–organic framework (MOF) under conditions relevant to carbon capture from flue gases. Single crystals of the small-pore MOF, Sc₂(BDC-NH₂)₃, (BDC-NH₂ = 2-amino-1,4-benzenedicarboxylate), with well-defined crystal form have been investigated during CO₂ uptake at partial pressures of 0.025-0.2 bar at 298–373 K. The enthalpy and diffusivity of adsorption determined from individual single crystals are consistent with values obtained from measurements on bulk samples. The brilliant SR IR source permits rapid collection of polarized spectra. Strong variations in absorbance on bulk samples. The brilliant SR IR source permits rapid collection of polarized spectra. Strong variations in absorbance at different orientations of molecules adsorbed within the MOF, Sc₂(BDC-NH₂)₃, as a carbon capture sorbent, through measurement of the heat of adsorption and the rate of desorption. This MOF shows enhanced uptake of CO₂ over its unfunctionalized variant[9] and the amino groups in the MOF exhibit properties that make them strong candidates for post combustion carbon capture, including acceptable uptakes of CO₂ and high selectivity, regenerability, and stability to water.[1] The conventional approach to assess a potential sorbent is to acquire adsorption isotherms at relevant temperatures. However, this can be slow, even when only single component adsorption is performed—the collection of multicomponent isotherms is much more demanding.[12]

IR spectroscopy is widely used to follow the uptake of CO₂ on powdered samples of microporous sorbents, where absorption frequencies and intensities give information on the type and amount of adsorption and variable temperature studies give enthalpies and entropies of uptake that can be compared to values determined by other methods, such as analysis of isotherms or calorimetry.[3–6] Where single crystals are available, IR microspectroscopic analysis (combined optical microscopy and IR spectroscopy) has been used for the determination of concentration-dependent diffusion parameters of hydrocarbons.[7,8] Here, we have used for the first time synchrotron-based single-microcrystal Fourier transform IR spectroscopy coupled with optical microscopy to quantify the performance of an amino-functionalized MOF, Sc₂(BDC-NH₂)₃, as a carbon capture sorbent, through measurement of the heat of adsorption and the rate of desorption. This MOF shows enhanced uptake of CO₂ over its unfunctionalized variant[9] and the amino groups in the MOF act as an internal reference for IR analysis. Furthermore, we make use of single-crystal microspectroscopy with polarized IR light to determine the orientation of adsorbed CO₂ molecules. For crystalline samples in which the orientation of the lattice can be associated with the external morphology of the crystal, single-crystal-polarized IR spectroscopy is able to determine the orientation of molecules adsorbed within the micropores.[10] Synchrotron IR radiation (which gives an about 100-fold increase in photon flux density over Globar laboratory sources) yields a large improvement in the signal-to-noise ratio so that high quality direction-dependent polarized IR spectra can be measured for anisotropic...
The first set of experiments investigated the kinetics and thermodynamics of CO₂ adsorption on single crystals of Sc₂(BDC-NH₂)₃ under a gas flow of 10% CO₂ in helium at temperatures relevant to temperature swing adsorption processes. Sites were selected on crystals under the microscope, bearing in mind that the incident beam size giving spectra with good signal-to-noise ratio (above 1000) was approximately 10 × 10 μm². MicroFTIR spectra were measured in transmission using a 15 × objective/con-denser with 512 scans (80 s) per point, at 2 cm⁻¹ resolution. More than 20 sites were chosen both on different crystals and also on the same crystal (Figure 1c). Spectra were taken using non-polarized IR radiation at 298 K on crystals pre-heated to 400 K, all in a dry He flow. The spectra were of such good quality that the asymmetric and symmetric NH₂ stretches were clearly visible, at 3513 and 3396 cm⁻¹ respectively. Switching the gas flow to 10% CO₂ in He enabled spectra to be measured in the presence of gas-phase CO₂. The background signal from gas-phase CO₂ could be subtracted successfully. The asymmetric stretching vibration of adsorbed CO₂ occurred at 2333 cm⁻¹, 15 cm⁻¹ below the gas-phase value. It was accompanied by a weak shoulder at about 2324 cm⁻¹. The relative intensity of the lower frequency shoulder remained constant independent of CO₂ loading (see the Supporting Information for the spectra). Switching to pure He resulted in a rapid decrease of the adsorbed CO₂ signal to 1% of its original value within 2 minutes, indicating rapid diffusion within the MOF. This was confirmed by zero length column experiments on a 13 mg sample, which follow desorption of CO₂ from a thin wafer of powder. These showed that desorption is 99% complete within a few tens of seconds at the flow rates used in the IR experiment (see the Supporting Information for details). Analysis shows that although the desorption is too fast to permit calculation of the diffusional time constant, an upper bound of R²/D of 5.3 s can be estimated,[13] corresponding to a lower limit for diffusivity along the channels, D, of 3 × 10⁻¹⁰ m² s⁻¹, higher than measured in different methods for zeolite 5A.[14]

In the light of this, an experiment was conducted in which spectra were measured on the selected crystal sites in the presence of 10% CO₂ as the temperature was raised stepwise from 298 to 393 K. The sample was allowed to equilibrate for approximately 5 minutes at each temperature before unpolarized IR spectra were collected. As the temperature was increased the magnitude of the adsorbed CO₂ asymmetric stretch decreased relative to the size of the peaks associated with the NH₂ stretches (see Figure 2 for a series of spectra from a single point). This indicates that the concentration of adsorbed CO₂ decreases with increasing temperatures, as expected for exothermic adsorption. Subsequently, similar series of experiments were performed as the partial pressure of CO₂ was adjusted to 0.025, 0.050, and 0.2 bar. Above this pressure the absorption from gas-phase CO₂ precluded accurate measurement.

IR spectra were analyzed using the OPUS 7.2 software.[15] Integrals were calculated for the NH₂ symmetric and asym-
metric stretches and the CO$_2$ asymmetric stretch. The combined integral associated with the NH$_2$ stretches was used as an internal reference to quantify the uptake of CO$_2$, by calculating the ratio of the integral of the CO$_2$ asymmetric stretch to that of the NH$_2$ region. At 100 mbar CO$_2$ and 298 K the specific uptake of CO$_2$ on Sc$_2$(BDC-NH$_2$)$_3$ was known from gravimetric measurements to be 0.393 mmol/g. Measured peak area ratios were used to estimate the uptakes at each temperature in each isobar. Figure 3a shows the calculated uptake at 0.1 bar on the single crystal shown in Figure 1c. The variation of the uptakes at 0.1 bar measured by IR spectroscopy on single crystals and from gravimetric isotherms (see the Supporting Information) shows good agreement. Figure 3b shows the uptake from several crystals for isobars at 0.025, 0.05, 0.1, and 0.2 bar CO$_2$.

The uptakes were used to calculate a fractional coverage and hence a value for the equilibrium constant $K$ for adsorption according to the equilibrium, CO$_2$(g) + S$\rightarrow$CO$_2^-$ (ads), where S is the adsorption site. Full coverage was taken as 5.1 mmol/g. The heat of adsorption for CO$_2$ in Sc$_2$(BDC-NH$_2$)$_3$ was calculated using these single-crystal data to be 31 ± 2 kJ mol$^{-1}$ from plots of $\ln K$ vs. $1/T$ (see the Supporting Information). This agrees with the isostERIC heats calculated from a series of adsorption isotherms at different temperatures, the average of which was 31 ± 3 kJ mol$^{-1}$. The heats of adsorption on the amino-functionalized material are higher than those reported previously on Sc$_2$BDC$_3$ (23 kJ mol$^{-1}$).[8] This is the result of interactions of CO$_2$ with NH$_2$.

IR spectroscopy can also be sensitive (in terms of frequency shifts) to molecular interactions. Upon CO$_2$ adsorption on Sc$_2$(BDC-NH$_2$)$_3$, the peak maxima for the symmetric and asymmetric NH$_2$ stretches shift by approximately 5 cm$^{-1}$ to lower values (3396 to 3392 cm$^{-1}$; 3513 to 3508 cm$^{-1}$, respectively) suggesting a weak additional interaction between the NH$_2$ groups and CO$_2$.

It is therefore possible to determine the rates, heat, and nature of adsorption of CO$_2$ on single crystals using IR microspectroscopy under realistic conditions. While these could be obtained from bulk samples, the microscopic approach can measure variation between different crystals. Furthermore, and importantly, synchrotron IR single-crystal microspectroscopy can give information inaccessible to bulk methods, in particular by the use of a polarized IR beam.

To understand the adsorption of CO$_2$ onto the MOF, non-polarized and polarized IR spectra were collected from crystals orientated parallel or perpendicular to the holographic ZnSe wire grid polarizers used to define the electric field direction of the IR beam being detected. The crystals of Sc$_2$(BDC-NH$_2$)$_3$ have well-defined facets, so that it is possible from the optical image to establish the crystal orientation with respect to the polarized beam: crystals were found to settle in one of three ways: with their (001), (011) or (010) plane parallel to the window (and perpendicular to the plane of the polarized IR light). Schematic representations of these orientations (illustrated by SEM micrographs) are shown in Figure 4. Spectra were collected at 298 K using unpolarized IR light and also IR light polarized parallel and perpendicular
to the crystal length, on activated crystals and in 0.1 bar CO$_2$.
Integrals were calculated for the NH$_2$ symmetric and the CO$_2$
asymmetric stretches, to enable details of the orientation of adsorbed molecules in the functionalized framework to be measured (see the Supporting Information).

In each case the polarized FTIR spectra reveal that the absorbance of the NH$_2$ symmetric stretch increases when the polarization is parallel to the long direction of the crystal, indicating that the CPh/C0 bonds aligned along the channels. Very similar NH$_2$ absorbance behavior is observed in crystals with and without adsorbed CO$_2$, suggesting that there is no significant re-orientation of the ligands upon uptake of CO$_2$. Furthermore, the CO$_2$ asymmetric stretch intensity is enhanced when the IR light is polarized along the crystal length, indicating that the average alignment of the CO$_2$ molecules is oriented along the channels.

A more quantitative estimation of the CO$_2$ alignment can be made if the structure of Sc$_2$(BDC-NH$_2$)$_3$ is considered (Figure 1d and Figure 4). Intensities of polarized SR IR spectra vary strongly according to orientation, but by comparing the relative enhancement or suppression of the CO$_2$ asymmetric stretch with respect to the symmetric NH$_2$ stretch (which is expected to give a dipole change parallel to the CPh–N bond) it is possible for each of the projections to determine whether the CO$_2$ molecules are aligned more or less closely to the channel axis than the net CPh–N vector. Furthermore, the CO$_2$ asymmetric stretch intensity is enhanced when the IR light is polarized along the crystal length, indicating that the average alignment of the CO$_2$ molecules is oriented along the channels.

A more quantitative estimation of the CO$_2$ alignment can be made if the structure of Sc$_2$(BDC-NH$_2$)$_3$ is considered (Figure 1d and Figure 4). Intensities of polarized SR IR spectra vary strongly according to orientation, but by comparing the relative enhancement or suppression of the CO$_2$ asymmetric stretch with respect to the symmetric NH$_2$ stretch (which is expected to give a dipole change parallel to the CPh–N bond) it is possible for each of the projections to determine whether the CO$_2$ molecules are aligned more or less closely to the channel axis than the net CPh–N vector. (It is not possible to locate the amine hydrogen atoms by diffraction, so we have not analyzed directional information from the asymmetric stretch.) The CPh–N vectors for all of the possible orientations of amino groups on the terephthalate ligands were measured from projections of the single-crystal structure down [001], [011] and [010], and a weighted average of their deviation from the [100] axis was determined (see the Supporting Information). The net CPh–N vector is close to parallel to the channel axis in the MOF (17$^\circ$ off-parallel viewed down [001], 13$^\circ$ off-parallel viewed down [011], and 11$^\circ$ off-parallel for [010]). The intensity of the asymmetric stretch of the linear O=C=O molecule is enhanced relative to the NH$_2$ symmetric stretch using IR light polarized along the crystal length when viewed down [001] (by ca. 90%) and [011] (by 23%) but is suppressed when viewed down [010] (by 17%). The projection of the CO$_2$ molecule is therefore more closely aligned to the channel axis than 17$^\circ$ when viewed down [001] and makes a larger angle than 11$^\circ$ when viewed down [010], in effect enabling triangulation of the relative orientation of the CO$_2$ molecules’ orientation in the channel, which is on average closer than approximately 20$^\circ$ to the channel axis.

A powerful new SR FTIR microspectroscopic technique has been developed which permits the rapid analysis of adsorption by porous materials under flowing gas conditions relevant to carbon capture. Investigations on an amino-functionalized MOF give a heat of adsorption and desorption rates on a single crystal and polarized IR light has been used to show a strong orientation dependency of adsorbed CO$_2$ molecules within the pores of Sc$_2$(BDC-NH$_2$)$_3$, even at rather low uptakes, a result which is experimentally difficult to attain by other means. Whereas previous diffraction measurements have located adsorbed CO$_2$ on MOFs at room temperature at loadings down to approximately 1 mmolg$^{-1}$,

[17] these IR measurements give acceptable signal-to-noise ratios for the asymmetric stretch of adsorbed CO$_2$ at < 0.1 mmolg$^{-1}$ (fractional site occupancies < 0.015). Furthermore, the method has the potential to follow temporal and spatial variation over a single crystal and so to determine adsorbate diffusivities. Although the diffusion of CO$_2$ in Sc$_2$(BDC-NH$_2$)$_3$ is too fast to
permit this, there are many examples of more slowly diffusing, IR-active molecules (e.g. H\textsubscript{2}O, N\textsubscript{2}O, small hydrocarbons or organics) in other porous solids than can be studied in this way, even when part of adsorbing mixtures, especially when developments in full field FTIR imaging using synchrotron radiation IR brilliance can offer faster acquisition and a larger field of view (see the Supporting Information).

The results reported here confirm the potential of amino-functionalized MOFs as carbon capture materials and indicate that in situ single-crystal gas adsorption and polarized IR microspectroscopy can rapidly provide unique insights into single- and eventually multi-component adsorption processes.
