Engineering improved bio-jet fuel tolerance in *Escherichia coli* using a transgenic library from the hydrocarbon-degrader *Marinobacter aquaeolei*

Timothy A. Tomko and Mary J. Dunlop*

**Abstract**

**Background:** Recent metabolic engineering efforts have generated microorganisms that can produce biofuels, including bio-jet fuels, however these fuels are often toxic to cells, limiting production yields. There are natural examples of microorganisms that have evolved mechanisms for tolerating hydrocarbon-rich environments, such as those that thrive near natural oil seeps and in oil-polluted waters.

**Results:** Using genomic DNA from the hydrocarbon-degrading microbe *Marinobacter aquaeolei*, we constructed a transgenic library that we expressed in *Escherichia coli*. We exposed cells to inhibitory levels of pinene, a monoterpene that can serve as a jet fuel precursor with chemical properties similar to existing tactical fuels. Using a sequential strategy with a fosmid library followed by a plasmid library, we were able to isolate a region of DNA from the *M. aquaeolei* genome that conferred pinene tolerance when expressed in *E. coli*. We determined that a single gene, *yceI*, was responsible for the tolerance improvements. Overexpression of this gene placed no additional burden on the host. We also tested tolerance to other monoterpenes and showed that *yceI* selectively improves tolerance.

**Conclusions:** The genomes of hydrocarbon-tolerant microbes represent a rich resource for tolerance engineering. Using a transgenic library, we were able to identify a single gene that improves *E. coli*’s tolerance to the bio-jet fuel precursor pinene.

**Keywords:** Biofuel tolerance, *Marinobacter aquaeolei*, *YceI*, Pinene, Monoterpene, Genomic library, Transgenic

**Background**

Microorganisms are capable of producing advanced biofuels that can be used as ‘drop-in’ alternatives to conventional petroleum-based liquid fuels [1–3]. However, many of these fuels are toxic to cells, introducing an undesirable trade off between cell survival and biofuel production. There are many natural examples of microorganisms that survive in hydrocarbon-rich environments [4, 5]. We asked whether the genomes of these microbes could be a source of biofuel tolerance mechanisms when expressed heterologously in a biofuel production host.

Microbes that tolerate hydrocarbons have been isolated near natural oil seepages and around oil spills. For example, a hydrocarbon-degrading microbe, *Marinobacter aquaeolei* VT8, was isolated at the head of an offshore oil well in Vietnam [6]. A previous study showed that this organism harbors two efflux pumps that can serve to improve biofuel tolerance [7]. That study also identified an efflux pump from *Alcanivorax borkumensis*, which is another hydrocarbon-degrader that thrives in oil-polluted waters. In addition to the ability to metabolize hydrocarbons, *A. borkumensis* possess multiple tolerance mechanisms, including the production of biosurfactants, efflux pumps, and niche-specific stress responses [8]. Studies of the microbial communities in the Gulf of Mexico after the Deepwater Horizon oil spill showed a high
and those that survive are screened using microarrays. Members of the library are then subjected to a stressor of choice, and transformed into the host. Cells containing sizes appropriate for subcloning, inserted into the vector, and have appeared in screens for tolerance genes [18, 25]. Stress response proteins can also mitigate biofuel toxicity; recent examples include [22–24]. General tolerance does not lead to an increase in biofuel production [26]. Other studies involving the overexpression of endogenous genes have shown improvements in isobutanol and ethanol tolerance in *Saccharomyces cerevisiae* [27], and ethanol [28] and n-butanol [22] tolerance in *E. coli*. A small number of studies have used transgenic DNA libraries to improve tolerance in processes related to biofuel production. Zingaro et al. identified several tolerance mechanisms from *Lactobacillus plantarum*, that when expressed in *E. coli* show improved survival and growth under ethanol stress [29]. Ruegg et al. increased ionic liquid tolerance in an *E. coli* host by screening a fosmid library from *Enterobacter lignolyticus* for tolerance genes [30]. Genomic libraries represent an efficient way of screening many genes for desirable traits and transgenic libraries extend this approach to a potentially rich resource of tolerance genes.

There are many examples of studies where screening for genes that improve tolerance to exogenous addition of biofuel has proved successful in identifying tolerance genes that also improve biofuel yields. For example, in a recent study of isopentanol tolerance in *E. coli*, six out of eight of the genes that were found to improve tolerance to exogenous biofuel also increased production titers [31]. An efflux pump that was identified to improve tolerance to limonene also increased yield in a production strain [7]. A study performed in *Saccharomyces cerevisiae* showed that improved ethanol tolerance translates to a more efficient glucose to ethanol conversion rate [32]. However, there are counterexamples where improved tolerance does not lead to an increase in biofuel production, for example Atsumi et al. identified mutations that improved isobutanol-tolerance in *E. coli*. However their mutants did not yield higher titers of the biofuel product [33]. Due to the burden biofuel production pathways place on the cell, it is often more straightforward to screen for tolerance improvements with exogenous biofuel addition and later incorporate the tolerance strategy into a production strain. This approach has proved successful in many previous studies, and in this work we screen for pinene tolerance using exogenous addition of the biofuel.

Our overall goal was to identify novel biofuel tolerance genes from a hydrocarbon-tolerant microbe that could be used in *E. coli*. Using a transgenic library approach, we first used a fosmid library with *M. aquaeolei* VT8 genomic DNA inserts and isolated a single fosmid that improved pinene tolerance. We then made a plasmid
sub-library from this fosmid DNA, which narrowed the field to two candidate genes. These genes were subcloned into new plasmids and tested for tolerance improvements. We identified a single gene, *yceI*, which provides improvements in pinene tolerance. Importantly, expression of *yceI* was not toxic under any of induction conditions we tested. The tolerance improvements also extended to another monoterpen, terpinolene, though not limonene or terpinene. In this study, we describe an approach for bioprospecting for new tolerance genes from microbes that survive in hydrocarbon-rich environments. As a proof of principle, we show that we are able to identify a single gene that can improve tolerance to the bio-jet fuel pinene without introducing additional toxic effects.

**Results and discussion**

To screen and identify genes that confer biofuel tolerance to *E. coli*, we created a transgenic library from *M. aquaeolei* VT8 genomic DNA (Methods). To provide good coverage and potentially include complex biofuel tolerance mechanisms that involve multiple genes we used relatively large (~40 kb) inserts to construct a fosmid library, which we screened in *E. coli*. Based on colony counts, we estimate that our library covers 100 % of the *M. aquaeolei* genome with 99.9 % certainty [34] (“Methods”). The *M. aquaeolei* fosmid library was screened in 0.05 % (v/v) pinene over the course of 96 h, using serial dilutions into fresh media with pinene every 12 h (Fig. 1a). We selected this pinene concentration because it severely inhibited growth of the negative control, while cultures with the library survived (see Additional file 1: Fig. S1). In principle, cells that contain the most beneficial transgenic DNA in the population stressed with pinene should outcompete other cells that do not have advantageous genes. We conducted parallel control experiments where we grew the library in the absence of pinene; we also included a fosmid negative control, where we grew cells without the library in the presence of pinene. The latter controls for *E. coli* genomic mutations that may arise due to pinene stress. We verified that cultures grown from a single colony isolated at the final time point were able to grow better in pinene than the samples with the control fosmid (see Additional file 2: Fig. S2).

At the 0, 24, 48, and 96-h time points we plated cells to isolate single colonies, extracted fosmids, and sequenced to check for library convergence. As expected, at 0 h all three samples that were sequenced were unique since no stress had been applied to the library yet (see Additional file 3: Table S1). Again, after 24 h, all sequenced samples were unique with no overlap between the inserts. By 48 h the three sequenced samples were identical and matched...
those that were subsequently extracted at the 96-h time point. We note that one of the three fosmids sequenced from the 24-h time point overlapped the fosmid sequence from 48 and 96 h, but the start and end points of the sequence differed. We refer to the converged fosmid here as pCC1FOS-96. The insert contained in pCC1FOS-96 had 43 complete genes from M. aquaeolei. The next step was to determine which gene or genes were conferring pinene tolerance to E. coli.

To efficiently screen for beneficial genes, we created a sub-library using the fosmid pCC1FOS-96 as the starting template. pCC1FOS-96 DNA was partially digested using the restriction enzyme Sau3A1. Cut sites for Sau3A1 (GATC) appear frequently in the sequence, so we used a partial digest, controlling the length of the reaction and the units of enzyme added (“Methods”). We extracted DNA in the 4–12 kb range, selecting this size to allow for complete genes or the possibility of multiple genes without creating inserts that would be prohibitive for cloning or those that return so many genes that it would be difficult to determine contributions. We cloned the inserts into the medium copy vector pBBa5k [35], using E. coli MG1655 for all subsequent experiments. In order to screen for genes that conferred tolerance, we repeated the selection procedure, stressing cells with 0.05 % pinene over the course of 96 h, as we did with the fosmid library (Fig. 1a). We conducted the same control experiments as in the fosmid library, replacing the negative control fosmid with pBBa5k-rfp, which expresses red fluorescent protein and does not confer pinene tolerance. Upon completion of the selection experiment, all colonies sampled contained identical plasmids, which we refer to as pBBa5k-96. We extracted and retransformed this plasmid into fresh E. coli MG1655 cells to control for the possibility that improvements in tolerance were due to genomic mutations, however the freshly transformed cells retained improved tolerance. This indicated that the presence of the pBBa5k-96 plasmid was responsible for conferring tolerance.

The plasmid pBBa5k-96 contains two complete genes from M. aquaeolei with additional truncated genes on each side (Fig. 1b). The complete genes encode for a YceI-family protein, Maqu_1680 [GenBank:YP_958951.1], and a hypothetical protein, Maqu_1681 [GenBank:YP_958952.1]. To determine which gene or genes were responsible for providing increased pinene tolerance, we subcloned the two complete genes individually and together into pBBa8k medium copy vectors [35]. The plasmid contains an arabinose-inducible pBAD promoter, allowing us to control the level of gene expression. Using 100 μM arabinose we tested the tolerance of cells containing plasmids with the individual and combined genes (Fig. 2a). Under no pinene stress, cells with YceI grew comparably to the negative control, while all cells expressing the hypothetical protein (alone, in combination with YceI, and on the original pBBa5k-96) experienced a reduction in growth. When exposed to 0.15 % pinene, only cells with the YceI protein showed improvements in growth relative to the negative control. Statistical analysis showed a significant benefit to having YceI in the samples when pinene is both present and absent (p value <0.001, ANOVA with Dunnett’s test). There was no statistical difference between samples with and without the hypothetical protein in the presence of pinene.

YceI-family proteins are diverse and remain largely uncharacterized. The YceI-like protein TT1927B from Thermus thermophiles HB8 functions as an isoprenoid transport or storage protein and may serve as a part of an unknown isoprenoid metabolic pathway [36]. The crystal structure for the protein was solved with the protein complexed with its ligand, a C40 isoprenoid. HP1286 from Helicobacter pylori is another YceI-like protein and is overexpressed in acid stress [37]. It binds to amphiphilic compounds containing approximately 22 carbon atoms. HP1286 is secreted by the cell, potentially to sequester and supply fatty acids from the environment for metabolism or to detoxify and protect the cell from the antimicrobial properties of fatty acids. E. coli harbors a periplasmic YceI-like protein that responds to basic, high pH conditions, but its function has not otherwise been characterized [38]. YceI from M. aquaeolei shares 36 % identity with TT1927b, a 31 % identity with HP1286, and a 35 % identity with the YceI-like protein from E. coli. Previously studied proteins in the YceI family have a multitude of functions, ranging from a potential role in the isoprenoid metabolic pathway to involvement in acid or base-induced stress.

We next tested different concentrations of pinene to determine the highest level cells expressing yceI could withstand (Fig. 2b). For all tested pinene levels up to 0.25 %, cells expressing yceI grew better than the control. Growth curves with 0.15 % pinene highlight differences in specific growth rates for strains with and without yceI (Fig. 2c). We also tested whether overexpression of yceI was toxic to cells. Other biofuel tolerance mechanisms, such as efflux pumps are known to provide a benefit under stress, but are toxic if overexpressed, leading to a trade off in expression levels for optimal cell survival [39]. We tested varying levels of inducer ranging from 0 to 1000 μM arabinose and observed no growth impact compared to the control at any concentration of inducer (Fig. 2d). For all concentrations of arabinose, growth of cells expressing the yceI gene were statistically equivalent to the negative control (one-way ANOVA test).

Due to the similar chemical structure of pinene to the bio-jet fuel precursors terpinolene, terpinene, and...
limonene [11], we tested tolerance using these chemicals as well. Cells expressing ycel were stressed in increasing concentrations of the three monoterpenic fuels. Our results indicate that ycel was beneficial in improving growth when cells were exposed to terpinolene (Fig. 3a), however for the two other fuel precursors tested, limonene and terpinene, we saw no significant improvement over the control (Figs. 3b, c).

**Conclusions**

In this study, we used a library approach to screen the genome of the hydrocarbon-degrading microbe *M. aquaeolei* for genes that impart tolerance to potential bio-jet fuel precursors. We showed that expression of the gene ycel from *M. aquaeolei* successfully increases pinene and terpinolene tolerance when expressed in *E. coli* MG1655. Based on previous accounts in the
literature, *yceI* may act by sequestering or transporting chemicals within the periplasmic space, thus alleviating some degree of biofuel toxicity. However, this protein family is poorly characterized and in the future it will be interesting to further explore the function of *M. aquaeolei yceI* in *E. coli*. We see no evidence of toxicity associated with the overexpression of *yceI* in our experiments, suggesting that this may be a novel, low-burden mechanism for improving pinene tolerance.

In the future it will be interesting to test *yceI* in a pinene production strain to determine the potential titer increase that could be achieved. Also, combining *yceI* with other known tolerance mechanisms has the potential to synergistically increase cell survival at higher biofuel concentrations. This has been shown in the past to be successful in boosting tolerance to higher levels than could achieved by one mechanism alone [39].

This method of library construction and competition could also be used to discover additional tolerance genes. Other hydrocarbon resistant microbes such as *A. borkumensis* or the strains isolated during the Deepwater Horizon disaster, would make excellent sources of genetic material for library construction. Alternatively, instead of selecting individual microbes for library screening, a metagenomic approach could be applied. Gathering samples of microbial populations from the environment has the potential to provide a diverse sample of genomic DNA.

Given the importance of liquid fuels in our society, it is critical to ensure that we have reliable and economical sources of these fuels for the future. Identifying better ways to produce advanced biofuels will help to lower the cost of their production and make biofuels more competitive with petroleum-derived fuels in the future.

### Methods

#### Fosmid library construction

*M. aquaeolei* VT8 genomic DNA was obtained from ATCC (#700491D-5) and was used for the construction of the fosmid library. The degree of genomic DNA fragmentation was determined via gel electrophoresis on a 0.7 % agarose gel run for 20 h at 30 volts. The gel was then stained and imaged. The genomic DNA had an average length of ~40 kb, which we used directly as the insert in the library construction process. A control fosmid was also created using the ~42 kb fragment of human X-chromosome DNA provided as a control in the kit.

*E. coli* EPI300-T1 cells were mixed with the prepared phage particles at different concentrations to determine an appropriate titer, and we selected a 1:10 dilution. The *M. aquaeolei* library and control fosmid were plated on Luria–Bertani (LB) agar plates containing 12.5 µg/ml chloramphenicol, yielding approximately 1000 colonies per plate after overnight growth at 37 °C. Library coverage was determined using the Clark-Carbon equation, based on the assumption that recombinant clones follow a Poisson distribution across the genome [34]. Based on these calculations, there is 99.9 % certainty that the library has full coverage. The colonies containing fosmids with *M. aquaeolei* DNA were scraped off the plate using a razor blade and 50 µl aliquots of the library were stored in a 20 % glycerol solution at −80 °C for later use. An individual colony from the control fosmid plate was used to create a glycerol stock.

#### Selection procedure: fosmid library

LB supplemented with 12.5 µg/ml of chloramphenicol was used to prepare two cultures containing *E. coli* EPI300-T1 cells harboring the *M. aquaeolei* fosmid library. A third
culture containing the human DNA control fosmid in *E. coli* EPI300-T1 was prepared in a similar manner. One of the *M. aquaeolei* library cultures and the control were stressed with 0.05 % pinene (v/v), while the other *M. aquaeolei* library culture received no exposure to pinene. Each of the cultures was diluted 1:100 into LB plus chloramphenicol and pinene, where applicable, every 12 h over the course of a 96 h period. Every 24 h, samples from each culture were plated on LB agar plates with chloramphenicol. Three colonies from each of the 0, 24, 48, and 96-h time points were selected and their fosmids were extracted as follows: Cells were grown in 5 ml of LB medium plus chloramphenicol and 10 µl of 500X CopyControl Fosmid Autoinduction solution from the Epicentre Kit. The culture was grown for 16 h and the fosmid DNA was then extracted using a Qia-gen QAprep Spin Miniprep Kit. The fosmid samples were sequenced using the pCC1 forward (5′-GGATGTGCTGCA AGGCAGATATTGTTG-3′) and reverse (5′-CTACTGTTTCTCCCATACCGTTTTTTTGG-3′) primers indicated in the Epicentre Kit protocol. The resulting sequences were aligned with the *M. aquaeolei* genome (see Additional file 3: Table S1). The converged fosmid from the 96-h time point, which we refer to as pCC1FOS-96, was saved for later use.

**Plasmid library construction**

The fosmid from the converged 96-h time point (pCC1FOS-96) was used as the starting material for plasmid library construction. 500 µg of the fosmid DNA was partially digested at 37 °C using varying concentrations (0.13U, 0.25U, 0.38U, and 0.50U) of the enzyme Sau3A (New England Biolabs). By reducing the digestion time to five minutes, we achieved a DNA insert length centered around 4–12 kb. The digested fosmid DNA from each of the four reactions was then gel extracted from the 4–12 kb range using the Qiagen QIAquick Gel Extraction Kit, as in [40]. We used pBbA5k [35] as the plasmid vector, which has a medium copy p15A origin of replication, PBAD promoter, and kanamycin resistance cassette. The DNA fragments were cloned using the Gibson Assembly Protocol [41]. Inserts were prepared using PCR and the vector was prepared by digesting pBbA8k-rfp with BamHI and BglII and gel extracting. Individual colonies of each construct were isolated and cloning success was verified via sequencing using the forward (5′-CTACTGTTTCTCCCATACCGTTTTTTTGG-3′) and reverse (5′-CGTTTTATTTGATGCCTGGAGAT-3′) primers for the pBbA5k vector [35].

**Tolerance testing procedure**

Overnight cultures were grown for 16 h in LB containing antibiotics and varying levels of arabinose (as required). Cultures for tolerance testing were prepared by first preparing a pre-culture, where we inoculated 5 ml of LB containing antibiotics and varying levels of arabinose (as required). Overnight cultures were grown for 16 h in LB containing antibiotics and 50 µL of the overnight culture. Cultures were grown until they reached an OD600 reading of 0.2, at which point varying levels of biofuel were added to each. The chemicals used for tolerance testing were obtained from Sigma Aldrich (α-pinene P45680, γ-terpinene 86478, limonene 183164, and terpinolene W304603). Growth measurements were taken after 12 h under biofuel stress. For the growth curve experiments, measurements were taken every 30 min for the first 4 h; after this point OD600 readings were taken every hour. All experiments were performed in triplicate.

**Additional files**

**Additional file 1: Figure S1.** Initial testing of *E. coli* EPI300-Ti cells containing the control fosmid and the *M. aquaeolei* fosmid library. 0.05 % pinene was selected for subsequent experiments.

**Additional file 2: Figure S2.** Pinene tolerance of *E. coli* EPI300-Ti cells containing the converged fosmid (pCC1FOS-96) in 0.2 % pinene measured after 16 h of growth.

**Additional file 3: Table S1.** Fosmid library convergence.
