Bose-Einstein beams:
Coherent propagation through a guide

P. Leboeuf and N. Pavloff

Abstract

We compute the stationary profiles of a coherent beam of Bose-Einstein condensed atoms propagating through a guide. Special emphasis is put on the effect of a disturbing obstacle present in the trajectory of the beam. The obstacle considered (such as a bend in the guide, or a laser field perpendicular to the beam) results in a repulsive or an attractive potential acting on the condensate. Different behaviors are observed when the beam velocity (with respect to the speed of sound), the size of the obstacle (relative to the healing length) and the intensity and sign of the potential are varied. The existence of bound states of the condensate is also considered.

1 Introduction

The field of Bose-Einstein condensation (BEC) of atomic vapors is undergoing rapid experimental development providing a rich new phenomenology and also allowing to test concepts that originated in other fields (mainly in the theory of superfluidity, in nonlinear optics and in atomic physics).

Along these lines, the possibility of building atom lasers by guiding condensed particles through various geometries opens up the prospects of a rich variety of interference, transport and/or coherence phenomena. Cold atoms have already been propagated in various guides (see e.g. [1–4] and references therein); more and more efficient coherent sources of atoms have recently been designed (using various output coupling schemes, see Refs. [5–9]) and continuous guided beams of condensed atoms will be accessible in the near future (see the preparatory study [10]).

The purpose of the present work is to explicitly determine the different propagating modes of a beam of condensed atoms through a guide, as a function of the various external control parameters. We consider the simplest geometry, in which a guide connects two reservoirs, and treat the case of atoms with a repulsive effective interaction, such as rubidium and sodium. First, the transmission through a straight guide is reevaluated: small amplitude density oscillations, cnoidal waves, and gray solitons are possible propagating modes. The main part of the paper is devoted to the study of coherent transmission modes in the presence of an obstacle. We find that, as a function of the speed of the incoming beam and the size and depth of the perturbing potential, many different transmission modes exist. For example, some are soliton-like modes (with a peak or a trough in the density) that are pinned to the obstacle. They may also have density oscillations in the region of the obstacle. On the contrary, other modes are step-like shaped. In general, the modes may or may not have a wake. The wake, however, always precedes the obstacle (it never occurs down-stream).

The obstacle is represented in our treatment by a potential that acts on the condensate along the axis of the guide. It can be repulsive or attractive. There are at least two simple ways to realize such an obstacle experimentally. The first is to bend the guide: a potential proportional to the square of the local curvature is created. This potential is always attractive. In view of future applications of the atom laser to more complicated geometries, the presence of bends seems unavoidable and their study is therefore far from academic. The second possibility is to illuminate the beam with a detuned laser field. Contrary to the case of a bend, attractive and repulsive potentials may be realized by varying the frequency of the laser. This latter method also has the advantage of allowing a better control of the relative speed between the obstacle and the beam (if using an acousto-optic deflector).

In the case of attractive potentials, aside from the transmission modes there may also exist bound states in the guide, in which condensed atoms are trapped without possibility of escape. These bound states are also analyzed here. In the case of a bend we show that, due to the intra-atomic interactions, the bound state can support only a limited number of condensed atoms, which is typically of the order of 100 for rubidium and sodium. However this number can be made much larger for an attractive potential originating from a red detuned laser field.

The paper is organized as follows. In Sec. 2 we set up the theoretical framework and notations. Our approach for describing the condensate motion is based on a one-dimensional reduction of the Gross-Pitaevskii equation [11]. The solutions described here can in some instances be explicitly written in an analytic form, for example, in terms of elliptic functions. Although we use this opportunity in some cases, we have chosen to keep the discussion at a qualitative level. This allows
us to cover a large range of experimental situations and gives a global view of all the possible solutions in the different regimes of the control parameters. In Section 3 we study the existence of a bound state of the condensate created by an attractive potential. We determine the maximum number of atoms the bound state can accommodate. In Secs. 4–7 we study the propagation of a condensate through a guide connecting two reservoirs. The analysis relies on an interpretation of the Gross-Pitaevskii equation in terms of a fictitious classical dynamics. We focus on different specific examples, starting with a straight waveguide without any potential (Sec. 4). We then study the motion in the presence of an obstacle represented by an attractive (Sec. 5) and a repulsive (Sec. 6) square well. Sec. 7 presents two alternative treatments for determining the transmission modes in the presence of an obstacle. The first one is a perturbative approach; the second approximates the external potential by a $\delta$ function. Sec. 8 contains an analysis of the results in view of future experimental realizations. We present our conclusions in Sec. 9. Some technical aspects concerning the adiabatic approximation used for deriving the 1D reduction of the Gross-Pitaevskii equation are included in the Appendix.

2 An effective one-dimensional equation

We consider BEC atoms at zero temperature confined to a wave-guide. Let $x$ be the coordinate along the axis of the guide (which is possibly bent) and $\mathbf{r}_\perp$ a perpendicular vector giving the transverse coordinates. We work in the adiabatic regime where the local curvature $\kappa(x)$ of the longitudinal motion of the atoms is small. If the transverse extension of the wavefunction is denoted by $R_\perp$, this is more precisely defined by the limit $R_\perp \kappa \ll 1$ and $|d\kappa/dx| \ll 1$ (see Appendix A). In this regime one can consider $x$ and $\mathbf{r}_\perp$ as Cartesian coordinates, i.e. for instance the volume element $d^3r$ is approximately $dx d^2r_\perp$.

It is consistent with the adiabatic approximation to make an ansatz for the condensate wavefunction $\Psi(\mathbf{r}, t)$ of the form [11]

$$\Psi(\mathbf{r}, t) = \psi(x, t) \phi(\mathbf{r}_\perp; n)$$

(1)

where $\phi$ is the equilibrium wave function for the transverse motion, normalized to unity, $\int d^2r_\perp |\phi|^2 = 1$. $\psi(x, t)$ describes the longitudinal motion, and the density per unit of longitudinal length is

$$n(x, t) = \int d^2r_\perp |\Psi|^2 = |\psi(x, t)|^2.$$

Notice that the transverse wave function depends parametrically on $n(x, t)$. The adiabatic approximation is in fact a local density approximation in the sense that one assumes that the transverse motion is not affected by densities at points other than $x$. As noted in Ref. [11] this corresponds to the assumption that the transverse scale of variation of the profile is much smaller than the longitudinal one (and corresponds indeed to the limit $R_\perp \kappa \ll 1$).

The beam is confined by a transverse potential $V_\perp(\mathbf{r}_\perp)$. Keeping in mind experimental realizations, we often consider below the particular case of a harmonic trapping $V_\perp(\mathbf{r}_\perp) = \frac{1}{2} \omega_\perp^2 r_\perp^2$ ($\omega_\perp$ is the pulsation of the harmonic oscillator; we set units such that $\hbar = m = 1$). As shown in Appendix A, within the adiabatic approximation the presence of a bend results in an attractive longitudinal
potential $V_\parallel(x)$ given by

$$V_\parallel(x) = -\kappa^2(x)/8.$$  

(2)

The Gross-Pitaevskii equations for the condensate are derived through a variational principle. One extremizes the action

$$S = \frac{i}{2} \int d^3r \, dt \left( \Psi^* \partial_t \Psi - \Psi \partial_t \Psi^* \right) - \int dt \, \mathcal{E}[\Psi],$$  

(3)

where $\mathcal{E}[\Psi]$ is the energy functional

$$\mathcal{E}[\Psi] = \int d^3r \left( \frac{1}{2} |\vec{\nabla}\Psi|^2 + 2\pi a_{sc} |\Psi|^4 + (V_\parallel + V_\perp)|\Psi|^2 \right).$$  

(4)

$a_{sc}$ is the s-wave scattering length of the inter-atomic potential (which is represented by a $\delta$ function interaction). In all the present work, we consider the case of repulsive inter-atomic interactions, $a_{sc} > 0$. The extremization of $S$ with Lagrange multiplier $\epsilon(n)$ imposing the normalization $\int d^2 r_\perp |\Psi|^2 = n$ for each $x$ (more precisely for each $n$) leads to the following equations [11]

$$-\frac{1}{2} \vec{\nabla}_\perp^2 \phi + (V_\perp + 4\pi a_{sc} n |\phi|^2) \phi = \epsilon(n) \phi,$$  

(5)

and

$$-\frac{1}{2} \partial_{xx}^2 \psi + (V_\parallel + \epsilon(n)) \psi = i \partial_t \psi.$$  

(6)

In (5) the non-linear term $\epsilon(n)$ (remember that $n = |\psi|^2$) is determined as a function of $n$ from Eq. (3). In the low density limit $a_{sc} n \ll 1$ the non-linearity in (3) is small. In this case, a perturbative solution of (3) leads to

$$\epsilon(n) = \epsilon_0 + 2 a_{sc} n/a^2_\perp,$$  

(7)

where $\epsilon_0$ is the eigen-energy of the ground-state $\phi_0$ of the transverse unperturbed Hamiltonian $-\frac{1}{2} \vec{\nabla}_\perp^2 + V_\perp$, and $a^2_\perp = 2 \pi \int |\phi_0|^4 d^2 r_\perp$. For a harmonic confining potential $a_\perp = \omega_-^{-1/2}$ is known as the oscillator length.

In the opposite large-density limit $n a_{sc} \gg 1$ the Thomas-Fermi approximation holds, namely the kinetic term in (3) can be neglected. $\epsilon$ is obtained as a function of $n$ through the relation $N_{TF}(\epsilon) = 2 a_{sc} n$, where $N_{TF}$ is the integrated Thomas-Fermi density of states $N_{TF}(\epsilon) = \int(\epsilon - V_\perp)\Theta(\epsilon - V_\perp) d^2 r_\perp/(2\pi)$. For a harmonic confining potential this reads

$$\epsilon(n) = 2 \omega_- \sqrt{n a_{sc}} + \epsilon_0.$$  

(8)

We remark here that the Gross-Pitaevskii equation is valid in the dilute gas approximation, when the 3D density $n_{3D}$ of the gas satisfies $n_{3D} a_{sc}^3 \ll 1$ [12]. This reads here $n a_{sc} \ll (a_\perp/a_{sc})^{2/\nu}$ ($\nu = 1$ in the dilute regime and $\nu = 1/2$ for high densities), $a_\perp/a_{sc}$ being typically of order $10^3$, this condition will be considered as always fulfilled, even at high longitudinal densities, when $n a_{sc} \gg 1$. 

On the other hand, the weakly interacting 1D Bose gas picture also breaks down at very low densities, in the Tonks gas regime (recent references relevant to this discussion are [13–16]). This occurs in the regime $na_{sc} \ll (a_{sc}/a_{\perp})^2 \sim 10^{-6}$ which we thus discard from the present study.

Eq. (6), together with Eqs. (7) and (8), are the main results of this section. They provide an effective one-dimensional equation for the description of the dynamics of the condensate along the guide. Notice that in general the non-linear term in Eq. (6) does not have the standard cubic form of the one-dimensional Gross-Pitaevskii equation. This happens only in the low density regime $a_{sc}n \ll 1$ when the non-linear potential $|\psi|^2$ is proportional to $|\psi|^2$.

We emphasize that Eq. (6) relies on an adiabatic approximation. It is well known that in many instances this approximation gives accurate results well beyond its strict domain of validity. Two examples relevant in the present context are Refs. [17] and [18], where the propagation of waves (without non-linear effects) was studied in the extreme non adiabatic case of wave guides with a discontinuous curvature and a sudden constriction, respectively. The adiabatic approximation was nevertheless shown to be applicable in these systems. On the basis of these examples (and of others), one can consider that the results presented here have a wide range of validity.

For practical purposes it will appear useful in the following to introduce a longitudinal healing length $\xi$ defined for a constant longitudinal density $n$ as

$$\frac{1}{2\xi^2} = \epsilon(n) - \epsilon_0. \tag{9}$$

This gives $\xi = \frac{1}{2}a_{\perp}(n a_{sc})^{-1/2}$ in the low density regime and $\xi = \frac{1}{4}a_{\perp}(n a_{sc})^{-1/4}$ for high densities in a harmonic confining potential.

We now study in detail the different solutions of Eq. (6). Although the attractive potential $V_{\parallel}(x)$ appearing in the equation of motion was due to the presence of a bend in the guide, our results are very general and $V_{\parallel}(x)$ could be of a completely different physical origin. In particular, we will consider in Sec. 3 the case of a repulsive potential which cannot be produced by a bend.

3 Bound states

We first study the existence of bound states in the guide due to an attractive potential $V_{\parallel}(x)$. The existence of bound states in the quantum mechanical motion of non-interacting particles in a bent wave guide has been extensively considered in the past (see e.g. [19, 21] and Refs. therein). It has been shown by Goldstone and Jaffe that at least one bound state exists in two and three dimensional bent tubes [19] (cf. the discussion in Appendix A). The particle is trapped because its energy is lower than the first propagating mode of the straight guide. In the case of a condensed beam, we are interested in whether bound states occur in the presence of interactions.

In the extreme dilute limit $a_{sc}n \to 0$ Eq. (6) reduces to an ordinary one dimensional Schrödinger equation and the existence of a bound state in $V_{\parallel}(x)$ is guaranteed by general theorems of quantum mechanics [22]. Hence there exists a state of the condensate whose energy is lower than the energy $\epsilon_0$ of the first propagating mode of the guide. This state is localized in the region where $V_{\parallel}$ is noticeable, and we assume for simplicity that this happens in some finite region around $x = 0$. With increasing number of atoms in the condensate the non-linear effects come into play. The repulsive intra-atomic interaction increases the energy of the bound state (as well as its spatial
extension), and there is a threshold beyond which this state disappears. Therefore for a sufficiently large number of atoms no bound-state is expected to occur. We now determine the threshold quantitatively by determining the maximum number of Bose condensed atoms the bound-state can accommodate.

Near the threshold the state is very weakly bound, and the wave function extends over distances much greater than the range of the potential $V_{\parallel}$. Hence, in this limit it is legitimate to make the approximation $V_{\parallel}(x) \approx \lambda \delta(x)$, with $\lambda = \int_{-\infty}^{+\infty} V_{\parallel}(x) \, dx < 0$. This approximation is not contradictory with the assumption of adiabaticity of the motion.

We look at stationary solutions of Eq. (6) of the form $\psi(x,t) = A(x) \exp(-i \mu t)$, $\mu$ being the chemical potential and $A$ a real function. In the regions where the potential is negligible (i.e., for $x \neq 0$ with the above replacement of $V_{\parallel}$ by a $\delta$ function) Eq. (6) can be integrated once, giving an equation for $n(x) = A^2$,

$$\frac{n''}{8} + \varepsilon(n) = \mu n, \quad \text{where} \quad \varepsilon(n) = \int_0^n \epsilon(\rho) \, d\rho. \quad (10)$$

With the convention defined in Section 2, the normalization is $\int_{-\infty}^{+\infty} n(x) \, dx = N$, where $N$ is the total number of particles in the bound state. The density $n$ can be shown to be an even function of $x$, and the matching condition at $x = 0$ reads $n'(0^+) = 2 \lambda n(0)$ (' denotes $d/dx$). Using (10) and these two conditions we arrive at a set of two equations determining $n(0)$ and $\mu$ as functions of $\lambda$ and $N$,

$$\frac{\lambda^2}{2} n(0) = \varepsilon(n(0)) - \mu n(0), \quad (11)$$

and

$$\int_0^{n(0)} \frac{(n/2)^{1/2}}{\sqrt{\varepsilon(n) - \mu n}} \, dn = N. \quad (12)$$

For solving this system, one needs to know the explicit form of the function $\varepsilon(n)$. We will see that for realistic values of $\lambda$ corresponding to an attraction issued from a bend in the guide the bound state can accommodate only a small number of particles. In the case of a bend, it is thus sensible to concentrate on the low density limit (see the estimate at the end of this section). Using (7), in the low density regime we have $\varepsilon(n) = \epsilon_0 n + a_{sc} n^2/a_{\perp}^2$ and we obtain

$$\mu = \epsilon_0 - \frac{1}{2} \left( \int_{-\infty}^{+\infty} V_{\parallel}(x) \, dx + \frac{a_{sc}}{a_{\perp}^2} N \right)^2. \quad (13)$$

The first, negative, term inside the large parentheses is due to the attractive potential produced by the bend (cf Eq. (2)), while the second one comes from intra-atomic repulsive interactions in the condensate. Eq. (13) clearly displays the existence of a threshold. When the number of atoms $N$ occupying the bound state increases, the chemical potential $\mu$ increases and eventually reaches the threshold $\epsilon_0$ at which the state disappears. This occurs for a number of atoms $N_{\text{max}}$ given by

$$N_{\text{max}} = \frac{a_{\perp}^2}{a_{sc}} \left| \int_{-\infty}^{+\infty} V_{\parallel}(x) \, dx \right|.$$
For an arbitrary potential, as \( N \to N_{\text{max}} \) the spatial extension of the bound-state diverges. Thus the approximation of \( V_{\|} \) by a \( \delta \)-function is well justified in that limit, and we expect Eq. (14) to be very accurate \(^{23}\).

The order of magnitude of \( N_{\text{max}} \) can be estimated by considering a bend of constant radius of curvature \( R_c \) and bending angle \( \Theta \). From (2) and (14) we get \( N_{\text{max}} = a_\perp^2 \Theta / (8a_{sc}R_c) \). For a guide with \( R_c = 5a_\perp \), \( \Theta = \pi/2 \) and \( a_\perp \) ranging from 1 \( \mu \)m to 10 \( \mu \)m, \( N_{\text{max}} \) ranges from 7 to 70 atoms for a condensate of \(^{87}\text{Rb} \) atoms (\( a_{sc} = 5.77 \) nm). For \(^{23}\text{Na} \), \( N_{\text{max}} \) is doubled (since the s-wave scattering length of \(^{23}\text{Na} \) is \( a_{sc} = 2.75 \) nm).

If the attractive potential originates from a red detuned laser beam, using the estimate of Sec. 8 (Eq. (53)) one obtains

\[
\int_{-\infty}^{+\infty} V_{\|}(x) \, dx \approx 10^6 \quad \text{(to be compared to the value } 10^{-1} \text{ that applies to a bend).}
\]

From this and from Eq. (14) it follows that for rubidium \( N_{\text{max}} \) can be as large as \( 10^9 \). Working in the high density regime instead, one obtains

\[
N_{\text{max}} = 3 \frac{a_\perp^4}{16a_{sc}} \left| \int_{-\infty}^{+\infty} V_{\|}(x) \, dx \right|^3.
\]

One gets from this equation a value of \( N_{\text{max}} \) of the order of \( 10^{20} \). Note, however, that in this regime the high density approximation is valid at \( x = 0 \), but violated for large \( x \) (when the density tends to zero). Hence, without giving a precise order of magnitude, it is nevertheless clear from the previous estimates that the maximum number of atoms the bound state can accommodate is very large in this case.

### 4 Transmission modes

From now on we concentrate on the stationary states of a beam of condensed atoms connecting two reservoirs. For that purpose we look at the stationary solutions (in the reference frame of the laboratory) of Eq. (8) with \( \psi \) having a finite value at \( x \to \pm \infty \). We write

\[
\psi(x,t) = \exp\{-i\mu t\} A(x) \exp\{i\varphi(x)\},
\]

with \( A \) and \( \varphi \) real functions. Since the wave function extends to infinity, the chemical potential satisfies \( \mu > \epsilon_0 \). The density is \( n = A^2 \), and the beam velocity is \( v = \varphi' \). After factorizing out the phases, Eq. (8) splits into two real equations corresponding to its imaginary and real parts. The former imposes flux conservation, namely the product \( n(x) v(x) \) is a constant that we denote by \( \Phi \),

\[
\Phi = n(x) v(x).
\]

The real part gives a Schrödinger-like equation for \( A(x) \)

\[
-\frac{1}{2} A'' + \left[ \epsilon(n) + V_{\|} + \frac{\Phi^2}{2n^2} \right] A = \mu A.
\]

In this section we consider the transmission modes of a condensate through a straight wave guide with no obstacle. This corresponds to solving Eq. (17) with \( V_{\|} \equiv 0 \). The modifications in the
beam density and phase produced by the presence of an obstacle are considered in the following sections. When \( V_1 \equiv 0 \), Eq. (17) can be integrated once, yielding

\[
\frac{1}{2} \alpha^2 + W(n) = E_{cl} \quad \text{with} \quad W(n) = -\varepsilon(n) + \mu n + \frac{\Phi^2}{2n}.
\] (18)

\( \varepsilon(n) \) in (18) is the same as in Eq. (10) and \( E_{cl} \) is an integration constant. This constant is denoted as a “classical energy” because (18) has an interpretation in terms of classical dynamics. It expresses the energy conservation of a one-dimensional Hamiltonian system for a fictitious classical particle with “position” \( A \) and “time” \( x \) moving in a potential \( W(n = A^2) \), \( E_{cl} \) being the total energy of the particle. The solutions \( A(x) \) therefore coincide with the “classical” solutions in the potential \( W(n = A^2) \). The chemical potential \( \mu \) and the flux \( \Phi \) fix the shape of the potential \( W(n) \), while \( E_{cl} \) selects a “trajectory” \( A(x) \) in this potential.

To clarify the physical meaning of \( E_{cl} \) consider the linear (i.e., non-interacting) case \( \varepsilon(n) = 0 \). Then the natural way to write the solution (16) is a superposition of plane waves,

\[
\psi(x,t) = \exp\{-i\mu t\} \left[ \alpha \exp(ikx) + \beta \exp(-ikx + i\theta) \right],
\] (19)

where \( k \) is the wavevector and \( \theta \) an arbitrary phase. In terms of the two real parameters \( \alpha \) and \( \beta \), the flux and the classical energy are written \( \Phi = k (\alpha^2 - \beta^2) \) and \( E_{cl} = k^2 (\alpha^2 + \beta^2) \). \( E_{cl} \) is therefore a measure of the total intensity of the left and right incoming beams. \( E_{cl} \) can be varied while keeping \( \Phi \) and \( \mu \) constant (and therefore \( W(n) \) constant) by changing the amplitudes \( \alpha \) and \( \beta \) simultaneously while preserving the difference \( (\alpha^2 - \beta^2) \).

For studying the shape of \( W(n) \) in Eq. (18) in the presence of interactions it is customary to plot \( \mu - dW/dn = \varepsilon(n) + \Phi^2/(2n^2) \) as a function of \( n \), as represented in the top part of Fig. 1. At low densities (\( n \to 0 \)) the term \( \Phi^2/(2n^2) \) dominates. At high densities the intra-atomic interaction contained in \( \varepsilon(n) \) takes over, and leads to a monotonic growth for large values of \( n \) (due to the repulsive interactions, \( \varepsilon(n) \) is an increasing function of \( n \)). At intermediate values there is a minimum at a density denoted \( n_0 \). The relevant case (leading to finite densities at infinity) corresponds to \( \mu \geq \varepsilon(n_0) + \Phi^2/(2n_0^2) \), and is shown in Fig. 1. Then the derivative of \( W(n) \) is zero for two densities \( n_1 \) and \( n_2 \), with \( n_1 \leq n_0 \leq n_2 \). The corresponding plot of the potential \( W(n) \) is shown in the lower part of the figure. In order to have a finite density at infinity one should also impose a bounded motion of the fictitious classical particle, and this results in the two additional conditions (i) \( W(n_1) \leq E_{cl} \leq W(n_2) \), and (ii) \( n(x) \leq n_2 \) for any value of \( x \).

The different types of solution \( A(x) \) are therefore described by the different motions a classical particle undergoes in a potential \( W(n) \) at the allowed energies \( E_{cl} \). The two simplest solutions correspond to the fixed points of the potential, \( n(x) = n_1 \) or \( n_2 \), where the “classical” particle remains at rest. They correspond to constant density solutions. Since the densities are different (\( n_2 > n_1 \)) and the flux has the same value \( \Phi \), the velocities \( v_j \) (\( j = 1 \) or \( 2 \)) of the condensed beam are also different, with \( v_2 < v_1 \). \( v_1 \) (resp. \( v_2 \)) corresponds to a beam velocity above (resp. below) the speed of sound. To see this, we first note (see below) that for a condensate at rest (i.e., \( v = 0 \)) with uniform density \( n(x) = n \), the sound velocity \( c \) is defined by

\[
c^2(n) = n \frac{d\varepsilon}{dn}.
\] (20)
In the case of a moving condensate with uniform density \( n \), one has a well defined velocity \( v = \Phi/n \) given by \( \mu = \epsilon(n) + \frac{1}{2}v^2 \) (see Eq. (17)). From Eqs. (18) and (20), we have moreover \( d^2W/dn^2 = (v^2 - c^2(n))/n \). Since \( d^2W/dn^2 \) at \( n_1 \) (resp. \( n_2 \)) is positive (resp. negative), it follows that \( v_1 > c(n_1) \) (resp. \( v_2 < c(n_2) \)).

We now consider the density profile of the transmission modes in the vicinity of the constant solution \( n(x) = n_1 \). For energies \( E_{cl} \) slightly higher than \( W(n_1) \) the stationary solutions are sinusoidal waves of the form

\[
A(x) = A_1 + \frac{\sqrt{2}}{k}[E_{cl} - W(n_1)]^{1/2} \cos (k \, x + \theta) ,
\]

where \( k^2 = d^2W/dA^2 \big|_{A_1} = 4(\Phi^2/n_1^2 - c^2(n_1)) \) and \( n_1 = A_1^2 \) is the constant density. This sinusoidal wave is reminiscent of a sound wave, but sound waves are progressive whereas Eq. (21) describes a standing wave. The structure of the sound wave (and the whole spectrum of elementary excitations) is better displayed by a slight modification of the procedure used so far. Instead of the stationary ansatz (16) one looks for solutions of the form \( \psi(x,t) = \exp(-i\mu t)A(x-ut) \exp(i\phi(x-ut)) \), where \( u \) is a constant parameter, physically interpreted as the velocity of an arbitrary moving frame. Mass conservation now reads \( \Phi = n(v - u) \) (\( \Phi \) is the flux in the moving frame) and Eqs. (17,18) keep the same form, with \( \mu \) replaced by \( \mu + u^2/2 \), all functions now depending on \( X = x - ut \) and not merely on \( x \). The constant solution \( n(x) = n_1 \) can now be given zero velocity \( (v_1 = 0) \) if one chooses \( u \) such that \( u + \Phi/n_1 = 0 \) (this is of importance because one wishes to study elementary
excitations in a system at rest). In this case, a perturbative treatment of (18) for $E_{cl}$ near $W(n_1)$ again gives a solution of the form (21) with $x$ replaced by $X$. This is a progressive wave depending on $k X = k x - \omega_k t$ with $\omega_k = k u$, and thus satisfying the Bogoliubov dispersion relation

$$
\omega_k^2 = k^2 \left( n_1 \frac{d\epsilon}{dn} \bigg|_{n_1} + \frac{k^2}{4} \right).
$$

The long wave-length limit of (22) corresponds indeed to sound waves with a sound velocity $c(n_1)$ as given by Eq. (20). It is also possible to obtain in this way the dispersion relation of the elementary excitations of a beam moving at constant velocity $v_1$ (which is simply Eq. (22) Doppler shifted).

Note that our approach is unable to reproduce the decrease of slope of the spectrum of elementary excitations that occurs in the high density regime, for wave vectors $k$ of the order of the transverse extension $R_\perp$ of the condensate. This effect, predicted in Refs. [24, 25] and observed numerically in [26] goes beyond the quasi-1D approach: it occurs when the excitation has a wavelength allowing exploration of side regions of the condensate that have lower local sound velocity. Hence, it cannot be reproduced by using the adiabatic ansatz (1).

The structure of the stationary solutions for energies $E_{cl}$ close to (but lower than) $W(n_2)$ is totally different from the sinusoidal waves we just discussed (which exist for $E_{cl} \lesssim W(n_1)$). The uniform solution $n(x) = n_2$ coexists with a solitary wave corresponding in the classical analogy to a motion along the separatrix located at $E_{cl} = W(n_2)$. This solitary wave has constant density $n_2$ at $x \to \pm \infty$, and a trough whose minimum density satisfies the condition $W(n_{min}) = W(n_2)$ (cf. Fig. 2, top part). As the energy is lowered from $E_{cl} = W(n_2)$, density oscillations appear whose amplitude decreases as $E_{cl}$ diminishes. These solutions are cnoidal waves (see, e.g., [27]) with periodic oscillation between two values $n_{min}$ and $n_{max}$, as defined in Fig. 1. As the energy $E_{cl}$ is further reduced the density profile tends continuously to the sinusoidal waves discussed above. This transition is illustrated in Fig. 2, which is drawn in the high density regime for a transverse harmonic confining potential (i.e., with $\epsilon(n)$ given by Eq. (8)). The same qualitative behavior is valid for any density regime.

Figure 2 summarizes the possible density profiles of the transmission modes of the condensate along a straight guide. In the remaining sections we consider the modifications induced by the presence of an obstacle in the flow of the condensate. Finding the transmission modes now reduces to a scattering problem in which two of the “free” modes discussed in this section are matched by the potential representing the obstacle. The correct boundary conditions to be imposed are determined by the relative value of the phase velocity

$$
v_p(k) = \frac{\omega_k}{k},
$$

with respect to the group velocity

$$
v_g(k) = \frac{\partial \omega_k}{\partial k} = v_p(k) \left( 1 + \frac{k^2}{k^2 + 4 c^2(n)} \right).
$$

Both functions start from the value $c(n)$ at $k = 0$ and then increase monotonically, with $v_g(k) > v_p(k)$ for any $k > 0$. For the stationary motion of an obstacle in a condensate at rest, $v_p$ coincides with the velocity of the obstacle with respect to the beam, this is the condition of stationarity. The
energy transferred to the fluid propagates with a velocity $v_g$ greater than the velocity of the obstacle with respect to the beam (since $v_g > v_p$). As a consequence, radiation conditions require that the wake is always located ahead of the obstacle (i.e., up-stream in a frame where the disturbance is at rest), with no long-range perturbation of the fluid on the down-stream side.

Figure 2: Beam density along a straight guide (high density regime) with $v_2/c_2 = 0.7$ (lengths are given in units of $\xi(n_2)$, see Eq. (5)). Top: solitary wave ($E_{cl} = W(n_2)$). Middle: cnoidal waves existing for $W(n_1) < E_{cl} < W(n_2)$. Bottom: for $E_{cl} \gtrsim W(n_1)$ the cnoidal wave deforms continuously to a sinusoidal small-amplitude wave.

5 The attractive square well

Having recalled the different solutions existing in a straight wave guide, we now discuss the influence on the transmission modes of a longitudinal potential representing a motionless obstacle placed in the trajectory of the beam. Specifically, we consider a potential $V_\parallel(x)$ that vanishes everywhere except in a finite region $0 \leq x \leq \sigma$ where it takes the constant value $-V_0$ ($V_0 > 0$). If its origin is the presence of a bend, the square well potential corresponds to a wave guide with a constant curvature over a finite length $0 < x < \sigma$ and straight elsewhere. Apart from considerations related to its physical origin, this model potential is of interest because it allows one to understand in a simple case the different stationary regimes occurring also in more complex potentials.

An important point for the determination of the transmission modes of the condensate along the guide is the boundary conditions. As discussed at the end of the previous section, amongst all the possible stationary solutions that exist in the presence of a scattering potential, the only physical ones are those that tend to a flat density down-stream. Hence we consider density profiles tending to a flat density at $x \to -\infty$, with $n(x \to -\infty) \to n_\infty$, and with a negative velocity $v_\infty = \Phi/n_\infty$. The sound velocity at infinity $c_\infty = c(n_\infty)$ will also be chosen negative in all the following. This corresponds to a beam incoming from the right, unperturbed far down-stream by the presence of $V_\parallel$, and characterized by the two parameters $v_\infty$ and $n_\infty$ (or equivalently by $\mu$ and
of space, in the case of a straight guide, one has an integral of motion, but it takes a different value in each region. Since the solution is flat far down-stream (when $x \to -\infty$) one has $E_{\text{cl}} = W(n_{\infty})$. Hence, as in the case of a straight guide, one has an integral of motion, but it takes a different value in each portion of space,

$$\begin{cases} \frac{1}{2} A'^2 + W(n) = E_{\text{cl}}^- & x \leq 0, \\ \frac{1}{2} A'^2 + W(n) + V_0 n = E_{\text{cl}}^0 & 0 \leq x \leq \sigma, \\ \frac{1}{2} A'^2 + W(n) = E_{\text{cl}}^+ & \sigma \leq x. \end{cases} \tag{25}$$

$W(n)$ in Eq. (25) is defined as in Eq. (18). $E_{\text{cl}}^-$, $E_{\text{cl}}^0$ and $E_{\text{cl}}^+$ are the values of the integration constant in each region. Since the solution is flat far down-stream (when $x \to -\infty$) one has $E_{\text{cl}}^- = W(n_{\infty})$. The matching at $x = 0$ and $x = \sigma$ imposes continuity of the density and of its derivative. This leads to

$$E_{\text{cl}}^- + V_0 n(0) = E_{\text{cl}}^0 = E_{\text{cl}}^+ + V_0 n(\sigma). \tag{26}$$

Different types of solution satisfying Eqs. (25) exist, depending whether the far down-stream beam velocity $v_{\infty}$ is greater or smaller than the speed of sound $c(n_{\infty}) = c_{\infty}$. We consider these two different regimes separately.

### 5.1 low beam velocity: $v_{\infty}/c_{\infty} < 1$

The first type of solution we consider is rather intuitive if employing a perturbative treatment (see Sec. 7). It corresponds to solutions with an increased density in the region of the potential. In the following, we refer to these solutions as “B-solutions” (where B stands for bump).

The B-solutions are found by looking for solutions with a density increasing when $x$ moves from $x = -\infty$ towards the origin. Since at $x \to -\infty$ the density has the constant value $n_{\infty}$, and since we are imposing $v_{\infty}/c_{\infty} < 1$, $n_{\infty}$ coincides with the uniform density denoted $n_2$ in Sec. 4, and $E_{\text{cl}}^- = W(n_{\infty})$. But contrary to the solitary wave of Sec. 4 in which the density decreases, in a type-B solution we move to the right of $n_{\infty} = n_2$ along the separatrix (see Fig. 3) and the B-solution has a density peak instead of a trough.

Since the boundary conditions are fixed down-stream, here and in all the following, we find it more convenient to integrate Eqs. (25) starting far in the rear of the obstacle, i.e. from left infinity (remember that the beam is incident from the right). Starting from a value $n_{\infty}$ at $x = -\infty$, the density has reached a value $n(0)$ at $x = 0$. From this point on the equivalent “classical particle” moves in the potential

$$W_0(n) = W(n) + V_0 n \tag{27}$$

at an energy $E_{\text{cl}}^0 = E_{\text{cl}}^- + V_0 n(0)$. At $x = \sigma$ it evolves again in $W(n)$. Since to reach a finite density when $x \to +\infty$ one needs to have $E_{\text{cl}}^+ \leq W(n_{\infty}) = E_{\text{cl}}^-$, from (24) this imposes $n(\sigma) \geq n(0)$. But, if the inequality is strict, one has $E_{\text{cl}}^+ < W(n_{\infty})$ and $n(\sigma) > n(0) \geq n_{\infty}$: this case should be excluded.
Figure 3: Type-B stationary solution in an attractive square well. The left plot displays the density profile. The two vertical solid lines indicate the location of the square well. This plot corresponds to $\sigma = 2\xi$ and $V_0\xi^2 = 0.5$ in a low-density beam at velocity $v_\infty/c_\infty = 0.7$ (the healing length $\xi$ is defined as in (9) and is computed at density $n_\infty$). The right plot illustrates the behavior of the solution in the diagram $(n, W(n))$. The solid curve represents $W(n)$ and the dashed one $W_0(n)$. In the rear of the obstacle, the density evolves from $n_\infty$ to $n(0)$ in the potential $W(n)$ with a classical energy $E_{cl}^- = W(n_\infty)$, then from $n(0)$ to $n_{max,0}$ and back to $n(0)$ in the potential $W_0(n)$ (with energy $E_{cl}^0$), and finally the up-stream density goes from $n(0)$ to $n_\infty$ in $W(n)$.

since from Fig. 3 one sees that this leads to a diverging density at right infinity (the classical particle escapes to infinity). Hence one should have $n(0) = n(\sigma)$, $E_{cl}^+ = E_{cl}^-$ and the B-solutions are even.

These solutions exist for any type of attractive square well. For a given beam (characterized by $n_\infty$ and $v_\infty$) and given values of $\sigma$ and $V_0$, the value of $A(0)$ is determined by demanding that the amplitude varies from $A(0)$ to its maximum value $A_{max,0}$ and back over a distance $\sigma$. $A_{max,0}$ is determined as a function of $A(0)$ from the equation $W_0(A) = E_{cl}^0$ whose two smallest positive solutions are denoted $A_{min,0}$ and $A_{max,0}$ (in all the following we denote with an index “0” the quantities concerning $W_0$ and defined as for $W$ in Fig. 3). We have

$$\sigma = 2\int_{A(0)}^{A_{max,0}} \frac{dA}{A^2} = \sqrt{2} \int_{A(0)}^{A_{max,0}} \frac{dA}{\sqrt{E_{cl}^0 - W_0(A)}}. \quad (28)$$

For sufficiently small $\sigma$ the only existing B-solution is the one described above. However, new B-solutions appear as the width $\sigma$ increases, because the “classical particle” before evolving back in $W(n)$ has enough “time” to make one (or several) oscillations in $W_0(n)$. The general density profile of the B-type increases from $n_\infty$ at $x = -\infty$ up to $x = 0$, and has $N$ maxima and $N - 1$ minima between $x = 0$ and $x = \sigma$, with $N = 1, 2, 3...$ We denote this a $B_N$-solution. Figure 3
corresponds to a B$_1$ solution. The behavior of a B$_2$ solution is illustrated in Fig. 4. For an arbitrary $N$, Eq. (28) takes the form

$$
\sigma = 2 \int_{A(0)}^{A_{max,0}} \frac{dA}{A'} + 2 (N - 1) \int_{A_{min,0}}^{A_{max,0}} \frac{dA}{A'},
$$

(29)

where $A_{min,0}$ and $A_{max,0}$ are, as indicated before, the two smallest positive solutions of $W_0(A) = E_0^{cl}$. The width of the potential below which a given solution disappears occurs when $A(0) = \sqrt{n_\infty} = A_{max,0}$. In this case the solution is perfectly flat for $x \leq 0$ and $x \geq \sigma$ and is a portion of cnoidal wave (with $N$ oscillations) in the region $0 \leq x \leq \sigma$. For a given $V_0$, this forces $\sigma$ to be larger than the value $\sigma_N(V_0)$,

$$
\sigma \geq \sigma_N(V_0) = \sqrt{2} (N - 1) \int_{\sqrt{n_\infty}}^{A_{max,0}} \frac{dA}{\sqrt{E_0^{cl} - W_0(A)}}.
$$

(30)

Figure 4: A B$_2$ solution in an attractive square well. Left and right parts as in Fig. 3. The plot corresponds to $\sigma = 4 \xi$ and $V_0 \xi^2 = 0.5$ in a low density beam at velocity $v_\infty/c_\infty = 0.7$. The down-stream density evolves from $n_\infty$ to $n(0)$ in the potential $W(n)$ with a classical energy $E_{cl} = W(n_\infty)$, then it makes a complete oscillation in $W_0(n)$ starting from $n(0)$ towards $n_{max,0}$ and ending again at $n(\sigma) = n(0)$. Finally the up-stream density goes from $n(\sigma)$ to $n_\infty$ in the potential $W(n)$.

Other types of solution, different from the B-family, exist for a beam velocity lower than the speed of sound. They correspond to density profiles that decrease from the down-stream asymptotic value $n_\infty$ as $x$ moves from $-\infty$ towards the origin, with $E_{cl}^- = W(n_\infty)$. Hence this type of solution is a portion of a solitary wave in the rear of the obstacle. We refer to these solutions as the D-solutions (where D stands for depressed).
For a D-solution, the density has a value $n(0) < n_\infty$ at $x = 0$ and from there on, the equivalent classical particle evolves in the potential $W_0$. In the simplest case the particle bounces once on the repulsive core at the origin, namely the density further decreases until it reaches a value $n_{min,0}$ (satisfying $E_{cl}^0 = W_0(n_{min,0})$) and then increases until $x = \sigma$. Then the classical particle evolves in $W(n)$ again, with and energy $E_{cl}^+$ that has to be lower than or equal to $W(n_\infty)$, and this imposes $n(\sigma) \geq n(0)$ (cf Eq. (26)). Note that here, contrary to the case of the B-solution, the strict inequality is possible; it corresponds to $E_{cl}^+ < W(n_\infty)$ and $n(\sigma) < n_\infty$, i.e., the up-stream solution is a cnoidal wave. In the particular case that $n(\sigma) = n(0)$ the solution is even. A generic density profile with a cnoidal wave is represented in Fig. 5(a), and the even solution is represented in Fig. 5(b).

![Diagram](image)

Figure 5: A D$_1$ solution in an attractive square well. Left and right parts as in Fig. 4. Plot (a) is the generic case (with $n(\sigma) > n(0)$) and (b) is the symmetric case where $n(\sigma) = n(0)$. These plots correspond to $\sigma = 2 \xi$ and $V_0 \xi^2 = 0.1$ in a low density beam at velocity $v_\infty/c_\infty = 0.7$. The right plot illustrates the behavior of the typical solution (such as displayed in part (a)) in the diagram $(n, W(n))$. The down-stream density evolves from $n_\infty$ to $n(0)$ in the potential $W(n)$ with a classical energy $E_{cl}^- = W(n_\infty)$. Then in $W_0$ (with an energy $E_{cl}^0$) from $n(0)$ to the minimum density $n_{min,0}$ and back to a value $n(\sigma)$ (larger than $n(0)$). Finally the up-stream density oscillates in the classical potential $W(n)$ as a cnoidal wave.

For a given well depth $V_0$ the simple D-solutions of Fig. 5 (which we denote as the D$_1$ solution, with one minimum in the region of the potential) do not exist for all values of $\sigma$. When the well becomes very large, $\sigma$ may exceed the period of the oscillation of density in the well (i.e., the “time”
period of the “classical particle” evolving in $W_0$). In that case the $D_1$-solution disappears. The limiting case corresponds to $n(0) = n_{\infty} = n(\sigma)$ i.e., to a flat density outside the region of the well having one oscillation in the region of the well. This upper limit is exactly the lower limit $\sigma_2(V_0)$ below which the $B_2$ solution does not exist. As a consequence, when $\sigma$ increases from a small value the $D_1$-solution disappears at $\sigma = \sigma_2(V_0)$ and becomes the $B_2$-solution (of the type illustrated in Fig. 4), which is then allowed for any larger value of $\sigma$. The point is that for a $B$-solution, when changing from potential $W$ to $W_0$ in the $(n,W)$ diagram, one can jump arbitrarily close to the separatrix of $W_0$, thus making the period in the region of the potential as large as desired. Hence, once a $B$-solution exists for a given $\sigma$, it exists also for any larger value. For a $D$-solution however the period in $W_0$ is limited: it takes its largest value if one enters and leaves the region of the potential $W_0$ with a flat density (i.e., $n(0) = n_{\infty} = n(\sigma)$).

The existence of the $D_1$ solution for $\sigma < \sigma_2(V_0)$ depends on the value of $V_0$ and of the relative positions of the curves $W(n)$ and $W_0(n)$ in the $(n,W)$ diagram. One regime is set by small values of $V_0$ such that the condition $n_{\min} < n_{1,0}$ is satisfied, where $n_{\min}$ is the smallest positive solution of $W(n) = W(n_{\infty})$ (see Fig. 3 in the case $E_{cl} = W(n_2 = n_{\infty})$) and $n_{1,0}$ is the first zero of $dW_0/dn$ (remember that we denote with an index “0” the quantities concerning the limiting case corresponds to $n = n_{\min}(0)$).

In that case the $D_1$-solution exists for any larger value of $\sigma$. For a $D$-solution however the period in $W_0$ is limited: it takes its largest value if one enters and leaves the region of the potential $W_0$ with a flat density (i.e., $n(0) = n_{\infty} = n(\sigma)$).

The situation for the solutions of type $D_1$ is summarized in Figure 7.

$D$-solutions can oscillate in the region of the well, as $B$-solutions do. We denote by $D_N$-solution a type-$D$ solution with $N$ minima. Contrary to the case of $B_N$-solutions, there exists a maximum width for $D_N$-solutions to occur. When the $D_N$-solution disappears, it becomes a $B_{N+1}$-solution (exactly as discussed above for $N = 1$). $D_N$ solutions are not necessarily even as $B_N$ solutions are; ahead of the obstacle (for $x \geq \sigma$) they typically consist of a cnoidal wave (see the discussion for $N = 1$ and Figure 5). In this case we do not consider that the minima of the cnoidal wave outside the well increase the index “$N$” in the name “$D_N$-solution” (for instance the profile of Fig. 5(a) corresponds to a $D_1$ solution although an infinity of minima occur up-stream). Furthermore, $D_N$-solutions have the additional feature that they may not exist for values of $\sigma$ lower than $\sigma_N(V_0)$. This was explained above in detail for the case $N = 1$. Figure 8 illustrates this generic behavior for a $D_2$-solution.

As for $N = 1$, for this family there are generically two main types of potential well, depending whether $n_{1,0}$ is larger (shallow potential) or smaller (deep potential) than $n_{\min}$ (left and right parts of Figure 8, respectively). In the case of a shallow potential the $D_2$ solution exists for any width below $\sigma_2(V_0)$; this is not the case for deep potentials. We will not comment on Figure 8 in great detail, but we note that even in the simple case of a shallow potential interesting bifurcations occur. Let us focus on this case. For simplicity we discard from the discussion solutions forming cnoidal waves up-stream (i.e., for $x \geq \sigma$). Then, for small widths, the only possible $D_2$ solutions are even.
5.2 high beam velocity: $v_\infty / c_\infty > 1$

We now consider beam velocities $v_\infty$ larger (in absolute value) than $c_\infty = c(n_\infty)$. In the language of Fig. 3, $n_\infty$ is in this case of type $n_1$ (the minimum of the potential) and $E_{cl}^- = W(n_1)$. The only possible flat solution far in the rear of the obstacle is a flat and constant density, namely
Figure 7: Synoptic diagram of the evolution of the morphology of the D\(_1\) solution for a given \(V_0\), as \(\sigma\) increases. The insets display the density profiles \(n(x)/n_\infty\). Hatched regions indicate values of \(\sigma\) for which the solution does not exist. For shallow potentials (for which \(n_{1,0} > n_{\min}\), upper part of the plot) the D\(_1\) solution exists for any width \(\sigma\) between 0 and \(\sigma_2(V_0)\). For deep potentials (\(n_{1,0} < n_{\min}\), lower part) it exists only if \(\sigma \in [\sigma_1^*(V_0), \sigma_2(V_0)]\). In both cases (shallow or deep potential) at \(\sigma = \sigma_2(V_0)\) the D\(_1\) solution disappears and becomes a B\(_2\) solution.

\[ n(x \leq 0) = n_\infty. \] The matching condition \((26)\) yields \(E_{cl}^+ = E_{cl}^- + V_0(n_\infty - n(\sigma))\). One should verify that \(E_{cl}^+ \geq W(n_1 = n_\infty) = E_{cl}^- \) (see Fig. 4) and this imposes \(n(\sigma) \leq n_\infty\). This inequality is trivially satisfied, because the solution inside the well is a cnoidal wave with \(n_{\max,0} = n_\infty\) (see Fig. 4). If we denote by \(n_2\) (as in Sec. 4) the second zero of \(dW/dn\) (the first one being \(n_1 = n_\infty\)) one has also to verify that \(E_{cl}^+ \leq W(n_2)\). This imposes

\[ n(\sigma) \geq n_{\sigma,inf} = n_\infty - \frac{1}{V_0} [W(n_2) - W(n_1)]. \] (32)

Once this condition is fulfilled, the up-stream solution is a cnoidal wave. Because these solutions have a constant down-stream density, we denote them C-solutions.

Two different cases are to be considered. The first and simpler one corresponds to \(n_{\min,0} > n_{\sigma,inf}\). It occurs for high beam velocity (when \(W(n_2) - W(n_1)\) is large) and for shallow potentials (when \(V_0\) is small). In that case, the density of the cnoidal wave inside the well oscillates between \(n_{\min,0}\) and \(n_{\max,0}\), and the matching at \(x = \sigma\) is always possible. The incoming wave (for \(x \geq \sigma\)) is
Figure 8: Synoptic diagram of the evolution of the morphology of the D$_2$ solution for given $V_0$, as $\sigma$ increases (see caption of Fig. 7). For $\sigma$ larger than $\sigma_3(V_0)$ the D$_2$ solution disappears (it becomes a B$_3$ solution). The left part corresponds to a shallow well and the right part to a deep well. For legibility, the cases denoted as “typical” have been taken to consist ahead of the obstacle (for $x \geq \sigma$) of a portion of a soliton (whereas the most generic solutions are cnoidal waves).

a cnoidal wave corresponding to oscillations of the “classical particle” in the potential $W(n)$. This behavior is illustrated in Fig. 9(a).

The other case corresponds to $n_{\sigma, inf} > n_{\min,0}$. Then all the widths are not acceptable, namely, $\sigma$ should be such that $n(\sigma) > n_{\sigma, inf}$. If one denotes by $L_a$ the length the density takes to go from the value $n_{\sigma, infty}$ to $n_{\max,0}$ and by $L_0$ the period of the cnoidal wave in the well, one has

$$L_a = \frac{1}{\sqrt{2}} \int_{\sqrt{n_{\min,0}}}^{\sqrt{n_{\max,0}}} \frac{dA}{\sqrt{E_{cl} - W_0(A)}} \quad \text{and} \quad L_0 = \sqrt{2} \int_{\sqrt{n_{\min,0}}}^{\sqrt{n_{\max,0}}} \frac{dA}{\sqrt{E_{cl} - W_0(A)}}. \quad (33)$$

The allowed values of $\sigma$ are in the intervals $[0, L_a] \cup [L_0 - L_a, L_0 + L_a] \cup [2L_0 - L_a, 2L_0 + L_a] \cup ...$.

The region of validity of the first case $n_{\min,0} > n_{\sigma, inf}$ can be evaluated analytically in the low density regime. In this regime one obtains $W(n_2) - W(n_1 = n_\infty) = n_\infty F(v_\infty/c_\infty)/(4\xi^2)$ where

$$F(z) = \left[ \frac{z^2}{4} \left( 1 + \sqrt{1 + \frac{8}{z^2}} \right) - 1 \right] \left[ \frac{5z^2}{4} + 1 - \frac{3z^2}{4} \sqrt{1 + \frac{8}{z^2}} \right]. \quad (34)$$

This yields $n_{\sigma, inf}/n_\infty = 1 - F(z)/(4V_0\xi^2)$ (we set $z = v_\infty/c_\infty$). One also obtains $n_{\min,0}/n_\infty = G(z, V_0 \xi^2)$ where

$$G(z, V_0 \xi^2) = \frac{z^2 + 1}{2} + 2V_0\xi^2 - \sqrt{\left( \frac{z^2 + 1}{2} + 2V_0\xi^2 \right)^2 - z^2}. \quad (35)$$
Figure 9: A C-solution in an attractive square well. Left and right parts as in Fig. 3. Both density plots on the left part concern a low density beam, with \( v_\infty/c_\infty = 1.6 \) and a square well of width \( \sigma/\xi = 4.68174 \). Plot (a) is the generic case and corresponds to \( V_0 \xi^2 = 0.1 \). For these values of \( V_0 \) and \( v_\infty \) the condition (32) is fulfilled for any \( \sigma \). Plot (b) corresponds to a well of depth \( V_0 \xi^2 = 0.5 \). The parameters have been chosen in this case such that \( E_{cl}^+ = W(n_2) \) and the C-solution is just about to disappear. The right plot illustrates the behavior of the typical solution (corresponding to part (a)) in the diagram \((n, W(n))\). The density is constant and equal to \( n_\infty \) for \( x \leq 0 \) in \( W(n) \). From \( x = 0 \) to \( x = \sigma \) the “classical particle” evolves in \( W_0(n) \) (with an energy \( E_{cl}^0 \)). Finally the up-stream density oscillates in the classical potential \( W(n) \) as a cnoidal wave.

The region of validity of the condition \( n_{\sigma,inf} < n_{min,0} \) (where all the potential widths are acceptable) can be displayed in a diagram \((z = v_\infty/c_\infty, V_0 \xi^2)\). It corresponds to the region

\[
1 - \frac{F(z)}{4V_0 \xi^2} < G(z, V_0 \xi^2) ,
\]

i.e., to the domain below the solid line in Fig. 10.

6 The repulsive square well

In this section we consider a simple repulsive potential, namely, we take \( V_\parallel(x) \) to be zero everywhere except in a finite region \( 0 \leq x \leq \sigma \) where it takes the constant value \( V_0 \) \((V_0 > 0)\). This type of potential cannot correspond to a bend in the guide, but it can be realized with a (blue detuned) far off-resonant laser field.

Eq. (25) still holds after changing the sign of \( V_0 \). Eq. (26) holds also, but we rewrite it here with the appropriate sign for future reference,

\[
E_{cl}^- - V_0 n(0) = E_{cl}^0 = E_{cl}^+ - V_0 n(\sigma) .
\]
Figure 10: Representation (for low density beams) of the part of the plane \((v_\infty, V_0)\) where the C solution is allowed for any potential width. The allowed region is located below the solid curve. We also display on the same diagram the region where C solutions are allowed for any width of a repulsive potential (see Sec. 6.1). It corresponds to the domain below the dashed curve for low density beams and below the dot-dashed one for high density beams.

and similarly one has here (instead of (27))

\[
W_0(n) = W(n) - V_0 n
\]  

(38)

The potential \(W_0(n)\) has, for \(V_0\) relatively small, the same behavior as \(W(n)\), namely one minimum at \(n_{1,0}\) and one maximum at \(n_{2,0}\), with \(n_1 < n_{1,0} < n_0 < n_{2,0} < n_2\) (the notations are defined in Sec. 4, see Fig. 1). On the other hand, for large \(V_0\), \(W_0\) is a monotonically decreasing function of \(n\). The transition between the two regimes occurs when \(\mu - V_0 = \epsilon(n_0) + \Phi^2/(2n_0^2)\). Hence, the terms “low” or “large” \(V_0\) we just defined (we also speak below of “weak” and “strong” potentials) are not intrinsic properties of the potential, but depend on the chemical potential \(\mu\) and on the flux \(\Phi\) of the incoming beam (this remark is made quantitative in Sec. 6.1 below).

Amongst all the possible solutions, we choose again to select those corresponding to a flat density at left infinity, \((n(x) \to n_\infty \text{ as } x \to -\infty)\), with a negative velocity \((v(x) \to v_\infty < 0)\). Under these conditions, the transmission modes through repulsive potentials appear to be simpler than for the attractive ones discussed in Sec. 5, as we are now going to show.

6.1 high beam velocity: \(v_\infty/c_\infty > 1\)

The stationary solutions of a supersonic beam encountering a repulsive square well have important similarities with the C-solutions of Sec. 5 and will be given the same name. For weak potentials \((V_0 < \mu - \epsilon(n_0) + \Phi^2/(2n_0^2))\) the solutions exist whatever the value of \(\sigma\), and their shape is very similar to the transmission mode illustrated in Fig. 9(a). The main difference is that here, one has
\( n(x) \geq n(0) = n_\infty \) in the region of the well (whereas the reverse inequality holds for C-solutions in an attractive well).

On the other hand, for strong potentials the solution in the region of the well is not (as for weak potentials) a cnoidal wave. In this region the density increases monotonically from \( x = 0 \) up to \( x = \sigma \); then “classical” motion occurs in \( W(n) \) and the up-stream density profile further oscillates as a cnoidal wave. This means that there exists a maximum value of \( \sigma \) above which no solution can be found in a strong potential. When \( \sigma \) reaches this maximum value, the solution for \( x \geq \sigma \) is a portion of a soliton and the whole solution has a step-like shape going from \( n_\infty = n_1 \) (far in the rear of the obstacle) up to \( n_2 \) at \( x \to +\infty \). The behavior in this limiting case is illustrated in Fig. 11. There is here a difference with the case of a strong attractive square well: when \( \sigma \) has exceeded this maximum value, no other stationary solution appears for larger widths. The reason is that in an attractive square well, the solution in the region of the well is periodic, whereas it increases here without limit for large wells.

Due to the similarities with the case of an attractive potential, it is interesting here also to determine more precisely for which beams a stationary supersonic solution can be found (for weak potentials) for all values of \( \sigma \). An analytical treatment is here possible in both the low and high density regimes. The two cases can be treated on the same footing by introducing an index \( \nu \) with \( \nu = 1 \) in the dilute regime and \( \nu = 1/2 \) for high densities. One has

\[
\epsilon(n) = \epsilon_0 + \frac{1}{2} \frac{\xi^2}{\mu} \left( \frac{n}{n_\infty} \right)^{\nu} \quad \text{and} \quad v^2 = \frac{\nu \mu^2}{2} \left( \frac{n_\infty}{n} \right)^2,
\]

where \( \mu = v_\infty/c_\infty \). One then obtains \( n_0/n_\infty = \frac{z^2}{\nu^2} \) \((n_0 \text{ is defined in Sec. 4, Fig. 1})\). The condition for a repulsive potential to be considered as weak is thus

\[
\mu - V_0 = \epsilon(n_0) + \Phi^2/(2n_0^2) = \epsilon_0 + (n_0/n_\infty)^{\nu} \left( 1 + \frac{\nu}{2} \right)/(2 \xi^2).
\]

Since \( \mu = v_\infty^2/2 + \epsilon(n_\infty) \), this reads

\[
V_0 \xi^2 \leq \frac{1}{2} + \frac{\mu^2}{4} - \frac{1}{2} \left( 1 + \frac{\nu}{2} \right) \frac{z^2}{\nu^2} - 1.
\]

This region of weak potential corresponds in Fig. 11 to the domain below the dashed curve in the dilute regime \( \nu = 1 \), and below the dot-dashed curve in the high density regime \( \nu = 1/2 \). As stated in the beginning of this Section, the terms weak or strong potential do not characterize an intrinsic property of the well. At \( v_\infty = c_\infty \) for instance, all the potentials are “strong”.

In view of future experimental studies of the system, it is also interesting to determine (in the regime of “strong potentials”) the critical value of \( \sigma \) after which no C-solution can be found. We denote this value by \( L_\tau \). Following a reasoning similar to the one of Sec. 5.2 one obtains

\[
L_\tau = \frac{1}{\sqrt{2}} \int_{\sqrt{n_{\min,0}}}^{\sqrt{n_{\sigma,\sup}}} \frac{dA}{\sqrt{E_{cl} - W_0(A)}} \quad \text{where} \quad n_{\sigma,\sup} = n_\infty + \frac{1}{V_0} [W(n_2) - W(n_1)].
\]

In the low density regime \( L_\tau \) can be expressed in terms of an elliptic integral:

\[
\frac{L_\tau}{\xi} = \int_0^{F(z)/(4V_0 \xi^2)} \frac{dx}{\sqrt{2} x \left[ x^2 + x(4V_0 \xi^2 + 1 - z^2) + 4V_0 \xi^2 \right]^{1/2}} \simeq \frac{1}{V_0 \xi^2} \left( \frac{F(z)}{8} \right)^{1/2}.
\]
Figure 11: A C-solution in a repulsive square well. The parameters have been chosen in this case such that $E_{cl} = W(n_2)$ and the C-solution is just about to disappear. Left and right parts as in Fig. 3. The left plot concerns a low density beam, with $v_\infty/c_\infty \simeq 1.6$ and a square well of width $\sigma/\xi = 3$ and depth $V_0 \xi^2 = 0.1$. The right plot illustrates the behavior of this solution in the diagram $(n,W(n))$. The down-stream density is constant and equal to $n_\infty$. From $x = 0$ to $x = \sigma$ the “classical particle” evolves in $W_0(n)$ (with an energy $E_0(n)$), then it evolves back in $W(n)$, just on the separatrix.

Note of course, that Eq. (42) is meaningful only when the condition (40) is violated. $L_a$ in Eq. (33) can also be defined with a similar expression in the low density regime. Both expressions are well approximated by the left part of (42), meaning that one has $8(L_r/a V_0 \xi^2) \simeq F(z)$. We will see below that this corresponds to approximating the potential by a $\delta$-function (cf. Sec. 7, Eq. (50)).

6.2 low beam velocity: $v_\infty/c_\infty < 1$

It is easy to check that in this case, only D_1 solutions can be observed (there are no other D-solutions, and B-solutions are forbidden). The down-stream solution starts at left infinity from a density $n_\infty$ which is of type $n_2$ in the terminology of Sec. 4. $n(x)$ decreases from this value, and in the diagram $(n,W(n))$ the fictitious classical particle evolves in the potential $W_0(n)$ during a “time” $\sigma$, and then evolves in $W(n)$ again. Since one should verify that $E_{cl}^+ \leq W(n_2) = E_{cl}^-$, from (37) this imposes $n(\sigma) \leq n(0)$. If the inequality is strict, the solution for $x > \sigma$ is a cnoidal wave. If $n(\sigma) = n(0)$ the final solution is a portion of a soliton.

Let us consider a strong potential first. If the well is narrow ($\sigma \rightarrow 0$), there are two possible solutions, depending whether, in the diagram $(n,W(n))$, one “jumps” rapidly or not from $W$ to $W_0$. This is illustrated on Fig. 12. When $\sigma$ increases, these two solutions merge and disappear. This behavior was already observed by Hakim in the case of a model repulsive $\delta$-potential [30]. Hakim showed (for the one dimensional Gross-Pitaevskii equation, i.e., in the dilute regime) that the solution which “jumps late” to $W_0$ (right part of Fig. 12) is unstable, and argued convincingly that the other is stable. The same situation is expected to occur here.

In the case of a weak potential there are also two types of solution, but they do not disappear
when $\sigma$ increases. The point is that one can have here $E_{\text{cl}}^0$ arbitrarily close to the separatrix energy $W_0(n_{2,0})$, and the period of motion in the potential $W_0$ can thus be made as large as desired. From (37), one has $E_{\text{cl}}^0 = W_0(n_{2,0})$ if $n(0) = n_0^*$ with

$$n_0^* = n_{2,0} + \frac{1}{W_0} [W(n_2) - W(n_{2,0})].$$

(43)

The expression “jumping soon” (or “late”) from $W$ to $W_0$ that we used in the discussion of strong potentials refers, for a weak potential, to the case where $n(0) > n_0^*$ (or $n(0) < n_0^*$). If $n(0) > n_0^*$, the density remains larger than $n_{2,0}$ and reaches this value at its minimum in the limit $\sigma \to \infty$. If $n(0) < n_0^*$, $E_{\text{cl}}^0 > W_0(n_{2,0})$ and the fictitious classical particle evolves above the separatrix in the potential $W_0$. As in the case of a strong potential, this solution is expected to be unstable. The other one is certainly stable since one can show that it is identical to the result of perturbation theory in the limit of a very weak potential.

7 Simple solutions in the presence of an obstacle

The aim of this section is to study, by means of perturbation theory, some simple solutions of Eq. (17) valid for a generic potential $V_\parallel(x)$. We will argue that near the speed of sound this approach fails, and that in this regime any potential can be approximated by a $\delta$-peak. We will then study the scattering modes of the condensate in the presence of this potential. It allows for a qualitative and simple understanding of the solutions obtained for more realistic potentials in the previous sections. Some of the results presented here have already been obtained by Hakim [30], who considered repulsive potentials only, in a slightly less general setting.
We again restrict the analysis to those transmission modes tending to a flat density at $x \to -\infty$, $n(x \to -\infty) \to n_\infty$, with a negative velocity $v_\infty$. These are of the form $A(x) = A_\infty + \delta A(x)$ (with $A_\infty^2 = n_\infty$). Denoting by $c_\infty$ the sound velocity at density $n_\infty$ (Eq. (20)), a perturbative treatment of Eq. (17) yields

$$\delta A'' + 4 (v_\infty^2 - c_\infty^2) \delta A = 2 A_\infty V_\parallel(x).$$

(44)

The solutions of (44) that tend to zero when $x \to -\infty$ are of the form

$$\delta A(x) = \begin{cases} -\frac{A_\infty}{k} \int_{-\infty}^{+\infty} V_\parallel(y) \exp(-k|y-x|) \, dy & \text{when } v_\infty/c_\infty < 1, \\ \frac{2A_\infty}{k} \int_{-\infty}^{x} V_\parallel(y) \sin(k(x-y)) \, dy & \text{when } v_\infty/c_\infty > 1, \end{cases} \quad (45)$$

where $k = 2|v_\infty^2 - c_\infty^2|^{1/2}$.

Denoting by $\sigma$ the typical range of the potential $V_\parallel$, in the limit $k\sigma \gg 1$ the Green function of (14) is almost a delta peak and Eqs. (15) take the simple form

$$\delta A(x) = \text{sgn}(v_\infty/c_\infty - 1) \frac{2A_\infty}{k^2} V_\parallel(x). \quad (46)$$

This result may seem unnatural at large velocities. Indeed, for a repulsive potential for instance, the density *increases* in the region of the potential. This kind of behavior was already found in Ref. [31], where a very special potential was designed for which this phenomenon occurs at any $v_\infty/c_\infty > 1$. From (46) we see that similar motional dressed states exist for any potential in the limit of very large velocities (when $k\sigma \gg 1$).

In the case $v_\infty/c_\infty > 1$, an asymptotic evaluation of (15) yields far ahead of the obstacle (in the limit $kx \gg 1$) an amplitude of the form

$$\delta A(x) = \frac{2A_\infty}{k} \text{Im}\left\{e^{ikx} \hat{V}_\parallel(k)\right\} + \frac{2A_\infty}{k^2} V_\parallel(x) + O\left(\frac{1}{k^3}\right), \quad (47)$$

where $\hat{V}_\parallel(k) = \int_{-\infty}^{+\infty} dx \exp(-ikx)V_\parallel(x)$ is the Fourier transform of $V_\parallel(x)$. This shows that, for $v_\infty/c_\infty > 1$, Eq. (45) corresponds to a C-solution. The fact that the up-stream solution oscillates with a wave-vector $k$ corresponds to the stationarity condition $v_p(k) = -v_\infty$ (see the end of Sec. 4). The wake is characterized by a wavelength $2\pi/k$ that depends on the velocity of the beam (it decreases when $v_\infty$ increases). This is due to the particular form of the dispersion relation (22), and does not occur above the Landau critical velocity in liquid helium for instance, where the location of the roton minimum fixes the wavelength of the wake [22].

When the beam velocity is lower than the speed of sound, for attractive (resp. repulsive) potentials Eq. (15) describes a $B_1$ (resp. $D_1$) solution. In the attractive case for instance, the bump density measured with respect to the constant density $n_\infty$ contains a number $\Delta N$ of atoms given by $\Delta N = \int_{-\infty}^{+\infty} \delta n(x) \, dx \approx -(4n_\infty/k^2) \int_{-\infty}^{+\infty} dx V_\parallel(x)$. This formula diverges when $v_\infty/c_\infty \to 1$ since $k \to 0$. In that limit, however, the perturbative treatment is not justified. Indeed, Eq. (15) gives a sensible result only if $|\delta A| \ll A_\infty$. Denoting by $V_0$ the typical value of the potential $V_\parallel$, this reads

$$\begin{cases} V_0 \sigma/k \ll 1 & \text{when } k\sigma \ll 1, \\ V_0/k^2 \ll 1 & \text{when } k\sigma \gg 1. \end{cases} \quad (48)$$
These conditions are satisfied only if the beam velocity $v_\infty$ and the sound velocity $c_\infty$ are not too close.

From Eqs. (43) we see that for $v_\infty/c_\infty < 1$ the typical length scale of variation of $\delta A$ is proportional to $k^{-1}$. If $|v_\infty|$ approaches $|c_\infty|$ from below, this length scale diverges and the spatial extension of $\delta A$ increases indefinitely. In this case it is legitimate to approximate $V_\parallel$ by a $\delta$-function. Hence, we do not pursue the perturbative treatment any longer and turn now to the study of solutions in a $\delta$-peak potential.

Consider a potential of the form $V_\parallel(x) = \lambda \delta(x)$ with $\lambda$ positive or negative. A realistic $V_\parallel$ can be approximated by such a potential if its typical length scale $\sigma$ is much lower than the healing length $\xi$. In this case the approximation is valid for any beam velocity. As discussed above, any potential $V_\parallel$ can be approximated by a $\delta$-function when $v_\infty$ approaches $c_\infty$, i.e., in the limit $k\sigma \ll 1$.

The allowed transmission modes of Eq. (17) when $V_\parallel$ is a $\delta$-potential are very simple. They are obtained by joining together the solutions of two straight guides (see Sec. 4), one down-stream ($x < 0$) and the other up-stream ($x > 0$), with the matching condition

$$A'(0^+ - A'(0^-) = 2\lambda A(0) .$$

The integration constant $E_{cl}$ of Eq. (18) changes discontinuously from the value $E_{cl}^-$ for $x < 0$ to the value $E_{cl}^+$ for $x > 0$ ($E_{cl}^\pm = 1/2\left[A'(0^\pm)^2 + W(n(0))\right]$). Using (49) these two values are related through $E_{cl}^+ = E_{cl}^- + \lambda A(0) [A'(0^-) + A'(0^+)]$.

![Figure 13: Domains of existence of the different solutions occurring for a dilute beam in a potential $V_\parallel(x) = \lambda \delta(x)$. Region I occurs only for $v_\infty/c_\infty > 1$ and corresponds to C-solutions. Region II corresponds to B1-solutions and occupies the domain under the dashed line (it occurs only for attractive potentials and for $v_\infty/c_\infty < 1$). Region III corresponds to D-solutions: D1-solutions for $\lambda > 0$ and D2 solutions when $\lambda < 0$.](image)

Let us first consider the case $v_\infty/c_\infty > 1$. We know from Secs. 5.2 and 5.1 that one should observe C-solutions. One has in this case a constant down-stream density $n_\infty = A_\infty^2$ and $E_{cl}^- = W(n_\infty)$. The matching condition imposes $E_{cl}^+ = E_{cl}^- + 2\lambda^2 n_\infty$ and $A'(0^+) = 2\lambda A_\infty$. In order to
have a finite solution at $x = +\infty$ one should moreover satisfy $W(n_\infty) \leq E_{cl}^+ \leq W(n_2)$. This fixes an upper bound for the intensity of the perturbation, given by $2 \lambda^2 n_\infty \leq W(n_2) - W(n_\infty)$. This is the criterion for observing C-solutions. In the low-density limit this relation takes the analytical form

$$8 \lambda^2 \xi^2 \leq F \left( \frac{v_\infty}{c_\infty} \right),$$

where the function $F$ is defined in (34). It corresponds to the region I of Fig. 13.

Let us now consider the case $v_\infty/c_\infty < 1$. The first and simpler solution is the B$_1$-solution which occurs for attractive potentials. The corresponding matching condition (49) reads in this case $n'(0)/n(0) = -2 \lambda$. It can be fulfilled whatever the value of $\lambda$ ($\lambda < 0$) because the function $(n'/n)^2 = 8 n^{-1}[E_{cl} - W(n)]$ can be made arbitrarily large (it grows as $8 \varepsilon(n)/n$ for large $n$). The domain of existence of B$_1$-solutions corresponds to region II in Fig. 13.

D-solutions can also be observed if $v_\infty/c_\infty < 1$. For $\lambda > 0$ these are the D$_1$ solutions whose behavior in the $(n,W(n))$ diagram is illustrated in Fig. 12 (in the case of a depth of finite width though). For $\lambda < 0$ these are D$_2$-solutions such as those shown in Fig. 8 for $\sigma \to 0$. The limiting case (beyond which these solutions disappear) is obtained for two symmetric portions of solitary waves. The matching condition (49) then fixes the maximum value of $|\lambda|$, which corresponds in both cases to

$$|\lambda| \xi = K \left( \frac{v_\infty}{c_\infty} \right),$$

where

$$K(z) = \frac{1}{4 z} \left\{ -8 z^4 - 20 z^2 + 1 + (1 + 8 z^2)^{3/2} \right\}^{1/2}.$$  \hspace{1cm} (51)

The corresponding domain is shown in Fig. 13 (region III).

8 Experimental considerations

In view of future experimental observation of the different flows past an obstacle, we now evaluate the orders of magnitude of the relevant dimensionless parameters identified above. For concreteness we consider a beam such as the one in preparation at the ENS [33]: $^{87}$Rb atoms are guided along the $x$ direction, with a harmonic transverse confinement ($\omega_\perp = 2 \pi \times 500$ Hz and $a_\perp = 0.5$ $\mu$m). The beam has a velocity $v_\infty$ of order of 0.5 m/s and a flux $\Phi$ varying from $10^4$ to $10^8$ atom.s$^{-1}$. Hence the quantity $n_\infty a_{sc}$ varies from $10^{-4}$ to 1. For a rough estimate of the order of magnitude of the relevant parameters, we will consider that this corresponds to the low density limit $n_\infty a_{sc} \ll 1$. Then, the healing length (defined in (3)) and the speed of sound vary from $\xi = 25$ $\mu$m and $c_{sc} = 20$ $\mu$m.s$^{-1}$ (for $n_\infty a_{sc} = 10^{-4}$) to $\xi = 0.25$ $\mu$m and $c_\infty = 2$ mm.s$^{-1}$ ($n_\infty a_{sc} = 1$). Note that the beam velocity is much larger than the speed of sound (the quantity $v_\infty/c_\infty$ is of order $10^5$ at least).

If the obstacle is a bend of constant radius of curvature $R_c$ and opening angle $\Theta$, $V_0 = -1/(8 R_c^2)$ and $\sigma = \Theta R_c$. A reasonable order of magnitude is $R_c = 5 a_\perp$, leading to $V_0 \xi^2 = \frac{1}{200} (\xi/a_\perp)^2$ which varies roughly from $10^{-3}$ to 10. For $\Theta = \pi/2$ one has $\sigma = 8 a_\perp$ and the obstacle can safely be treated perturbatively because in this case $k \sigma \sim 10^4 \gg 1$ and Eq. (18) is satisfied since

$$V_0/k^2 \approx 10^{-8} \ll 1.$$  

For this configuration one thus expects profiles in agreement with Eq. (15) (case $v_\infty/c_\infty > 1$), i.e. C-solutions. Also, since we are in the regime $k \sigma \gg 1$ Eq. (16) holds, meaning that the wake ahead
of the obstacle is very weak, and that there is a decrease in the density in the region of the bend. However, this decrease is extremely small: it corresponds to a number of atoms smaller than unity, and under these conditions nothing noticeable is expected to occur in the bend.

The situation changes drastically if the obstacle is due to a transverse laser beam because the potential can be made much stronger. It can moreover be attractive or repulsive depending on the laser’s frequency, and also the velocity of the obstacle relative to the beam can be modified by using an acousto-optic deflector.

We consider a laser with power $P = 70$ mW and a wavelength $\lambda_L$ varying from 780 to 790 nm (the atomic transition corresponds to a wavelength $\lambda_A = 780.2$ nm and has a natural width $\Gamma = 12 \pi$ MHz). The laser beam has a typical waist $\sigma$ of the order of 50 $\mu$m. Then one obtains for the transverse potential

$$V_\parallel(x) = V_0 \exp\left(-\frac{x^2}{\sigma^2}\right) \quad \text{where} \quad V_0 = \frac{\hbar \Gamma^2 P}{4 \pi \delta \sigma^2 I_S}, \quad (52)$$

\[\delta = \omega_A - \omega_L\] being the detuning and $I_S = 16$ W.m$^{-2}$ is the saturation intensity. This yields

$$V_0 \sigma^2 = \frac{1}{4 \pi} \left(\frac{\Gamma^2}{\delta \omega_\perp}\right) \left(\frac{P}{I_S a_\perp^2}\right) \sim \pm 10^8. \quad (53)$$

In this case one is in the regime $k \sigma \gg 1$, with $V_0/k^2 \sim 10^{-2}$ or $10^{-1}$. Hence one is on the edge of applicability of the perturbative approach. By changing the wavelength of the laser or its velocity with respect to the beam, one may enter into the non-perturbative regime. One can still find C-solutions for this type of potential if the parameters of the system remain in the appropriate region of figure 10. C-solutions exist for any value of $\sigma$ if $V_0 \xi^2 \leq \frac{1}{16} (v_\infty/c_\infty)^4$ in the case of an attractive potential, and if $V_0 \xi^2 \leq \frac{1}{4} (v_\infty/c_\infty)^2$ in the case of repulsive potential (since $v_\infty/c_\infty \gg 1$ we consider here the asymptotic versions of Eqs. (36) and (40)). By modifying the value of the healing length and of the beam velocity these conditions can easily be satisfied or violated (especially in the case of repulsion). In the region where these conditions are violated one can experimentally study the transition from a stationary flow (of type C) to a time dependent one. For instance, it would be of great interest to study the modification of the drag at the transition.

Just at the boundary between the two regions, for a repulsive potential the density profile has the behavior shown in Fig. 11 (for an attractive potential the density profile corresponds to Fig. 9(b)). The density has a step-like shape, and the beam ahead of the obstacle has a velocity lower than the speed of sound. One has just at the transition $\sigma = L_r$ (or $L_a$ in the case of an attractive potential) with $8 (V_0 L_r \xi)^2 \approx F(v_\infty/c_\infty) \approx (v_\infty/c_\infty)^4/4$ (see the end of Sec. 6.1). From the estimate (52), this occurs for $\xi/\sigma \sim 10^{-2}$ or $10^{-3}$. For a laser, one can tune the waist $\sigma$ by a factor of order 5 say, and more important, by changing the density one can modify the value of $\xi$ and indeed reach the appropriate regime. This would have a very important effect on the beam, since the velocity ahead of the obstacle would be lower than the speed of sound whereas it is of the order of 1 m.s$^{-1}$ down-stream. Accordingly, the density along the beam would go from $n_\infty = n_2$ to $n_1$ (see Fig. 11). It is not difficult to see that, in the dilute regime, in the limit $v_\infty/c_\infty \gg 1$ one has $n_2 \approx n_1 (v_\infty/c_\infty)^2/4$. Thus the down-stream beam density is divided by a factor of order $10^6$ with respect to the up-stream one and, by conservation of the flux, the velocity is multiplied by the same factor. The beam velocity ahead of the obstacle is then of the order of a few micron per second!
9 Conclusions

In this paper we have studied the different stationary profiles of a Bose-Einstein condensed beam propagating through a guide with an obstacle. The beam far down-stream is characterized by its velocity $v_\infty$ and density $n_\infty$ (or equivalently, its healing length $\xi$). The obstacle is represented by a one dimensional square well of depth $\pm V_0$ and width $\sigma$. Let us denote by $\Delta$ the region along the guide where the potential is different from zero. Our study allows to identify the relevant dimensionless parameters governing the flow across the obstacle. These are $n_\infty a_{sc}$, $v_\infty/c_\infty$, $\sigma/\xi$ and $V_0 \xi^2$. By varying these parameters one obtains a wide range of density profiles (we identify three main stationary families denoted as B, C and D-solutions). We have numerically checked that similar results are obtained for potentials other than square wells (such as $V_\parallel(x) = \pm V_0 \exp\left(-x^2/\sigma^2\right)$ for instance) and we thus believe that our analysis of the flow is quite general.

The richest case occurs when the external potential is attractive. In the subsonic regime (beam velocity lower than the corresponding speed of sound) the simplest solution is a symmetric density having a peak in $\Delta$ (B-family). These solutions may have density oscillations in $\Delta$, and are always symmetric. Another type of transmission mode is a soliton-like depressed solution pinned to the obstacle (D-family), which may also have density oscillations in $\Delta$ and, unlike the B-family, a wake up-stream. Finally, the supersonic transmission modes (C-solutions) possess, in the simplest case, a density trough in $\Delta$ and are constant outside. They may also have density oscillations in $\Delta$ and an up-stream wake.

For a repulsive potential, in the subsonic regime the transmission modes are of type D with no density oscillations in $\Delta$. In the supersonic case, the modes are of type C but with a density peak instead of a trough. Step-like solutions of increasing density across the obstacle (with or without wake) also exist. Specifically, we have identified an interesting (and experimentally reachable) regime where the beam is almost stopped by a repulsive obstacle and gains ahead of it several orders of magnitude in density (see Sec. 8).

An important aspect of the problem that remains open are considerations related to the stability of the solutions. Some related work is in progress. We just note here that the limiting C-solution shown in Figs. 9b and 11 can be turned into a D-solution by exchanging the down-stream and the up-stream behavior of the flow. However, these are part of a continuous family of flow patterns and are probably unstable. The C-solutions on the other hand, as selected by the radiation condition (see the end of Sec. 4), are the only acceptable ones for $v_\infty/c_\infty > 1$. Another aspect concerns Bose gases with attractive intra-atomic interactions, which may also be treated with our formalism. In this case the potential $W(n)$ introduced in Sec. 4 has a single-well shape, and the number of different transmission modes whose density tends to a constant at the input of the guide is greatly reduced with respect to the case of repulsive interactions considered here.

We conclude by noting that a branch of BEC that is now expanding is the non-linear counterpart of transport experiments of mesoscopic physics in condensed matter. In the latter case the coherent transport of two-dimensional electron gases through various geometries has been considered in great detail. Future developments of transport experiments of Bose condensates should extend those to non-linear regimes.

Acknowledgments
It is a pleasure to thank S. Brazovskii, C. Schmit, J. Treiner and D. Ullmo for fruitful discussions. Special thanks to F. Dalfovo and S. Stringari for discussing the results of this paper and bringing Ref. [32] to our attention. We also would like to thank warmly D. Guéry-Odelin for numerous fruitful exchanges.

Appendix A

In this Appendix we recall the conditions for existence of a bound state in a bend of an ordinary wave guide (i.e. without non-linear terms in the Schrödinger equation) and put the adiabatic limit used in the text on firmer mathematical grounds.

Let us consider a curve $C$, of parametric equation $r_C(x)$, $x$ being a curvilinear abscissa along $C$. The Frenet frame $(\vec{t}, \vec{n}, \vec{b})$, the curvature $\kappa(x)$ and the torsion $\tau(x)$ are defined by $\vec{t} = dx_C/dx$, $d\vec{t}/dx = \kappa \vec{n}$, $d\vec{n}/dx = -\kappa \vec{t} + \tau \vec{b}$ and $d\vec{b}/dx = -\tau \vec{n}$.

We first introduce a curvilinear coordinate system. The position of a point of space is specified by coordinates $(x, y, z)$ through

$$\vec{r}(x, y, z) = r_C(x) + y \vec{N} + z \vec{B},$$

(A1)

where $N(x) = \cos \theta \vec{n} + \sin \theta \vec{b}$, $B(x) = -\sin \theta \vec{n} + \cos \theta \vec{b}$ and $\theta(x)$ is defined through $d\theta/dx = -\tau(x)$. We then select a potential of the form $V_\perp(y, z)$. Note that the choice of vectors $\vec{N}$ and $\vec{B}$ for defining the transverse coordinates $y$ and $z$ is not irrelevant, i.e., the manner in which $V_\perp$ winds round $C$ does matter: it has to be the same as the way $(\vec{N}, \vec{B})$ winds around $\vec{t}$. Indeed one can see that some torsion may create a repulsive potential along $x$ which could cancel the localizing effect of the bend. This is avoided with the type of coordinate dependence we have chosen. A simple way of seeing this is by noticing that $\vec{N}$ has coordinates $(h^{-1} \partial_x, \partial_y, \partial_z)$ in the $(\vec{t}, \vec{N}, \vec{B})$ frame (with $h(x, y, z) = 1 - \kappa (y \cos \theta - z \cos \theta)$) and the force $-\nabla V_\perp(y, z)$ thus has no tangential component. It would have been more natural to define the $(y, z)$ coordinates as in (A1) but using the $\vec{n}, \vec{b}$ vectors instead of $(\vec{N}, \vec{B})$. In this case however the force $-\nabla V_\perp(y, z)$ would generically have a tangential component which could spoil the localizing properties of the bend. Note that the latter discussion is of course irrelevant for a potential $V_\perp$ with circular symmetry (as any simple experimental wave guide is expected to have).

Denoting $h' = \partial_x h$ and $h'' = \partial_{xx}^2 h$, the Schrödinger equation for $\Phi = h^{1/2} \Psi$ reads

$$-\frac{1}{2} \left( \frac{1}{h^2} \partial_x^2 + \partial_y^2 + \partial_z^2 \right) \Phi + \frac{h'}{h^3} \partial_x \Phi + \left[ \frac{\kappa^2}{8 h^2} - \frac{5 (h')^2}{8 h^4} + \frac{h''}{4 h^3} + V_\perp(y, z) \right] \Phi = \mu \Phi. \quad (A2)$$

Note that in (A2) as in the rest of the paper, we take $\hbar = m = 1$. The choice of coordinates (A1) gives a volume element $d^3r = h \, dx \, dy \, dz$ and $\Phi$ is thus normalized as $\int dx \, dy \, dz |\Phi|^2 = 1$.

The adiabatic limit is defined by $h \to 1$, $\kappa \gg h'$, $\kappa \gg \sqrt{h''}$. In this limit Eq. (A2) decouples into a longitudinal and a transverse equation. One obtains for the longitudinal equation a potential $V_\parallel(x) = -\kappa^2(x)/8$, attractive in the region of the bend. Since any attractive potential in one dimension has a bound state [23], in this limit there exists a quantum state localized in the bend.

The theorem of Goldstone and Jaffe [19] establishes the existence of a bound state for much more general wave-guides, with arbitrary curvature. It was originally demonstrated for sharp-walls
wave guides, but the proof can be straightforwardly extended to the case of a smooth confining potential. Hence we do not reproduce its derivation here. We just note that for some points of space, the coordinate system \( \{A_1\} \) can be ambiguous. This imposes for the sharp wall problem the requirement that the transverse size of the guide does not exceed the radius of curvature of \( C \). For the smooth potential problem, the same restriction requires that the typical range of \( V_\perp \) (or equivalently the spatial extension of \( \phi_\perp \)) is lower than the radius of curvature of \( C \). Obviously this condition is much weaker than the condition of adiabaticity. Note also that the Goldstone-Jaffe theorem has the same limitation as above, namely some torsion may destroy the localizing effect of the bend and the way \( V_\perp \) winds around the curve \( C \) is not irrelevant. A potential \( V_\perp(y, z) \) where the coordinates \( y \) and \( z \) are defined above (Eqs. \( \{A_1\} \)) ensures the applicability of the theorem.

Careful derivation shows that (13) is applicable for $N = 0$ in the limit $\sigma^{-2} \gg V_0$, where $V_0$ and $\sigma$ are typical orders of magnitude for the depth and range of $V_{\parallel}(x)$, respectively. This condition corresponds to shallow potentials with a zero point energy much larger than $V_0$. If this condition is fulfilled for $N = 0$, increasing $N$ increases the spatial extension of the bound state and makes the approximation even better justified. When $N$ tends to $N_{\text{max}}$ the approximation is valid for any type of potential (not necessarily shallow).

As discussed at the end of Sec. 2, such bendings have been treated successfully for linear waves in Ref. [17] with an adiabatic approximation of the type (1).
