Keywords: Activated Random Walks; Interacting Particles System

Abstract
We prove that for the Activated Random Walks model on transitive unimodular graphs, if there is fixation, then every particle eventually fixates, almost surely. We deduce that the critical density is at most 1. Our methods apply for much more general processes on unimodular graphs. Roughly put, our result apply whenever the path of each particle has an automorphism invariant distribution and is independent of other particles’ paths, and the interaction between particles is automorphism invariant and local. In particular, we do not require the particles path distribution to be Markovian. This allows us to answer a question of Rolla and Sidoravicius [3,4], in a more general setting then had been previously known (by Shellef [5]).

1 Introduction
Let G = (V, E) be an infinite, locally finite transitive graph. Let μ be a distribution on N. The activated random walk (ARW) model is an interacting particle system on G, in which the number of particles initially on each vertex is independently distributed according to law μ. At the onset, all the particles are active. Each active particle independently performs a continuous time rate 1 simple random walk on G and also becomes inactive independently at rate λ. An inactive particle stays put as long as there are no other particles at the same vertex. Once there is another particle (necessarily active) at the vertex of an inactive particle, the inactive particle immediately becomes active. In particular, as long as there are two (or more) particles at a vertex, none of them become inactive.

We say that a vertex v fixates at time t, if t is the minimal time such that there are no active particles at v after t. If v fixates at some time t, we say it is fixating, otherwise it is nonfixating. Similarly, define when a particle fixates at time t, in which case it is fixating and otherwise it is nonfixating. We say that the model is vertex fixating if every vertex fixates almost surely and particle fixating if every particle fixates almost surely.
The main question of interest in this model is under which conditions does the system (vertex-)fixate? For a comprehensive survey of known results, conjectures and simulations we refer the reader to [1].

Recall that a transitive graph is unimodular, if for any two vertices \(x, y\) we have \(|A(x, y)| = |A(y, x)|\), where \(A(x, y) = \{f(y) \mid f \in \operatorname{Aut}(G), f(x) = x\}\). These include all amenable transitive graphs, all Cayley graphs as well as all regular trees (see [2], chapter 8). For unimodular graphs the following symmetry principle holds:

**Mass Transport Principle**: Let \(G = (V, E)\) be a unimodular graph, and assume \(F : V \times V \rightarrow [0, 1]\) is automorphism invariant (i.e. \(F(\gamma v, \gamma y) = f(x, y)\) for any \(\gamma \in \operatorname{Aut}(G)\)), then for any \(v \in V\) we have

\[
\sum_{w \in V} F(v, w) = \sum_{w \in V} F(w, v)
\]

Loosely speaking, the mass transport principle says that under enough symmetry, the amount of mass transmitted from a vertex \(v\) is equal to the amount of mass entering \(v\). For proofs, applications and generalizations to other graphs, the reader is referred to chapter 8 of [2].

Before stating our results, we wish to generalize the setting to include other, possibly non-Markovian, behaviors of the particles. A path is a function \(y : \mathbb{R}^+ \rightarrow V\) such that there is an infinite sequence \(0 = t_0 < t_1 < \ldots \rightarrow \infty\) and \(v_0, v_1, \ldots \in V\) satisfying \(y(t_{i+1}) \equiv v_i\) and \((v_i, v_{i+1}) \in E\). This is the path of the particle parameterized by its inner time. A distribution \(Y\) on paths beginning at some fixed vertex \(y(0)\), is invariant if for every \(\gamma \in \operatorname{Aut}(G, y(0))\) we have \(\gamma \circ Y = Y\), where \(\operatorname{Aut}(G, v)\) is the group of automorphisms preserving \(v\). A distribution \(Y\) on paths has infinite range if the range of a path sampled from this distribution is a.s. infinite. Finally, we say that the model is transitive if there is a transitive subgroup \(H \leq \operatorname{Aut}(G)\) such that the path distribution of particles starting at \(v\) is the image of the path distribution of particles starting at \(u\) under any \(h \in H\) for which \(h(v) = u\). If the model is both invariant and transitive, we might as well take \(H = \operatorname{Aut}(G)\).

Obviously, the original ARW model, with particles performing continuous time, simple random walk is invariant, transitive and has infinite range.

Given the path distribution, one can define the corresponding generalized activated random walk model by randomizing a Poisson process indicating at which times the particle becomes inactive if it is alone on a vertex. Similarly, one may define other models by using different interaction rules. We may consider any interaction which affects only the rate in which particles move along their paths (including rendering particles inactive). Thus, an interaction rule for a particle is a function from all possible states of the system at time \(t\) (that is, the actual paths of all particles until time \(t\)) into \(\mathbb{R}^+\). The output of this function determines the rate in which the actual path of the particle progresses along its putative path. In order to account for random interactions, we equip each particle with an independent \(U[0, 1]\) random variable, which the interaction rule is also given as input.

In this paper we will only be interested in automorphism invariant interaction rules, which are also local, that is, the function actually depends only on those particles at some finite radius around our particle.

Of course, for some path distributions and interaction rules the resulting model might not be well defined or unique or local (i.e. that every vertex is visited by only finitely many particles in any finite time interval). We do not concern ourselves with these questions in this paper. Rather, we assume that the model is well defined, unique and local.

**Theorem 1.1.** If an invariant, transitive, infinite-range, local model on a unimodular graph is vertex-fixating, then it is particle-fixating.
We remark that since we only need the model to be invariant w.r.t. some unimodular group (in order to use the mass transport principle), hence, if the graph is amenable, one can dismiss the requirement that the path distribution is invariant, and only require the model to be transitive (since any transitive group of automorphisms is unimodular in that case). In particular, Theorem 1.1 applies to any translation-invariant model on $\mathbb{Z}^d$.

Using Theorem 1.1 we immediately get the following corollary, which answers a question of Rolla and Sidoravicius [3,4].

**Corollary 1.2.** An invariant, transitive, infinite-range generalized ARW model on a unimodular graph with $\mathbb{E}(\mu) > 1$ is not vertex-fixating.

**Proof.** Assume that the model is vertex-fixating. Let $F(u, v)$ be the probability that some particle, starting at $u$ fixates at $v$. Obviously, $F$ is automorphism invariant. Since only 1 particle may fixate at a given vertex we have $\sum_{v \in V} F(u, v) \leq 1$. By the mass transport principle this is equal to $\sum_{v \in V} F(u, v)$ which is therefore also at most 1. By Theorem 1.1 all particles fixate, so this sum is equal to $\mathbb{E}(\mu)$ which is therefore at most 1.

Of course, the corollary applies to any model in which only 1 particle may fixate at any given vertex.

If the starting distribution $\mu$ is taken to be Poisson with expectation $\zeta$, then Rolla and Sidoravicius [3,4] show that for a fixed sleeping rate $\lambda$, fixation is monotone in $\zeta$ and that there is a critical density $\zeta_c$ such that for $\zeta > \zeta_c$ the system does not fixate and for $\zeta < \zeta_c$ it does. Corollary 1.2 then implies:

**Corollary 1.3.** The ARW model on a unimodular graph has $\zeta_c \leq 1$.

We remark that it is conjectured, but not known, that $0 < \zeta_c < 1$ for any generalized ARW model (see [1]).

For the original ARW model, corollary 1.3 was proved independently by Shellef [5], using completely different methods, on any bounded degree graph. The main merit of our proof is that although the graph has be unimodular, it works for a broad class of random walks and interaction rules.

## 2 Proof of Theorem 1.1

We will assume the system is not particle-fixating, and show that the system cannot be vertex-fixating.

Let $N_v$ be the number of particles starting at $v$, which is distributed according to the law of $\mu$ independently for each vertex. We number the particles and name the $i$-th particle starting at vertex $v$ by $x_{v,i}$. For each of these particles a putative path $y_{v,i}$ is independently randomized using $\nu$, the invariant, infinite-range distribution on paths. The real path of the particle $x_{v,i}$ follows the putative path with a time change determined by the interaction with other particles.

Let $A_v^i$ be the event “$N_v > i$ and $x_{v,i}$ is nonfixating”. Since the system is not particle-fixating, for some $i$ we have $\mathbb{P}(A_v^i) > 0$. In fact, we have $\mathbb{P}(A_v^{i,0}) > 0$, since conditioned on $N_v > i$, particles $x_{v,i}^i$ and $x_{v,0}^0$ are exchangeable, that is, they have the same conditional distribution, and hence the same conditional probability of not fixating. Let $a = \mathbb{P}(A_v^{i,0})$.

Now, since our system is local, $A_v^{i,0}$ can be $\epsilon$-approximated by another event $B_v^{i,0}$ which depends only on the behavior of those particles starting in some finite radius $R$ around $v$ and up to some finite time $T$. If $B_v^{i,0}$ occurs we call $x_{v,0}$ a candidate. A candidate which is actually non-fixating is
good and the rest of the candidates are bad. By our approximations, the probability that \( x^{v,0} \) is a bad candidate is bounded by \( \epsilon \). Let \( b = \mathbb{P}(B^{v,0}) \geq a - \epsilon \) which is positive for \( \epsilon \) small enough.

Let \( \mathcal{F}_T \) be the \( \sigma \)-algebra consisting of \( \{N_i\}_{i \in V} \) and \( \{y^{v,i}_{[0,T]}\}_{i \in \mathbb{N}} \), as well as the \( U[0,1] \) random variables used to determine local interactions. This \( \sigma \)-algebra determines the process of candidates, which is a 2R-dependent process since \( B^{v,0} \) depends only on \( y^{v,i}_{[0,T]} \) for \( i \) of distance at most \( R \) from \( v \). Fix some integer \( n \) and let \( z^{v,0} \) be a vertex chosen uniformly and independently from the first \( n \) distinct vertices in the path \( y^{v,0} \) (there are \( n \) distinct vertices in the path a.s. since the path distribution is infinite-range).

Let \( C(v,u) \) be the event “\( B^{v,0} \) and \( z^{v,0} = u \)”. Obviously, for any \( v \) and \( u \), the probability of \( C(v,u) \) is at most \( 1/n \), even conditioned on \( \mathcal{F}_T \). Let \( q(v,u) = \mathbb{P}(C(v,u) | \mathcal{F}_T) \) and let \( Q(u) = \sum_{v \in V} q(v,u) \).

**Claim 2.1.** \( Q(u) \sim b \) as \( n \to \infty \).

**Proof.** Consider the mass transport \( F : V \times V \to [0,1] \) defined by \( F(v,u) = \mathbb{P}(C(v,u)) \). It is automorphism invariant, so by the mass transport principle,

\[
\mathbb{E}(Q(u)) = \sum_{v \in V} F(v,u) = \sum_{u \in V} F(v,u) = \mathbb{P}(B^{v,0}) = b .
\]

Since

\[
\text{Var}(q(v,u)) \leq \mathbb{E}((q(v,u))^2) \leq \mathbb{E}(q(v,u))/n
\]

we have

\[
\sum_{v \in V} \text{Var}(q(v,u)) \leq b/n \to 0 .
\]

Similarly, \( \text{Cov}(q(v,u), q(w,u)) \leq \mathbb{E}(q(v,u))/n \) if \( v \) and \( w \) are at most \( 2R \) apart, and \( \text{Cov}(q(v,u), q(w,u)) = 0 \) otherwise. Hence,

\[
\sum_{v \in V} \sum_{w \in V} \text{Cov}(q(v,u), q(w,u)) \leq \sum_{v \in V} q^{2R} \frac{\mathbb{E}(q(v,u))}{n} \leq \frac{d^{2R} b}{n} \to 0
\]

where \( d \) is the degree of a vertex in \( G \). Put together, we get \( \text{Var}(Q(u)) \to 0 \), completing the proof.

Let \( Z(u) = \sum_{v \in V} 1_{C(v,u)} \), that is, the number of candidates for which \( z^{v,0} = u \).

**Claim 2.2.** \( \lim_{n \to \infty} \mathbb{P}(Z(u) > 0 | \mathcal{F}_T) \geq 1 - e^{-b} \).

**Proof.**

\[
\mathbb{P}(Z(u) = 0 | \mathcal{F}_T) = \prod_{v \in V} (1 - q(v,u)) \leq e^{-Q(u)} \to e^{-b}
\]

Let \( D(v,u) \) be the event “\( B^{v,0} \) and not \( A^{v,0} \) and \( z^{v,0} = u \)”, and let \( Z(u) = \sum_{v \in V} 1_{D(v,u)} \), that is, we count the number of bad candidates for which \( z^{v,0} = u \).

**Claim 2.3.** \( \mathbb{E}(Z(u)) \leq \epsilon \)

**Proof.** Consider the mass transport \( F : V \times V \to [0,1] \) defined by \( F(v,u) = \mathbb{P}(D(v,u)) \). It is automorphism invariant, so by the mass transport principle,

\[
\mathbb{E}(Z(u)) = \sum_{v \in V} F(v,u) = \sum_{u \in V} F(v,u) = \mathbb{P}(B^{v,0} \cap \overline{A^{v,0}}) \leq \epsilon
\]

where the last inequality is due to the fact that bad candidates are rare.
It follows from lemma 2.2 and 2.3 that the probability of the event “There exists a good candidate $x^{v,0}$ such that $z^{v,0} = u$” is at least $P(Z(u) > 0) - P(\bar{Z}(u) > 0) \geq 1 - e^{-a+\epsilon} - 2\epsilon$ when $n$ is large enough, which is positive when $\epsilon$ is small enough. But if $z^{v,0} = u$ and $x^{v,0}$ is nonfixating, then there is some $t$ such that $x^{v,0}_t = u$. In particular, if the above event happens then the vertex $u$ has not fixated until time $t$. For any $T'$, the probability that $t < T'$ tends to 0 as $n \to \infty$. Hence, the probability of any vertex to fixate before time $T'$ does not tend to 1.

We wish to remark that although in the proof we only had to show that the probability of a vertex to fixate is not 1, it is, in fact, 0. In the proof above, we picked a single vertex, $z^{v,0}$, uniformly from the first $n$ distinct vertices in the path of $y^{v,0}$, and used this to show that the probability of nonfixation is at least $1 - e^{-a+\epsilon} - 2\epsilon$. In order to improve the bound, we simply pick $k$ independent such vertices, $z^{v,0}_1, \ldots, z^{v,0}_k$. We now get that the probability of the event “There exists a good candidate $x^{v,0}$ such that $z^{v,0}_\ell = u$, for some $\ell \leq k$” is at least $1 - e^{-ka+k\epsilon} - 2k\epsilon$ which is as close to 1 as we want, when $k$ is large enough and $\epsilon \ll 1/k$ small enough.
