Abstract Oxidized 1-palmitoyl-2-arachidonyl-sn-glycero-3-phosphocholine (OxPAPC) and its component phospholipids accumulate in atherosclerotic lesions and regulate the expression of >1,000 genes, many proatherogenic, in human aortic endothelial cells (HAECs). In contrast, there is evidence in the literature that HDL protects the vasculature from inflammatory insult. We have previously shown that in HAECs, HDL attenuates the expression of several proatherogenic genes regulated by OxPAPC and 1-palmitoyl-2-(5,6-epoxyisoprostane E2)-sn-glycero-3-phosphocholine. We now demonstrate that HDL reverses >50% of the OxPAPC transcriptional response. Genes reversed by HDL are enriched for inflammatory and vascular development pathways, while genes not affected by HDL are enriched for oxidative stress response pathways. The protective effect of HDL is partially mimicked by cholesterol repletion and treatment with apoA1 but does not require signaling through scavenger receptor class B type I. Furthermore, our data demonstrate that HDL protection requires direct interaction with OxPAPC. HDL-associated platelet-activating factor acetylhydrolase (PAF-AH) hydrolyzes short-chain bioactive phospholipids in OxPAPC; however, inhibiting PAF-AH activity does not prevent HDL protection. Our results are consistent with HDL sequestering specific bioactive lipids in OxPAPC, thereby preventing their regulation of select target genes. Overall, this work implicates HDL as a major regulator of OxPAPC action in endothelial cells via multiple mechanisms.—Emert, B., Y. Hasin-Brumshtein, J. R. Springstead, L. Vakili, J. A. Berlinger, and A. J. Lusis. HDL inhibits the effects of oxidized phospholipids on endothelial cell gene expression via multiple mechanisms. J. Lipid Res. 2014. 55: 1678–1692.

Over the past 50 years, epidemiological and clinical studies have implicated the major serum lipoproteins in coronary artery disease (CAD) (1, 2). Elevated LDL is strongly associated with CAD in patient populations, and the products of the oxidative modification of LDL particles initiate an inflammatory cascade in the vessel wall that contributes to atherosclerosis (3–5). Oxidation products of 1-palmitoyl-2-arachidonyl-sn-glycero-3-phosphatidylcholine (OxPAPC) are major proatherogenic components of minimally modified LDL, which accumulate in atherosclerotic lesions and induce a strong transcriptional response of >1,000 genes in human aortic endothelial cells (HAECs) (6–9). OxPAPC treatment regulates the abundance of transcripts enriched for several gene ontology categories in HAECs, including the unfolded protein response (UPR), endocytosis, inflamm-

Over the past 50 years, epidemiological and clinical studies have implicated the major serum lipoproteins in coronary artery disease (CAD) (1, 2). Elevated LDL is strongly associated with CAD in patient populations, and the products of the oxidative modification of LDL particles initiate an inflammatory cascade in the vessel wall that contributes to atherosclerosis (3–5). Oxidation products of 1-palmitoyl-2-arachidonyl-sn-glycero-3-phosphatidylcholine (OxPAPC) are major proatherogenic components of minimally modified LDL, which accumulate in atherosclerotic lesions and induce a strong transcriptional response of >1,000 genes in human aortic endothelial cells (HAECs) (6–9). OxPAPC treatment regulates the abundance of transcripts enriched for several gene ontology categories in HAECs, including the unfolded protein response (UPR), endocytosis, inflamm-
mation, angiogenesis, and others. Importantly, molecules that inhibit oxidized phospholipid activity have therapeutic benefits in models of atherosclerosis, implying a causal role for oxidized phospholipids in atherogenesis (10–14).

Contrary to oxidized LDL, HDL functions in many ways to reduce plaque burden and protect the vasculature (15, 16). In addition to its role in cholesterol transport, HDL possesses anti-inflammatory, antioxidant, and antiatherothrombotic properties (17–19). These include directly inhibiting the oxidation of LDL, sequestering by-products of lipid oxidation, and promoting eNOS stability and accumulation in the vessel wall (17, 18, 20–22). In addition, members of our group have previously reported that HDL inhibits the induction by OxPAPC of chemotactic cytokines [interleukin (IL) 8, monocyte chemotactic protein 1 (MCP-1), and IL-6], UPR transcription factors [activating transcription factor 3 (ATF3), activating transcription factor 4 (ATF4), and X-box binding protein 1 (XBP1)], and sterol biosynthetic genes [LDL receptor (LDLR), Insig-1, and HMG-CoA synthase] in HAECs (23). Although research has clearly defined a significant role for HDL in vascular health, recent clinical trials and causal genetic studies have failed to corroborate the link between HDL cholesterol and CAD (24–27). However, the measurement of HDL cholesterol used in these studies may not accurately reflect important HDL functions (19, 27). Thus, further research is needed to understand the complex role of HDL in vascular biology.

The objective of the current study was to explore the ability of HDL to antagonize the effects of OxPAPC on genomewide gene expression in HAECs. Our results demonstrate that HDL inhibits >50% of the gene expression regulated by OxPAPC but does not inhibit the activation of oxidative stress response pathways. We also examined a number of potential mechanisms of HDL protection involving both effects on endothelial cells and on OxPAPC. We conclude that HDL antagonizes OxPAPC signaling via multiple mechanisms.

MATERIALS AND METHODS

Reagents

PAPC was purchased from Avanti Polar Lipids Inc. (Alabaster, AL) and oxidized via exposure to air for 24–48 h to produce OxPAPC as described previously (6). The 5,6-epoxyisoprostane (E1) was synthesized as described previously, and a single analog, E14, was used in this study (28). Cholesterol-cyclodextrin complex was purchased from Sigma-Aldrich. Rabbit polyclonal anti-EI4, was used in this study (28). Cholesterol-cyclodextrin complex was synthesized as described previously, and a single analog, E14, was used in this study (28). Cholesterol-cyclodextrin complex was synthesized as described previously, and a single analog, E14, was used in this study (28). Radiation activation factor acetylhydrolase (PAF-AH) inhibitor was removed by overnight dialysis before treating cells.

Microarray analysis

RNAarray concentrations were measured with the Nano Drop 2000 (Thermo Fisher), and quality was checked with the Agilent Bioanalyzer 2100 (Agilent). Microarray hybridization was performed on the Illumina HT12 v4 microarray by the UCLA EpiGenetics and Genetics core. Expression profiles without background or normalization were determined using Direct Hybridization module in the GenomeStudio software. Expression profiles of multiple donors were then analyzed with the “limma” R package using ‘neqc’ function for quantile normalization and background correction, with donors used as biological replicates. Probe annotation was obtained from illuminaHumanv4.db R package, and probes that were annotated as “Bad” or “No match” were removed from downstream analysis. Contrast matrix was constructed to represent all the comparisons, and differential expression was tested using linear models and ‘ebayes’ function. All P value cutoffs refer to adjusted P values that reflect false discovery rate correction for multiple testing.

For quantitative PCR (qPCR), cDNA was prepared using the ABI High Capacity cDNA Reverse Transcription Kit using equal amounts of input mRNA. Reactions were set up using the SYBR Green mastermix (Kapa Biosystems) and measured on the Roche LightCycler 480 (Roche Diagnostics).

Lipid extraction and quantification by HPLC-MS

OxPAPC (100 µg) was incubated with or without 100 µg of HDL in PBS lacking calcium and magnesium for 1 h at 37°C. Lipids were extracted using a modification of the method of Bligh and Dyer (30). In brief, 3 vol of chloroform-methanol (2:1) containing 0.01% butylated hydroxytoluene (BHT) was added to each sample before vortexing. Samples were then stored under argon at 4°C overnight, and 3 µg of 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) was added as an internal control. An additional volume of methanol and 0.8 vol of PBS were added (final ratio chloroform-methanol-aqueous, 2:2:1.8), and the samples were vortexed and centrifuged at 2,800 rpm for 10 min (Eppendorf 5810R rotor A-4-82). The organic phase was carefully removed and dried under a stream of nitrogen. Dried samples were stored under argon at ~80°C. For HPLC-MS, samples were resuspended in 1:1 chloroform-methanol and loaded onto an ACE C8 Ultra-Inert Analytical 3 micron HPLC column. Gradient elution was set at a flow rate of 0.2 ml/min. Mobile phase A consisted of 0.3% formic acid in water, and mobile phase B consisted of 0.3% formic acid in methanol. The gradient was programmed as follows: 0–11 min, linear gradient from 75.0% to 98.0% B; 11–15 min, 98.0% B; 15–15.1 min, linear gradient from 98.0% to 75.0% B; 15.1–20 min, 75.0% B. Mass spectra were measured with the LCT-Premier XE TOF Instrument controlled by Masslynx 4.1.
software. The mass spectrometer was equipped with a Multi-Mode Source operated in the electrospray mode. The m/z ratios of monitored ions were as follows: 496 bisphosphatidylcholine (LPC), 594 [1-palmitoyl-2-(5-oxovaleroyl)-sn-glycero-3-phosphocholine (POVPC)], 610 [1-palmitoyl-2-gluataryl-sn-glycero-3-phosphocholine (PGPC)], 678 (DMPC), 782 (PAPC), and 828 [1-palmitoyl-2-(5,6-epoxysisoprostane E2)-sn-glycero-3-phosphocholine (PEIPC)]. LPC, POVPC, PGPC, PAPC, and PEIPC were normalized to DMPC to quantify each species.

RESULTS

Effect of HDL on transcript levels in response to OxPAPC

We have previously reported that HDL inhibits OxPAPC-induced transcription of specific genes that were used as molecular markers of particular cellular pathways (23). Later studies demonstrated that OxPAPC induces transcriptional changes in >1,000 genes in HAECs (8). We sought to examine the effects of HDL on the HAEC response to OxPAPC in a more comprehensive manner using microarrays. To this end, we treated HAECs from four different donors with HDL, OxPAPC, and OxPAPC+HDL and compared the transcriptional response of OxPAPC-treated samples versus OxPAPC+HDL-treated samples relative to control.

Clustering of the different donors and treatments clearly shows that HDL has a pronounced effect on expression of OxPAPC-regulated genes, while control samples treated with HDL alone cluster by donor (Fig. 1A). Markedly, HDL alone had virtually no effect on HAEC gene expression. In contrast, OxPAPC induced significant changes in the expression of 1,679 genes (FDR corrected P < 0.05). However, only 806 of these genes were significantly affected by OxPAPC in the presence of HDL (Fig. 1B, C). These results show that HDL has a broad effect on HAEC response to OxPAPC, affecting >50% of genes regulated by OxPAPC. We defined “HDL response” and “genes reversed by HDL” as the difference between HAEC transcriptional response to OxPAPC and to OxPAPC+HDL [i.e., in this experiment, HDL reversed 873 out of 1,679 genes (52%)] (Fig. 1C).

Many of the genes that are significantly affected by OxPAPC show a modest response in terms of fold change. For example, out of 1,679 genes affected by OxPAPC, the expression of only 240 genes was affected >2-fold (Fig. 1B and supplementary Table I). We examined whether HDL primarily affects genes that are subtly regulated by OxPAPC versus genes that show a large response to OxPAPC treatment (supplementary Table I). Surprisingly, the proportion of genes reversed by HDL was independent of the magnitude of effect of OxPAPC, and imposing fold change cutoffs only marginally increased the fraction of genes reversed by HDL to 60% (supplementary Table I).

A recent study by Romanoski et al. (8) examined the OxPAPC response in HAEC from 150 donors and demonstrated that OxPAPC responsive genes can be classified into 12 modules based on their coexpression profiles. These modules were enriched for genes from particular gene ontology (GO) categories, suggesting that they reflect activation or inhibition of specific pathways. In order to determine whether the HDL response is limited to particular pathways or modules, we compared our results with the network analysis published in that study. We found that while there is some variation in the proportion of HDL-affected genes in the different modules, there are no apparent preferences to specific modules (supplementary Table II). We note that the OxPAPC response observed in our study only partially recapitulates the OxPAPC response described previously, which is likely attributable to the different number of donors examined in each study. To identify pathways that were significantly affected by OxPAPC treatment and examine the effect of HDL on these pathways, we used the Signaling Pathway Impact Analysis (SPIA) R package (Table 1). Altogether, HDL inhibited the OxPAPC on 22 out of 24 KEGG pathways. We also examined which genes were most robustly affected by HDL and found that the OxPAPC-mediated induction of several members of the Krüppel-like factor (KLF) family of transcription factors, particularly KLF2, was completely reversed by HDL cotreatment (supplementary Fig. I). Interestingly, HDL did not significantly affect the regulation of genes involved in the oxidative stress response, although several are among the most strongly induced by OxPAPC (supplementary Fig. II).

SR-BI and apoA1 as potential mediators of HDL protection

In order to gain greater insight into the mechanisms mediating the effect of HDL on OxPAPC signaling, we investigated the role of the principal HDL receptor SR-BI. In hepatocytes, SR-BI regulates the uptake of cholesterol from HDL during reverse cholesterol transport, and in endothelial cells, SR-BI has been shown to mediate eNOS activation and cholesterol repletion via interaction with apoA1 (16). Transfection of HAECs with siRNA targeting SR-BI reduced SR-BI mRNA levels by 95% with a concomitant decrease in SR-BI protein levels (supplementary Fig. III). In siRNA-transfected HAECs, HDL maintained the ability to inhibit OxPAPC-mediated induction of KLF2, ATF3, and INSIG1 expression (Fig. 2A). Similarly, cotreatment of HAECs with anti-SR-BI blocking antiserum did not attenuate the effect of HDL on OxPAPC signaling (Fig. 2B).

Treatment of HAECs with purified apoA1 partly mimicked HDL’s effect on OxPAPC signaling (Fig. 2C). ApoA1 at 50 μg/ml reduced the induction of KLF2, ATF3, and INSIG1 by OxPAPC. In contrast to the effect of HDL, which reduced IL-8 induction, apoA1 did not reduce IL-8 expression. Treatment with lower concentrations of apoA1 did not effect OxPAPC-mediated induction of these genes (data not shown). These results suggest that HDL, and to a lesser extent apoA1, can antagonize the effect of OxPAPC on gene expression in human endothelial cells independent of SR-BI.

Cholesterol repletion as mediator of HDL protection

Treatment of endothelial cells with oxidized LDL or OxPAPC depletes caveolar membrane cholesterol, causing
the activation of sterol-regulatory element binding protein (SREBP) and induction of SREBP target genes INSIG1 and LDLR (31). HDL can mitigate this effect by donating cholesterol to endothelial cells treated with oxidized LDL, thereby stabilizing caveolar membrane structure (32, 33).

As presented in Fig. 3, cotreatment of HAECs with 20 μg/ml of cholesterol-cyclodextrin inhibited the induction of INSIG1 and LDLR by OxPAPC to a similar extent as 50 μg/ml of HDL. In contrast, cholesterol-cyclodextrin had no effect on the induction of ATF3 expression and augmented the induction of KLF2 expression in HAECs exposed to OxPAPC, a marked difference between the effects of cholesterol-cyclodextrin and HDL (Fig. 3A).

To assess more accurately which aspects of the HDL response can be mimicked by cholesterol loading, we used microarrays to compare genome-wide expression of...
We next examined whether the effects of cholesterol loading and HDL are comparable at the pathway rather than individual gene level. Comparison of gene ontology categories affected by OxPAPC versus OxPAPC+HDL and OxPAPC + cholesterol loading (supplementary Table III) showed that cholesterol loading inhibited 43% of the GO biological processes reversed by HDL. Among the top 10 GO processes affected by OxPAPC treatment and reversed by HDL, only “positive regulation of defense response” was similarly reversed by cholesterol loading (Table 2). Other gene ontology categories induced by OxPAPC and inhibited both by HDL and cholesterol loading include “toll signaling pathway” and “regulation of innate immune response,” suggesting that cholesterol repletion may mediate anti-inflammatory properties of HDL. However, we also observe GO categories regulated by HDL for which cholesterol loading did not have an observable effect. These include categories related to blood vessel formation such as blood vessel morphogenesis, vasculature development, and smooth muscle cell differentiation. These effects are consistent with HDL not only reducing the inflammatory effects of oxidized phospholipids, but also promoting vascular integrity (35, 36). In addition, preliminary results suggest that HDL protects against endothelial barrier disruption induced by OxPAPC as measured by transendothelial electrical resistance (data not shown). In total, the effects of HDL on endothelial cells mediated by SR-BI, apoA1, and cholesterol repletion are unable to explain a majority of the inhibition we observe on OxPAPC signaling, suggesting that HDL may directly affect OxPAPC composition and activity.

**Cell-independent effects of HDL on OxPAPC**

We assessed whether cotreatment with OxPAPC is necessary and sufficient for HDL protection of HAECs by testing several different treatment conditions: pretreatment alone
The effect of HDL on OxPAPC signaling is not mediated by SR-BI. HAECs were transfected with either siRNA targeting SR-BI or scramble control siRNA and treated 48 h later with media, OxPAPC (50 µg/ml), HDL (50 µg/ml), or OxPAPC and HDL (50 µg/ml) as described in the Materials and Methods. The mRNA expression levels of KLF2, ATF3, INSIG1, IL8, and HO1 were determined by qPCR and normalized to GAPDH expression levels. All data are presented as average log2-fold change of triplicates ± SEM. Asterisks indicate significance level in unpaired Student’s t-test (*P < 0.05, **P < 0.01, ***P < 0.001) A: Despite effective silencing of SR-BI, the expression patterns of KLF2, ATF3, LDLR, and IL-8 after OxPAPC or OxPAPC+HDL treatment were unchanged. Results were confirmed using two separate siRNAs. B: Similarly, blocking of SR-BI using SR-BI antiserum (1:300 dilution) had no effect on the HDL response of KLF2, ATF3, LDLR, or IL-8. Rabbit IgG was used as control. C: HAECs were either untreated or treated with OxPAPC (50 µg/ml) in the presence or absence of HDL (50 µg/ml) or delipidated apoA1 (25–50 µg/ml). HDL and apoA1 were added for 1 h of pretreatment and 4 h of cotreatment. The mRNA expression levels of KLF2, ATF3, INSIG1, IL8, and HO1 were determined by qPCR and normalized to GAPDH expression levels.
pretreatment of HAECs, was as effective as our standard condition at attenuating the OxPAPC response in HAECs (Fig. 4C). These data indicate the effect of HDL on the OxPAPC response in HAECs requires cotreatment and suggest that HDL inhibits OxPAPC activity via direct interactions.

The specificity of HDL protection suggests that HDL affects OxPAPC activity in a lipid-specific manner

The results of the microarray studies suggest that the effects of HDL on OxPAPC signaling in HAECs are gene specific, with 48% of genes regulated by OxPAPC unaffected by pretreatment with HDL preceding OxPAPC treatment, posttreatment with HDL following OxPAPC treatment, and coinubcation of OxPAPC and HDL preceding cotreatment. The transcriptional responses of HAECs following each of these conditions were compared in parallel with our standard treatment condition shown in Fig. 1 (1 h HDL pretreatment followed by 4 h treatment with OxPAPC in the presence of HDL). As presented in Fig. 4, neither pretreatment alone with HDL nor posttreatment with HDL were able to inhibit the induction of KLF2, ATF3, INSIG1, LDLR, and KLF4 by OxPAPC to the same extent as our standard condition. Furthermore, coinubcation of OxPAPC with HDL, without

with HDL preceding OxPAPC treatment, posttreatment with HDL following OxPAPC treatment, and coinubcation of OxPAPC and HDL preceding cotreatment. The transcriptional responses of HAECs following each of these conditions were compared in parallel with our standard treatment condition shown in Fig. 1 (1 h HDL pretreatment followed by 4 h treatment with OxPAPC in the presence of HDL).

As presented in Fig. 4, neither pretreatment alone with HDL nor posttreatment with HDL were able to inhibit the induction of KLF2, ATF3, INSIG1, LDLR, and KLF4 by OxPAPC to the same extent as our standard condition. Furthermore, coinubcation of OxPAPC with HDL, without

pretreatment of HAECs, was as effective as our standard condition at attenuating the OxPAPC response in HAECs (Fig. 4C). These data indicate the effect of HDL on the OxPAPC response in HAECs requires cotreatment and suggest that HDL inhibits OxPAPC activity via direct interactions.

The specificity of HDL protection suggests that HDL affects OxPAPC activity in a lipid-specific manner

The results of the microarray studies suggest that the effects of HDL on OxPAPC signaling in HAECs are gene specific, with 48% of genes regulated by OxPAPC unaffected by
cotreatment with HDL (Fig. 1). One possible explanation for this finding is that HDL nonselectively sequesters all components of OxPAPC, thereby effectively reducing the exposure of HAECs to bioactive oxidized phospholipids. In this scenario, genes that are sensitive to low concentrations of OxPAPC might be relatively unaffected by HDL at low concentrations and affected at higher concentrations. To address the role of nonspecific sequestration, we examined OxPAPC dose-response curves for several transcripts in the absence or presence of HDL at several concentrations. For the UPR transcription factor ATF3, HDL shifted the OxPAPC dose-response curve to the right in a concentration-dependent manner that is consistent with the sequestration hypothesis (Fig 5A). In the dose response, HDL reversed the induction of KL2 at all concentrations of OxPAPC and HDL tested (Fig 5C). While not affected by HDL treatment alone, KL2 expression was repressed in the presence of both OxPAPC and HDL, indicating a synergistic effect of cotreatment. In contrast, the OxPAPC dose-response curve of HO1, a marker of the oxidative stress response in HAECs, was marginally affected by HDL cotreatment at either 20 μg/ml or 40 μg/ml of HDL, consistent with our microarray results and previous findings (23) (Fig 5B). We also examined the effect of HDL on the abundance of 12 oxidative stress-response-related transcripts (supplementary Fig. II). OxPAPC significantly affected the expression of 6 of these transcripts, and HDL did not reverse these changes. Together, these results confirm that the effects of HDL on OxPAPC signaling are gene specific and argue against a model in which HDL nonselectively sequesters all the bioactive lipid components of OxPAPC.

**Role of phospholipid hydrolysis by HDL-associated enzymes in HDL protection**

Various enzymes on HDL hydrolyze oxidized phospholipids (29, 37, 38). PAF-AH is a calcium-independent type VII phospholipase associated with HDL that hydrolyzes biologically active oxidized phospholipids in minimally modified LDL (mmLDL), thereby limiting their inflammatory effects on endothelial cells, including the ability to promote monocyte-endothelial interactions (29, 39). We assessed the enzymatic effects of HDL on OxPAPC by incubating OxPAPC with HDL and resolating phospholipids for analysis by HPLC-MS. Under these conditions, HDL minimally reduced the abundance of PEIPC (m/z 828.3), while strongly augmenting the hydrolysis of POVP C (m/z 594.2) and reducing the levels of PGPC (m/z 610.2) by ~50% (Table 3). Native PAPC (m/z 782.3) was minimally hydrolyzed in the presence of HDL. Consistent with the degradation of these phospholipids, the levels of LPC increased nearly 20-fold in the samples of OxPAPC coincubated with HDL relative to the net abundance in OxPAPC and HDL incubated separately. Addition of Pefabloc or MAFP, nonreversible inhibitors of PAF-AH, markedly reduced the degradation of POVP C and PGPC as well as the accumulation of LPC (Table 3). Surprisingly, the loss of PEIPC was enhanced by the inactivation of PAF-AH. Combined with the fact that this experiment was done using buffer lacking calcium, which precludes activity of calcium-dependent phospholipases, these results demonstrate that HDL effectively catalyzes the degradation of several components of OxPAPC in a PAF-AH-dependent manner.

To test whether PAF-AH activity is important in mediating the effects of HDL on HAECs exposed to OxPAPC, we incubated HDL with Pefabloc and assessed its ability to inhibit OxPAPC signaling. HDL treated with Pefabloc was as effective as untreated HDL at attenuating the induction of KL2, ATF3, and INSIG1 by OxPAPC (Fig 6A).

Enrichment of GO terms was assessed using topGO R package. Biological processes that showed significant enrichment in OxPAPC-treated sample but not in OxPAPC+HDL-treated sample were ranked by enrichment $P$ value in OxPAPC-treated sample. Top 10 biological processes are shown (see supplementary Table III for the full list). Notably, 9 of the 10 most significant process reversed by HDL were not reversed by cholesterol loading. CHOL, cholesterol.
Fig. 4. The effect of HDL on the OxPAPC response is mediated predominantly by direct interactions between HDL and OxPAPC. A: HDL pretreatment alone has minimal effect on the OxPAPC response. HAECs were pretreated for 2 h with HDL (50 μg/ml), washed three times with PBS to remove HDL, and then cells treated for 4 h with OxPAPC (50 μg/ml). In contrast to the standard cotreatment (shown as OxPAPC+HDL), pretreatment alone with HDL did not inhibit the effect of OxPAPC on the expression of KLF2, ATF3, INSIG1, and KLF4 and modestly reduced the induction of LDLR. For the standard treatment, cells were incubated without (dark blue bar) or with HDL (light blue bar) for 1 h, and then OxPAPC was added to the media for 4 h. B: Post-treatment with HDL does not inhibit the effect of OxPAPC on HAEC gene expression. HAECs were treated for 3 h with OxPAPC (50 μg/ml), washed three times with PBS to remove OxPAPC, and post-treated with either control media or media containing HDL (50 μg/ml) for an additional 3 h. Posttreatment with HDL did not reduce the induction of KLF2, ATF3, INSIG1, and KLF4 and only marginally affected the induction of LDLR compared with posttreatment with media alone. C: In contrast, coincubation of OxPAPC with HDL reduces the OxPAPC response to a similar extent as our standard HAEC pretreatment with HDL followed by cotreatment. OxPAPC (50 μg/ml) was incubated for 1 h at 37°C in medium M199 + 1% FBS with or without HDL (50 μg/ml). The solution was then used to treat HAECs for 4 h in parallel with standard control, OxPAPC (50 μg/ml), and OxPAPC+HDL (50 μg/ml) treatments. In both cases, OxPAPC was cotreated with HDL for 4 h. Data are presented as average log2-fold change of triplicate samples ± SEM. * P < 0.05, ** P < 0.01, *** P < 0.001 for indicated comparisons. P values defined by unpaired Student’s t-test.
HDL protection does not involve OxPAPC binding to cysteine residues on HDL

Previous studies have shown that circulating HDL can accumulate oxidized phospholipids and that apoA1 can...
bind oxidized phospholipids in OxPAPC (40, 41). In addition, we previously demonstrated that bioactive phospholipid components of OxPAPC can form Michael adducts with cysteine residues on proteins in HAECs (42). We therefore hypothesized that a protective mechanism of HDL might involve covalent binding of OxPAPC to protein constituents of HDL via nucleophilic cysteine residues. However, irreversibly blocking cysteine residues on HDL using 100 mM iodoacetamide did not affect the ability of HDL to inhibit OxPAPC signaling in HAECs, implying that either noncysteine nucleophiles or noncovalent interactions may predominate in HDL regulation of OxPAPC activity (Fig. 6B).

Oxidized phospholipids are the target of the HDL protection

Previous work from our group demonstrated that the effect of HDL on one major component of OxPAPC, PEIPC, was similar to that seen for total OxPAPC. HDL reduced the induction of ATF3 and LDLR by PEIPC while HO1 induction was unaffected (23). We therefore addressed the question of whether HDL can protect against the effects of the epoxyisoprostane (EI) formed from the sn-2 hydrolysis of PEIPC. EI has recently been characterized and shown to recapitulate ~50% of the effects of PEIPC, including the activation of oxidative stress response and ER stress response pathways (28). However, in contrast to OxPAPC and PEIPC, EI induces an anti-inflammatory phenotype in HAECs. Cotreatment of HAECs with EI and HDL demonstrated that HDL is unable to inhibit the effects of EI on the expression of several genes regulated by both PEIPC and EI (Fig. 6C). This suggests that oxidized phospholipids and not their fatty acids are targets of HDL protection.

DISCUSSION

HDL effects on transcription in the presence and absence of OxPAPC

The aim of this current study was to determine the effects of HDL on the genome-wide transcriptional response of HAECs exposed to OxPAPC and identify the proximate mechanisms mediating these effects. For this study, we used OxPAPC rather than individual oxidized phospholipids because circulating HDL interacts with multiple oxidized phospholipids that accumulate in both blood and the vessel wall (43–45). These combined phospholipids would likely interact differently with HDL than would individual phospholipids. Our microarray data consistently demonstrated that HDL attenuates 50–60% of the transcriptional changes induced by OxPAPC, and this effect is observed in multiple donors. Pathway analysis using SPIA also indicated that HDL acts on the majority of OxPAPC affected pathways, and comparison with OxPAPC network analysis suggested that the HDL effect is not limited to particular modules of genes coregulated by OxPAPC (8). Furthermore, we demonstrate that there is no relationship between the extent of OxPAPC gene regulation and the ability of HDL to inhibit OxPAPC signaling.

Previously published studies explored the role of HDL alone as a transcriptional regulator using microarrays of human endothelial cells treated with fetal or reconstituted HDL (46, 47). Both studies reported extensive regulation of transcription by reconstituted HDL (rHDL), although for the vast majority of genes, the fold change was small. In addition, McGrath et al. (46) showed that for some of the most regulated genes, the effect of rHDL was time and concentration dependent, and these authors observed no effect on gene expression after a 4 h treatment. More recently, Tabet et al. (48) found that human coronary artery endothelial cells treated with 1 mg/ml of plasma-isolated HDL for 16 h differentially expressed 120 genes, an effect partly mediated by transfer of microRNA-223 from HDL. In contrast, our study found that treatment with HDL alone at 50 μg/ml does not alter gene expression in HAECs after 5 h. These results were robust across several concentrations of HDL, donors, and experiments suggesting that concentration, exposure time, endothelial subtype, and use of rHDL versus serum isolated are important variables in assessing the effects of HDL on human endothelial cells.

Mechanisms of HDL protection

We examined several cell-dependent mechanisms by which HDL might attenuate the OxPAPC response in HAECs. SR-BI mediates several of the vasoprotective effects of HDL including the inhibition of adhesion molecule expression in endothelial cells following proinflammatory stimuli, the induction of cyclooxygenase 2 and prostacyclin production, and the stimulation of endothelial cell migration and reendothelialization following vascular injury (49–52). A majority of these responses are dependent...
on NO production following SR-BI mediated eNOS activation (17, 53). In contrast to these studies, we found that knockdown of SR-BI and cotreatment with blocking antibodies toward SR-BI had no effect on the ability of HDL to inhibit OxPAPC signaling (Fig. 2). Signaling via SR-BI by HDL is primarily mediated by apoA1, and in this

**Fig. 6.** The effect of HDL on OxPAPC signaling in HAECs is not dependent on the activity of PAF-AH or direct binding to cysteine residues but is specific to phospholipid components of OxPAPC. HDL (5 mg/ml) was incubated with 1 mM Pefabloc at 37°C for 1 h to inactivate lipoprotein-associated PAF-AH. The HDL was then dialyzed overnight and used in cotreatments with OxPAPC. After the inactivation of PAF-AH, HDL (50 μg/ml) reduced the effects of OxPAPC on markers of inflammatory response (IL-8 and KLF2), ER stress (ATF3), and cholesterol depletion (INSIG1) (A). Shown are the results from one of three representative experiments. Data are presented as average log2-fold change of duplicate samples ± (Max / Min)/2. B: HDL (5 mg/ml) was incubated with 100 mM iodoacetamide at 37°C for 1 h to irreversibly block free thiol residues on HDL. The HDL was then dialyzed overnight and used in HAEC treatments as described in the Materials and Methods. Treatment with iodoacetamide did not affect the ability of HDL to inhibit OxPAPC signaling in HAECs indicating that OxPAPC binding to cysteine residues on HDL is not mediating HDL protection. Data are presented as average log2-fold change of triplicates ± SEM. * P < 0.05, ** P < 0.01, *** P < 0.001 for comparison with OxPAPC log2-fold changes. P values defined by unpaired Student’s t-test. C: HAECs were treated with 1 μg/ml E1 in the absence or presence of 50 μg/ml HDL for 4 h as described in the Materials and Methods. Unlike for OxPAPC, HDL cotreatment did not mitigate the effects of E1 on the expression of IL-8, KLF2, ATF3, or HO1 as determined by qPCR. Data are presented as average log2-fold change versus control treated samples. All treatments were run in triplicate, and error bars correspond to SEM.
study, we found that apoA1 had a small but significant effect on the activity of OxPAPC. We hypothesize that this modest effect of apoA1 may be due to binding of specific bioactive oxidized phospholipids rather than signaling through SR-BI (16, 40).

We also examined the possibility that despite the results with apoA1 and SR-BI, cholesterol transport was involved in the HDL protection against OxPAPC-dependent gene regulation. HDL participates in bidirectional cholesterol flux with the endothelium, thereby supporting cellular cholesterol homeostasis (16, 54). In contrast, it has been shown that OxPAPC depletes caveolar membrane cholesterol from HAECs leading to the activation of SREBP and induction of IL-8 and LDLR expression (31). To determine the extent to which cholesterol repletion could account for the observed effects of HDL on OxPAPC signaling, we collected microarray expression data from HAECs treated with cholesterol-cyclodextrin, HDL, and OxPAPC. Cotreatment of HAECs with cholesterol-cyclodextrin and OxPAPC recapitulated HDL’s effect on key SREBP target genes, INSIG1 and LDLR, as well as key inflammatory pathways (Fig. 3A and supplementary Table III). However, only 23% of the genes affected by OxPAPC treatment and reversed by HDL cotreatment were similarly reversed by cholesterol-cyclodextrin. The remaining 77% of transcripts unaffected by cholesterol-cyclodextrin were enriched among GO categories related to blood vessel development, consistent with reports of HDL activating endothelial repair mechanisms (16). These results indicate that cholesterol repletion is insufficient to explain a majority of the HDL response, though it likely plays a role in regulating genes affected by OxPAPC and HDL related to cholesterol homeostasis.

Because the major known protective effects of HDL on endothelial cells did not account for the ability of HDL to robustly inhibit OxPAPC signaling, we tested the hypothesis that HDL affects OxPAPC composition and activity directly. Our evidence that HDL cotreatment with OxPAPC is required for HDL protection supports this hypothesis. Coincubation of OxPAPC with HDL, without pretreatment of HAECs with HDL, was sufficient to reduce the induction of KLF2, ATF3, INSIG1, and KLF4 by OxPAPC; whereas pretreatment or posttreatment alone with HDL, without cotreatment with OxPAPC, only modestly reduced the induction of LDLR and did not affect the upregulation of KLF2, ATF3, INSIG1, and KLF4 (Fig. 4). These data strongly suggest that the effect of HDL on the OxPAPC response in HAECs is mediated predominantly by direct interactions between HDL and OxPAPC.

We next addressed the question of how the HDL OxPAPC interaction mediates protection. The large number of OxPAPC-regulated genes affected by HDL suggested that nonspecific sequestration of OxPAPC lipids by HDL might account for the changes in gene expression. However, our data provide evidence against this mechanism. Transcriptional changes of multiple genes in dose-response experiments, using varying concentrations of OxPAPC and HDL, are inconsistent with nonspecific sequestration of OxPAPC by HDL. This is further supported by the fact that OxPAPC retains the ability to activate oxidative stress response pathways during cotreatment with HDL (supplementary Fig. II).

As possible direct and specific effects of HDL on OxPAPC activity, we examined the role of HDL-mediated degradation or binding to select oxidized lipids. Our group and others have shown that several HDL-associated enzymes catalyze the degradation of oxidized phospholipids including those contained in OxPAPC (29, 38, 39). Because our HDL preparations are isolated in the presence of EDTA and lack calcium-dependent phospholipase activity, we investigated the role of calcium-independent PAF-AH in mediating the HDL response. Coincubation of HDL with OxPAPC induced a large accumulation of LPC in cell-free conditions, an effect inhibited by the addition of PAF-AH inhibitors (Table 3). The increase in LPC was accompanied by a marked 86% decrease in the abundance of POVC, a 39% reduction of PGPC, and a 26% reduction of PEIPC. Inhibition of PAF-AH activity using Pefabloc or MAFP attenuated the degradation of POVC and PGPC. However, incubation of HDL with Pefabloc did not affect HDL’s ability to inhibit OxPAPC signaling, indicating that the degradation of POVC and PGPC via PAF-AH does not play a role in the HDL response (Fig. 6A). PEIPC was only slightly reduced by incubation of OxPAPC with HDL, suggesting that degradation of PEIPC plays a minimal role in HDL protection. Five isomers of PEIPC are produced from the oxidation of PAPC, and it is possible that enzymes on HDL are active toward only some of these molecules (55). In addition, other phospholipases carried by HDL may play a more predominate role in attenuating OxPAPC activity. Still, these data suggest that HDL catalyzes the degradation of OxPAPC by PAF-AH in a phospholipid-specific manner, but this degradation is not responsible for HDL protection.

We also present evidence that direct interactions between OxPAPC and HDL involving binding to cysteine residues are not involved in mediating the HDL response. The major bioactive component of OxPAPC in regulating transcription, PEIPC, has been shown to bind cysteine residues of proteins in HAECs, and this interaction is important in mediating the effects of OxPAPC on gene expression (42). Furthermore, human apoA1 as well as the apoA1 mimetic 4-F peptide bind OxPAPC with high affinity (40). However, irreversibly blocking cysteine residues on HDL with iodoacetamide did not attenuate HDL’s effect on OxPAPC signaling in HAECs (Fig. 6B). OxPAPC may form adducts with proteins on HDL at nucleophilic residues other than cysteine as Szapacs and colleagues (56) demonstrated using a biotin-sulfoxide analogue of 1-palmitoyl-2-linoleoylglycerolphosphatidylethanolamine (PLPBSO). More recently, a novel enrichment method was used to demonstrate the covalent modification of oxidized HDL by a variety of oxidized phospholipids primarily at lysine and histidine residues (57). Assessing the role of these interactions in mediating the HDL response warrants further investigation. Furthermore, while we have not delineated all the mechanisms by which HDL inhibits the effects of OxPAPC on HAECs, we present evidence that this protection is specific for oxidized phospholipids by showing that the
effects of EI, which regulates many of the same genes as OxPAPC and PEIPC (28), are undiminished by cotreatment with HDL. Additional research may identify other bioactive constituents of OxPAPC, or products of OxPAPC degradation, which remain active toward HAEcs in the presence of HDL.

In summary, we have shown that HDL can block the regulation of >50% of the 1,000 or more genes regulated by OxPAPC in primary HAEcs, a cell type particularly relevant to atherosclerosis development. In addition, we have preliminary evidence that HDL also blocks the rapid effect of OxPAPC on endothelial monolayer permeability. While recent genetic studies and clinical trials cast doubt on whether HDL cholesterol is causally associated with CAD (24–26), our results support the view that in vitro a relatively short exposure to HDL has atheroprotective effects, which are likely mediated by multiple mechanisms acting in concert. Cholesterol loading and apoA1 are partially involved in the protective effects of HDL; however, neither is sufficient to explain it entirely. Our evidence suggests that HDL interacts directly with OxPAPC to affect composition and activity. We hypothesize that this interaction involves oxidized phospholipids being degraded by phospholipases carried by HDL, binding to nucleophilic residues on HDL, and integrating into the phospholipid monolayer of HDL, altogether reducing the activation of some but not other OxPAPC signaling pathways. Taken together, our study provides important insight into the complexity of the effects of HDL on endothelial cells and highlights the importance of more systematic and global approaches to understanding HDL function.

The authors would like to thank the Atherosclerosis Research Unit at UCLA and in particular Alan Wagner, Elizabeth Tarling, and Thomas de Aguiar Vallim for technical advice and valuable discussion; and Sangderk Lee at the University of Kentucky for important insight.
