Transcription factor IIA has been shown to interact with the TATA-binding protein and to act early during preinitiation complex formation. The human factor is composed of three subunits (α, β, γ). A human cDNA clone encoding the largest subunit of TFIIA (α) was isolated. The recombinant α polypeptide, together with the β and γ subunits, was capable of reconstituting TFIIA activity. Studies using antibodies raised against recombinant α polypeptide demonstrate that TFIIA can be an integral component of the preinitiation complex. We demonstrate that TFIIA not only interacts with TBP but also can associate with the TFIIID complex. Functional assays establish that TFIIA has no apparent role in basal transcription but plays an important role in activation of transcription. Interestingly, amino acid sequence analyses of the β-subunit demonstrate these residues to be entirely contained within the carboxyl terminus of the cDNA clone encoding the α-subunit.

[Key Words: TFIIA; TATA-binding protein; preinitiation complex; antirepression; transcriptional activation]

TFIIA antirepression and activation

Molecular cloning of the largest subunit (a) of TFIIA

The ability of TFIIA to stimulate the binding of TBP to the TATA motif [Buratowski et al. 1989; Maldonado et al. 1990, Lee et al. 1992] was used as an assay to purify TFIIA [Usuda et al. 1991; Cortes et al. 1992]. This procedure resulted in a protein preparation containing three predominant polypeptides with Rf values of ~37 (a), 19 (b), and 13 (c) kD [Cortes et al. 1992]. The polypeptide composition of this protein preparation is in perfect agreement with previous studies that reconstituted TFIIA activity from renatured polypeptides [Cortes et al. 1992]. The 37-, 19-, and 13-kD polypeptides in the TFIIA protein fraction were transferred to PVDF membrane and digested with different proteases as described in Materials and methods. Peptides were recovered and sequenced. Lysyl-endopeptidase treatment of the 37-kD subunit generated three peptides, the sequences of which are shown in Figure 1A [peptides e-g].

A degenerate oligonucleotide was synthesized on the basis of the amino acid sequence from peptide g [see Fig. 1A] and used to screen a HeLa cellular cDNA library. Eight positive cDNA clones were isolated from 3 x 10⁶ independent clones. The complete nucleotide sequence of the longer cDNA clone isolated [TFIIA-a] is shown in Figure 1A. The nucleotide sequence of the cDNA predicts a long open reading frame encoding a polypeptide of 376 amino acids, with a calculated M, of 41,511 and an isoelectric point of 4.25. The sequence of the longest cDNA clone contained all of the peptide sequences derived from the 37-kD polypeptide [Fig. 1]. A second cDNA clone [TFIIA-a+], whose open reading frame started at residue 40, was also isolated [Fig. 1A].

Computer search of the SWISSPROT data base failed to detect any genes with extensive sequence similarity to the cDNAs. cDNA clones encoding the yeast Saccharomyces cerevisiae TFIIA have been isolated [Ranish et al. 1992]. Amino acid sequence comparison between the cDNA clone encoding the yeast TFIIA large subunit and the longer human TFIIA cDNA clone revealed low homology [21% identity, 45% similarity]. Amino acid conservation between these cDNA clones was most evident when the amino- and carboxy-terminal residues were analyzed [Fig. 1B].

The polypeptide encoded by the longer cDNA clone was found to contain three glutamine-rich regions among positions 69–104, 173–204, and 247–272, with glutamine contents of 44%, 41%, and 39%, respectively. Interestingly, there are seven consecutive histidine residues within the glutamine residues. Tracts of histidine residues have also been observed in other transcription factors such as YY1 [Harrihan et al. 1991; Park and Anchison 1991; Shi et al. 1991; Flanagan 1992], homeotic proteins [LaRosa and Gudas 1988], and POU-related proteins [Monuki et al. 1990; He et al. 1991]. The function of this motif is presently not known. Of potential interest are two acidic regions between positions 282–300 and 310–332, in which the content of acidic residues is 89% and 52%, respectively. It is noteworthy that the larger subunit of yeast TFIIA also contains two acidic regions [Ranish et al. 1992]. It has been shown that lysine residues in the basic region of TBP are involved in the interaction with TFIIA [Buratowski and Zhou 1992, Lee et al. 1992]. It is thus possible that the acidic regions in TFIIA may mediate the interaction with TBP. On the other hand, glutamine- or acid-rich residues have been proposed to constitute activation domains. We have found that the TFIIA-a cDNA clone can activate transcription of reporter genes bearing LexA DNA recognition elements in yeast when fused to a LexA DNA-binding domain [data not shown].

Results

Molecular cloning of the largest subunit (a) of TFIIA

TFIIA [Ha et al. 1993], TFIIA [Usuda et al. 1991, Cortes et al. 1992, Coulombe et al. 1992; also see below], and RNAPII [Usheva et al. 1992; for review, see Drapkin et al. 1993]. Furthermore, TBP has been shown to be an integral component of a protein complex implicated in RNAPII and RNAPIII transcription (for review, see Hernandez 1993).

Significant progress has been made in our understanding of the role and requirement of TFIIA in transcription. In the past, variable requirements for TFIIA in reconstituted transcription systems were reported. Reinberg et al. (1987) found that TFIIA was required when purified, but not crude preparations of TFIIA were used. Cortes et al. (1992) determined that crude preparations of TFIIA consisted of two distinguishable activities: TFIIA, which was purified to homogeneity, and TFII. In agreement with earlier observations demonstrating a requirement for the TFIIA protein fraction [containing TFII] in transcription, TFII was found to be essential for transcription only when highly purified TFIIID or recombinant TBP was used. Crude TFIIID preparations obviate the TFII requirement because of contaminating TFIIII [Flores et al. 1992]. Interestingly, TFIIA could stimulate basal transcription when native TFIIA was utilized but was without effect when TBP was used. Cortes et al. (1992) postulated that TFIIA may function to remove, by way of its association with TBP, negative components that associate with TFIIID. Support for this hypothesis was recently provided by Merino et al. (1993), who observed that the activity of Dr2, a repressor of basal transcription present in TFIIID, is counteracted by TFIIA [for review, see Drapkin et al. 1993]. Buratowski and Zhou (1992) have shown that the area of TBP mediating the interaction with TFIIA is within the highly conserved carboxy-terminal domain. Mutations to the conserved basic region separating the direct repeats in yeast TBP abolish its ability to interact with human TFIIA. TFIIA was recently cloned from yeast and found to be capable of replacing human TFIIA in a reconstituted system [Ranish and Hahn 1992, Ranish et al. 1992].

Here, we report the isolation of a cDNA encoding the largest subunit of human TFIIA. Our studies demonstrate that TFIIA is associated with the TFIIID complex. Our findings indicate that TFIIA has no role in basal transcription but is necessary for activation.
**Figure 1.** Nucleotide sequence of a cDNA encoding the largest subunit of TFIIA. (A) Nucleotide and amino acid sequence (single-letter code) of the largest cDNA clone isolated. The coding sequence of TFIIA-a starts at nucleotide 140. The start codon of TFIIA-a* starts at nucleotide 259, which corresponds to the codon encoding amino acid residue 40 of TFIIA-a (indicated by an arrow). The 5'-untranslated sequence of the cDNA encoding a* is 5'-ACACGTGATCACGCGAGCGTTGGAGAGGC-3' and continues with nucleotide residue 172 of TFIIA-a. The underlined nucleotides denote a translational stop codon. The underlined amino acids indicate the different peptide sequences obtained. Lowercase letters a-d and e--g denote peptides isolated after cleavage with LysC- and lysyl-endopeptidases, respectively. Numbers 1-3, at the carboxyl terminus of the cDNA, denote peptides obtained after LysC-endopeptidase cleavage of the 19-kD subunit of TFIIA. (B) Amino acid sequence comparison at the amino and carboxyl termini of the human and yeast TFIIA largest subunit. Vertical lines and asterisks indicate identities and similarities, respectively.

The polypeptide encoded by the longest cDNA clone is a component of TFIIA

To analyze whether the isolated cDNA encoded TFIIA-a, the recombinant protein was purified and used to generate antibodies. Because the cDNA clone uncovered the presence of seven consecutive histidine residues in the protein, we analyzed whether TFIIA activity could be retained on a nickel column. The result of this analysis is shown in Figure 2. TFIIA activity was retained on a nickel column [Fig. 2B], and the 37-kD polypeptide could be immunologically detected in the bound fraction [Fig.
TFIIA can associate with different preinitiation complex intermediates (Cortes et al. 1992; Flores et al. 1992).

The formation of a transcription-competent complex is a highly ordered process featuring numerous distinct preinitiation complex intermediates that can be resolved using the gel mobility shift assay (Buratowski et al. 1989; Flores et al. 1992). An early intermediate is the association of TBP with the TATA motif. The TBP–DNA protein complex is recognized by TFIIA and/or TFIIIB generating the DA, DB, and DAB complexes (see Fig. 3A). The addition of antibodies raised against the recombinant TFIIA-α polypeptide resulted in a supershift of the DA and DAB complexes (lanes 2 and 4, respectively). The DAB complex provides the foundation for the entry of the RNAPII–IF complex, resulting in the DABPolF complex (lane 5). This complex was also supershifted by the antibodies (lane 6). The observed supershift of the complexes by the antibodies was specifically attributable to the presence of TFIIA, as complexes formed in the absence of TFIIA (DB and DABPolF, see lane 7) were not affected by the antibodies (lane 8). These results, together with those presented in Figure 2, establish that the cDNA described above encodes a polypeptide that is contained in the TFIIA protein fraction.

To analyze whether the protein encoded by the longest cDNA could reconstitute TFIIA activity, recombinant protein was isolated from Escherichia coli and analyzed for its ability to interact with TBP in a gel mobility shift assay. No activity could be demonstrated with the recombinant polypeptides in the absence of the other TFIIA subunits (data not shown). However, when the recombinant α polypeptide was mixed with the other two components of TFIIA (isolated from a polyacrylamide–SDS gel followed by renaturation), a DA complex was demonstrated that comigrated on a native gel with the complex formed with native TFIIA (see Fig. 3B, cf. lanes 3 and 4). The 19- and 13-kD subunits of TFIIA, in the absence of recombinant α, were unable to affect the mobility of the TBP–TATA complex (lane 5). The polypeptide encoded by the shorter cDNA (α*) was capable, but to a much lesser extent with respect to α, of forming the DA complex (cf. lanes 3 and 4). Thus, the results of Figure 3 demonstrate that the longer cDNA encodes the largest subunit of TFIIA. Moreover, the result obtained with α* indicates that the amino-terminal 39 amino acids of TFIIA-α are functionally important.

### TFIIA and the preinitiation complex

The studies presented above indicate that antibodies raised against the recombinant protein reacted with a polypeptide determined previously to be a component of TFIIA. To further scrutinize the specificity of the antibodies to a subunit of TFIIA, their effect on different preinitiation complex intermediates was analyzed. Previous studies have demonstrated that TFIIA is dispensable for basal transcription and is consequently not essential for the formation of a transcription competent complex. However, because TFIIA interacts with TBP, TFIIA can associate with different preinitiation complex intermediates (Cortes et al. 1992; Flores et al. 1992).

### TFIIA and transcription

Having demonstrated that the longer cDNA clone encodes the α-subunit of TFIIA, we analyzed the effect of the antibodies on transcription. In agreement with our previous observations demonstrating that TFIIA has no effect on transcription when reactions are reconstituted with highly purified factors and TBP (in lieu of TFIIID), we were unable to demonstrate an effect of TFIIA (Fig. 4A, cf. lanes 1 and 2) or of the anti-TFIIA-α antibodies in basal transcription (lanes 3–5). However, when transcription reactions are reconstituted with TFIIID (in lieu of TBP), TFIIA has a stimulatory effect (see below; Cortes...
Ma et al.

Figure 3. The polypeptide encoded by the longest cDNA is the α-subunit of TFIIA. (A) The DA, DAB, and DABPolF intermediates and complexes in the absence of TFIIA [i.e., DB and DBPolF], were formed on the Ad-MLP-TATA motif as described in Materials and methods. Half of the various complex was incubated with anti-TFIIA-α antibodies, as indicated at the top. The complexes were separated on a native polyacrylamide gel. The migration of the different DNA–protein complexes is indicated at left. (SSC) Complexes that were super-shifted due to the association of the antibodies. (B) Recombinant α or α* polypeptide (400 ng each, isolated as described in Materials and methods) was mixed with 5 ng each of the β- and γ-subunits of TFIIA (see Materials and methods), as indicated at the top. After denaturation and renaturation of the different mixtures, one-thirtieth was added to DNA-binding assays composed of a DNA fragment containing the Ad-MLP–TATA motif and yeast TBP. DNA–protein complexes were formed and separated on a native polyacrylamide gel as described by Usuda et al. (1991). The control reaction (lane 1) contained TFIIA (5 ng), which was purified by TBP affinity chromatography, as described by Usuda et al. (1991). The migration of the different complexes is indicated at left.

et al. 1992). We reason that this stimulatory effect of TFIIA is attributable, in part, to the presence of negative factors in TFIID that are displaced from the complex upon interaction of TFIIA with the TBP component of TFIID. One such factor is Dr2 (Merino et al. 1993). We analyzed whether anti-TFIIA-α antibodies affected the ability of TFIIA to overcome Dr2-mediated repression of transcription. In reactions reconstituted with TBP, the addition of Dr2 resulted in repression of transcription (Fig. 4B, lanes 3–6). TFIIA could effectively overcome this repression (lanes 7–9), recapitulating the effect of TFIIA in transcription assays reconstituted with TFIID. The addition of anti-TFIIA-α antibodies suppressed the ability of TFIIA to overcome repression by Dr2 (lanes 10–13).

To investigate whether TFIIA has any role in activated transcription, reactions were performed with nuclear extracts supplemented with the activator Gal4–VP16 and with DNA templates containing or lacking Gal4-binding sites [for details, see Materials and methods]. The addition of Gal4–VP16 resulted in activation of transcription only from the template containing the Gal4 responsive elements [Fig. 4C, cf. lane 1 and 2]. The addition of anti-TFIIA-α antibodies resulted in inhibition of activated transcription [lanes 3–6]. The inhibition was specific, as the addition of excess TFIIA could overcome this inhibition [lanes 7–9]. Because transcription was directed by TFIID [in lieu of TBP], the template lacking Gal4 responsive elements was also stimulated by TFIIA [cf. lane 1 with lanes 7–9]. Therefore, transcription from this template was no longer refractory to the TFIIA-α antibodies [lane 6]. However, it is interesting to note that the antibodies have a much greater effect on activated transcription. These results are not activator specific, as different activators [Gal4–Pro] yielded similar results [data not shown]. The most logical interpretation of these observations is that TFIIA plays an important role in transcriptional activation. These results, however, do not rule out the possibility that TFIIA may influence activation in an indirect fashion. It is possible that TFIIA is necessary solely to remove repressors that have a dominant effect. Regardless of the precise mechanisms, our observations demonstrate that (1) TFIIA has no role in basal transcription, (2) TFIIA can overcome the action of repressors such as Dr2, and (3) TFIIA plays a role in the activation process. These results are in agreement with the observations of Hahn and colleagues demonstrating that TFIIA is essential for viability in yeast (Ranish et al. 1992).

TFIIA associates with the TFIID complex

Previous studies have demonstrated that TFIIA interacts with TBP. Moreover, the results presented above, implicating the involvement of TFIIA in activated transcription, suggest that TFIIA interacts with the TFIID complex. The nature of this interaction was analyzed by immunoprecipitation with anti-TFIIA-α antibodies, monoclonal antibodies [SL39-2-575] recognizing the species-specific amino terminus of human TBP (gift of Dr. N. Hernandez, Cold Spring Harbor Laboratory, NY), as well as TAF80 and TAF150 monoclonal antibodies shown to immunoprecipitate the TFIID complex (gift of Dr. R. Tjian, University of California, Berkeley). Immunoprecipitation of a polypeptide of ~37 kD from nuclear extracts with TBP monoclonal antibodies was detected in a Western blot with anti-TFIIA-α antibodies [Fig. 5A, lane 1]. This polypeptide represents the largest subunit.
TFIIA antirepression and activation

Te protein fraction was incubated in the presence and absence of TFIIA and proteins immunoprecipitated with anti-TFIIA antibodies followed by Western blot analysis using anti-TBP antibodies. The results in Figure 5B demonstrate that a polyepitope of ~40 kD is precipitated by both the SL39-2-575 monoclonal antibodies and by TFIIA antibodies (lanes 4 and 2, respectively). This polypeptide represents TBP because, in addition to being immunoprecipitated by the SL39-2-575 monoclonal antibodies, it comigrates with TBP on PAA–SDS gels [data not shown] and is absent in a crude TFIIA protein fraction (Fig. 5B, lane 3; see also Cortes et al. 1992) devoid of TBP (lane 3). The interaction between TFIIA and TFIIID was analyzed further using immunoaffinity-purified TFIIID and antibodies directed against TAF80 and TAF150. Purified TFIIID complexes were incubated in the presence and absence of TFIIA and proteins immunoprecipitated with anti-TAF80 or anti-TAF150 antibodies. The presence of TFIIA in the TFIIID complex was detected by Western blot analysis using anti-TFIIA-α antibodies. Both TAF antibodies immunoprecipitated TFIIA (Fig. 5C, lanes 2, 4). The extent of TFIIA varied with the TAF antibodies (Fig. 5C) but correlated with the amount of TBP that was immunoprecipitated by the TAF antibodies [data not shown]. Thus, the analyses presented above demonstrate an interaction between TFIIA with the TFIIID complex.

The complexity of the gene encoding the α-subunit of TFIIA

The molecular cloning of the TFIIA-α subunit resulted in the isolation of two different cDNA clones differing in their 5’ sequences (Fig 1). These cDNAs have the capacity to produce two polypeptides—one that lacks the first 39 amino acids (Fig. 1). We were not able to detect the polypeptide encoded by the smaller cDNA clone [TFIIA-α*] in our Western blot analysis; thus, its relevance in vivo is not clear. Northern blot analysis using poly[A]+ RNA isolated from HeLa cells and various other tissues demonstrates a 7.0-kb RNA that hybridizes specifically with the cDNA encoding TFIIA-α (Fig. 6A). Variable levels of RNA complementary to TFIIA-α were observed among the tissues tested (Fig. 6A). The difference in the amounts of RNA was not attributable to the amount of poly[A]+ RNA on the blot, as similar levels of steady-state RNA complementary to actin was observed in most of the tissues analyzed, with the exception of skeletal muscle and liver (Fig. 6B). Moreover, variable amounts of RNA complementary to TFIIB were observed in the different tissues (Fig. 6C). Interestingly, steady-state levels of RNA complementary to TFIIB and TFIIA were not congruent in the tissues analyzed. This indicates that the expression of the general transcription factors [TFIIA and TFIIID] varies in different tissues. In interpreting these data, it is pertinent to underscore that TFIIA may not be a basal transcription factor but is involved in antirepression and transcriptional activation. Thus, its level of expression may not necessarily be coordinated with the GTFs (see Discussion).
Ma et al.

Figure 5. Immunoprecipitation of the TFIID-TFIIA complex. (A) The p37 subunit of TFIIA was visualized using TFIIA-α antibodies in Western blot analysis from immunoprecipitation reactions of nuclear extracts (NE) using TBP monoclonal antibodies [lane 1] or anti-TFIIA-α antibodies [lane 2]. Immunoprecipitation of p37 was from a partially purified fraction of TFIIA [DEAE-5PW] with TBP antibodies [lane 3] or with anti-TFIIA-α antibodies [lane 4]. TFIIA from the DEAE-5PW protein fraction was loaded directly and visualized with TFIIA-α antibodies [lane 5]. (B) Western blot analysis using TBP monoclonal antibodies to visualize TBP shows that anti-TFIIA-α antibodies do not coimmunoprecipitate TBP from a purified fraction of TFIID [DEAE-52, see Maldonado et al. 1990] [lane 1] but coimmunoprecipitate TBP in the presence of purified TFIIA [DEAE-5PW, lane 2]. Immunoprecipitation reactions were performed with TBP antibodies with purified TFIIA [DEAE-5PW, lane 3] or purified TFIID [DEAE-52, lane 4]. Molecular mass markers are indicated at right. The arrow denotes TBP. (C) Western blot analysis of the TFIIA-α protein coimmunoprecipitated from an affinity-purified TFIID fraction using TAF80 monoclonal antibodies in the absence [lane 1] and in the presence of TFIIA [DEAE-5PW, lane 2]. The same analysis was performed using TAF150 monoclonal antibodies in the absence [lane 3] and in the presence of TFIID [lane 4]. Lane 5 represents the purified TFIIA fraction [DEAE-5PW] loaded directly and visualized using anti-TFIIA-α antibodies. The TFIID complex was immunopurified as described by Pugh and Tjian [1990]. The complex was washed extensively with a buffer containing 1.0% NP-40, followed by a wash with PBS (see Materials and methods). The complex was then mixed with TFIIA and reimmunoprecipitated as indicated above.

An unexpected and interesting finding was made when amino acid sequences derived from the 19-kD component of TFIIA β-subunit) were analyzed. Digestion of the β-subunit of TFIIA with LysC-endopeptidase resulted in the recovery of three peptides that were sequenced. Surprisingly, the sequence of each of these peptides was entirely contained in the carboxyl terminus of the cDNA clone encoding TFIIA-α [Fig. 1A, peptides 1–3]. Thus, this result led us to estimate the mass of the recombinant protein with respect to the α-subunit of TFIIA. The recombinant protein produced two predominant polypeptides that specifically reacted with the anti-TFIIA-α antibodies [Fig. 7A, lane 2]: a polypeptide of ~60 kD, representing the polypeptide encoded by the cDNA, and a polypeptide of ~85 kD, representing a fusion of glutathione S-transferase (GST) and the protein encoded by the cDNA (data not shown). The α-subunit of TFIIA migrated on SDS-PAGE with a mass of ~37 kD [lane 1]. This observation indicates that the isolated cDNA clone encodes a precursor of TFIIA-α. Whether this clone also encoded the β-subunits of TFIIA, which is produced by protein processing, remains a possibility and is currently under study.

Discussion

We report the isolation of a human cDNA clone encoding the largest subunit of TFIIA. These analyses allow us to conclude that 1) the gene encoding the α-subunit of TFIIA is complex and capable of producing three differ-

Figure 6. Northern blot analysis of RNA complementary to TFIIB and TFIIA-α. The entire coding sequences of TFIIA-α and TFIIB were labeled by random priming and used in the analysis. Filters containing similar amounts of poly[A]+ RNA obtained from different human tissues was obtained from Clonetech and used as described.
The TFIIA-α cDNA clone encodes a polypeptide larger than the α-subunit of TFIIA. The polypeptide encoded by the longest cDNA clone was expressed as a fusion protein with GST in bacteria. Recombinant protein was purified by glutathione affinity chromatography. An aliquot of the sample (20 μg) was digested with thrombin, and the recombinant protein was repurified by glutathione affinity chromatography. An aliquot of the flowthrough of the affinity column (100 ng) was analyzed by electrophoresis on a 15% polyacrylamide-SDS gel, followed by western blot using antibodies directed against the amino-terminal 50 amino acids of TFIIA-α. (Lane 1) The reaction observed with highly purified TFIIA (see Fig. 2A). Molecular mass markers are indicated at left. The notation on the right side of the panel denotes the α-polypeptide of TFIIA, the putative precursor of TFIIA-α (IIAαp), and the GST fusion protein (GST-IIAαp).

Two different cDNA clones differing in their 5' sequences were isolated. The longer cDNA encoded the largest subunit of TFIIA as demonstrated by independent assays. We found that antibodies raised against the recombinant protein interfere with TFIIA activities. Importantly, our studies demonstrated that the recombinant polypeptide could reconstitute TFIIA activity when mixed with the two other subunits of TFIIA (Fig. 3B). The shorter cDNA clone encoded a protein lacking the first amino-terminal 39 amino acids. This protein (α*) was not able to fully reconstitute the ability of TFIIA to interact with a TBP-DNA complex under conditions where the α-subunit fully reconstituted TFIIA activity (in the presence of β- and γ-subunits of TFIIA), suggesting that the amino-terminal 39 amino acids of α are important for TFIIA activity.

Whereas human TFIIA activity is composed of three polypeptides, the yeast TFIIA homolog is composed of two subunits, each of which is encoded by a different gene, TOA1 and TOA2 respectively (Ranish et al. 1992). The human α-subunit of TFIIA shows sequence homology with TOA1, albeit the regions in common are restricted to the amino and carboxyl termini of the proteins (Fig. 1B). Most of the amino-terminal residues shared by the human and yeast factors are absent in the α*-polypeptide. Hahn and co-workers have demonstrated that the amino- and carboxy-terminal residues of the large subunit of yeast TFIIA are important for activity (S. Hahn, pers. comm.). Our results demonstrating that α*-polypeptide cannot fully reconstitute TFIIA activity are in agreement with the studies obtained with the yeast factor. The function of α* is presently not known, however, it is important to note that we were unable to find this polypeptide in HeLa cells using Western blot analysis with antibodies directed against α or α*. Thus, whether this truncated form of TFIIA-α exists in vivo is questionable.

In attempts to isolate the other subunits composing TFIIA, we found that the amino acid sequences derived from three peptides obtained from the 19-kD subunit were entirely contained within the carboxyl terminus of TFIIA-α (Fig. 1). We believe that the 19-kD subunit is encoded by the same gene encoding the α-subunit of TFIIA and that either alternative splicing or protein processing is involved in its synthesis. Recently, it was discovered that the polypeptides composing the transcription factor HCF were generated by protein processing. HCF, or host cell factor, is a multisubunit complex that links Oct-1 to the viral activator VP16 (Gerster and Roeder 1988; Kristic and Sharp 1990; Stern and Herr 1991). Wilson et al. (1993) demonstrated that a 300-kD precursor polypeptide is processed into a multitude of subunits that remain associated and constitute HCF activity. Our preliminary results, together with observations analyzing the Drosophila TFIIA, suggest that protein processing is utilized to generate the 19-kD β-subunit of TFIIA. Drosophila TFIIA, like its human counterpart, appears to be composed of three subunits with molecular masses of ~30, 20, and 13 kD (R. Tjian, pers. comm.). A Drosophila cDNA clone encoding a polypeptide of ~48 kD and sharing extensive homology at the amino and carboxyl termini to the yeast and human TFIIA largest subunits was isolated (R. Tjian, pers. comm.). Interestingly, the polypeptide encoded by the Drosophila cDNA clone appears to be a precursor, which is processed in vivo to generate the 30- and 20-kD subunits of TFIIA (Yokomori et al., this issue). Although we cannot conclude unequivocally that the 19-kD subunit of human TFIIA is generated by protein processing, as appears to be the case in Drosophila, it is important to note that by using the two-hybrid system in yeast (Chien et al. 1991; Zervos et al. 1993), we were able to isolate a partial cDNA clone encoding a protease that specifically interacts with the α-subunit of human TFIIA (R. Shiekhattar, F. Romero, and D. Reinberg, unpubl.). In the context of the data presented here, this finding further
supports a model whereby the human β-subunit of TFIIA is generated by protein processing.

**TFIIA functions as a coactivator**

The role of TFIIA in transcription has been a subject of major controversy, as variable requirements for the factor in transcription have been reported. This controversy can now be reconciled because of two observations. First, the TFIIA protein fraction described initially was found to contain two activities, TFIIA and TFIIJ (Flores et al. 1992). TFIIJ is required for basal transcription. Second, TFIIA and TFIIJ are present in the TFIID protein fraction (Flores et al. 1992). Thus, depending on the purity of the TFIID fraction used to reconstitute transcription, variable requirements for the TFIIA protein fraction can be observed. Moreover, the studies described here and elsewhere (Cortes et al. 1992) demonstrate that TFIIA has no role in basal transcription, provided that the transcription system is reconstituted with purified components. Earlier studies (Usuda et al. 1991; Cortes et al. 1992; Coulombe et al. 1992) demonstrated that TFIIA interacts with the TBP. Despite the fact that an interaction between TBP and TFIIA could be demonstrated, Cortes et al. (1992) found that transcription reactions reconstituted with TBP were unaffected by TFIIA. However, when the transcription assays were reconstituted with TFIID (in lieu of TBP), TFIIA stimulated transcription. These apparently conflicting reports were reconciled by postulating the presence of factors in the TFIID complex that negatively affected transcription (Cortes et al. 1992). Since this initial hypothesis, factors that interact with TBP and repress transcription have been isolated in human cells (Meisterernst and Roeder 1991; Meisterernst et al. 1991; Inostroza et al. 1992; Merino et al. 1993) and in yeast (Auble and Hahn 1993). Moreover, the interaction between the negative components of transcription and TBP appears to be in competition with TFIIA (Meisterernst and Roeder 1991; Meisterernst et al. 1991; Auble and Hahn 1993; Merino et al. 1993). In the studies presented here, we extended these observations and demonstrated that anti-TFIIA antibodies can block the ability of TFIIA to overcome repression, thus emphasizing the role of TFIIA in this function. The most revealing finding was the discovery that TFIIA is required for activation of transcription by Gal4–VP16 and Gal4–Pro. The antibodies raised against the largest recombinant subunit of TFIIA can block activation. Because physiological levels of activated transcription cannot yet be achieved in a system reconstituted with purified components, the activation assays were performed using nuclear extracts. Moreover, because reconstitution of transcriptional activation in vitro requires Dr2, a repressor of transcription (Merino et al. 1993; for review, see Drapkin et al. 1993), we are unable to invoke a direct effect of TFIIA in this process other than removing factors that negatively affect transcription and possess a dominant effect. However, our results demonstrating a function of TFIIA in activation of transcription, together with those that detect human (Fig. 5) and Drosophila (Yokomori et al., this issue) TFIIA in the TFIID complex, strongly suggest a functional role for TFIIA in activation. These observations are supported further by studies demonstrating that TFIIA not only interacts with the TBP component of TFIID but also with the Drosophila TAF110 (R. Tjian, pers. comm.), a TAF important for Sp1 activation (Hoey et al. 1993). Thus, our studies, together with those obtained with Drosophila TFIIA, demonstrate a role of the factor in transcriptional activation. Our results are consistent with studies in yeast demonstrating that the genes encoding each of the subunits of TFIIA are essential for viability.

**Materials and methods**

**Purification of TFIIA**

TFIIA was purified from the phosphocellulose 0.1 M KCl protein fraction (Reinberg et al. 1987) as described previously by Usuda et al. (1991) and Cortes et al. (1992). Both a functional transcription assay and the ability of TFIIA to affect the binding of TBP to the TATA motif on a gel mobility shift assay were employed to isolate TFIIA. The last step of the purification involves TBP affinity chromatography. This sample was precipitated with TCA, and the precipitate was resolved by SDS-PAGE. The polypeptides comprising TFIIA were directly excised from the gel or transferred to PVDF membrane. The subunits of TFIIA were digested with lysyl– or LysC–endopeptidases. Peptides were fractionated by reverse-phase HPLC and subjected to microsequencing.

The sequence of the largest subunit of TFIIA reveals the presence of seven consecutive histidine residues; thus, TFIIA was purified using nickel and TBP affinity chromatography. One hundred milliliters of the phosphocellulose 0.1 M KCl fraction (2.8 mg/ml) was dialyzed against buffer C [20 mM Tris·HCl (pH 7.9), 10% glycerol, 1 mM ethylenediamine tetraacetic acid, 0.2 mM phenylmethylsulfonyl fluoride, and 20 mM β-mercaptoethanol] containing 0.5 M KCl and 1 mM imidazole. The protein mixture was then mixed with 3 ml of nickel–agarose that had been equilibrated with the same buffer and incubated at 4°C for 1 hr with constant agitation. The nickel resin was recovered by centrifugation on a tabletop centrifuge and washed with 10 column volumes (30 ml) of buffer C containing 0.1 M KCl and 1 mM imidazole. This wash was followed by a second wash in which the concentration of imidazole was increased to 5 mM. The activity eluted between 20 and 30 mM imidazole. The protein pool (18 ml, 0.6 mg/ml) was dialyzed against buffer C containing 0.1 M NaCl and 20% glycerol and loaded onto a 1.3 ml TBP affinity column (Cortes et al. 1992). The column was washed with 20 ml of buffer C/0.1 NaCl, and the activity eluted with a 4-ml wash of buffer C containing 0.5 M NaCl. The protein concentration of the recovered sample was ~23 μg/ml.

**Molecular cloning of the large subunit of TFIIA**

Treatment of the TFIIA/37-kD polypeptide with LysC–endopeptidase resulted in the recovery of four peptides (Fig. 1A, a–d) that were subjected to microsequencing. Treatment of the polypeptide with lysyl–endopeptidase resulted in the recovery of three peptides (Fig. 1A, e–g). A degenerate oligonucleotide deduced from the amino acid sequence derived from peptide g was synthesized: 5'-CAA/GGTIATICCIACIACIGTI-
Antibodies against TFIIA-a arid TFIIA-c~* polypeptides, as well as the other subunits of TFIIA t{3 and ~1, were obtained using PCR. The DNA fragments were inserted into the Smal site of pGEX-2T (Pharmacia). E. coli cells were transformed, and induction was performed. The GST fusion proteins were purified by glutathione affinity chromatography according to the manufacturer's specifications. Four hundred microliters of affinity-purified GST-a and GST-a~* was digested with thrombin (1.5 U/ml) and then sequentially passed through benzamidine-Sepharose and glutathione-Sepharose to remove thrombin. The GST-a and GST-a~* polypeptides were digested with thrombin (1.5 U/ml) and then sequentially passed through benzamidine-Sepharose and glutathione-Sepharose to remove thrombin and GST. The flowthrough fraction was used as recombinant a and a~*. Because extensive degradation of the E. coli-expressed polypeptides was observed occasionally, the following procedure was used to isolate recombinant proteins. Proteins were expressed in E. coli, lysed, and separated immediately by preparative SDS-PAGE. The GSTs and GSTa~* polypeptides were isolated from the gel. Following renaturation, the fusion proteins were digested with thrombin. GST and thrombin were removed as described above. Renaturation of the recombinant polypeptides, as well as the other subunits of TFIIA (β and γ), was performed as described previously (Cortes et al. 1992).

Antibodies against TFIIA-a and TFIIA-a~*

Recombinant proteins were isolated from preparative SDS-PAGE. The bands corresponding to the recombinant fusion proteins were recovered (~200 μg) and purified further by GST affinity chromatography. The protein sample was mixed with complete Freund’s adjuvant and injected into rabbits. Fifteen days after the first injection, another injection was given in incomplete Freund’s adjuvant with the protein prepared as described above. Bleeding was performed 10 days after the second injection, and serum was prepared.

Transcription and DNA-binding assays

A DNA template containing five GAL4–DNA-binding sites upstream of the TATA motif of the adenovirus major late promoter (Ad-MLP) was mixed with a second template lacking GAL4–DNA-binding sites. Transcription reactions were performed as described previously. Each reaction contained 200 ng of each DNA template. Transcription factors and RNApolyII (Lu et al. 1991) were purified as described previously: rIIA (Ha et al. 1991), rID or TBP (as described in the figures, Maldonado et al. 1990), rIE (Peterson et al. 1991), rIF (L. Zawel and D. Reinberg, in prep.), rIIJ (Flores et al. 1992), and rIIH (Lu et al. 1992). The RNA products were analyzed on a polyacrylamide–urea gel. The synthetic transcriptional activators GAL4–VP16 and the DNA-binding domain of GAL4(1–94) were purified as described (Chasman et al. 1989, Baichwal and Tjian 1990). All proteins were kept in buffer C containing 0.1 M KCl. Dr2 was purified from the phosphocellulose 1.0 M fraction described previously (Merino et al. 1993). DNA-binding assays were performed as described by Maldonado et al. (1990).

Immunoprecipitation reactions and Western blot analysis

Antibodies against TFIIA and TBP were incubated with protein A–Sepharose (Repligen) for 30 min at 23°C followed by the addition of nuclear extracts or purified fractions and then incubated for an additional 2 hr at 4°C with mixing. Immunoprecipitates were washed with ice-cold lysis buffer containing 50 mM Tris-HCl buffer (pH 7.5), 50 mM NaF, 100 μM NaVO4, 150 mM NaCl, 1 mM PMSF, and 1% NP-40 and one time with PBS. Samples were then eluted from the protein A–resin antibody complexes using 200 mM glycine-HCl (pH 2.6). Micrococcal nuclease (600 U/ml) was added to the samples and incubated for 30 min at 37°C. The sample was transferred to a new tube and treated with 10 μg/ml pancreatic RNase A for 30 min at 37°C. Protein A–resin was added and washed with PBS, 1% NP-40, and 0.5% Tween 20 for 3 hr. Samples were then eluted from the protein A–resin antibody complexes using 200 mM glycine-HCl (pH 2.6), boyled for 5 min in Laemmli sample buffer, resolved by 13% SDS–polyacrylamide gel electrophoresis, and transferred to nitrocellulose membrane. The blot was blocked with 5% BSA in TBS, 0.05% Tween 20 for 2 hr, and incubated with either TFIIA-a or monoclonal TBP antibodies for 2 hr at room temperature, followed by secondary antibodies conjugated to either horseradish peroxidase or alkaline phosphatase for 1 hr. Horseradish peroxidase conjugates were visualized using the chemiluminescence system (Amersham), and alkaline phosphatase–coupled material was visualized using nitro blue tetrazolium (NBT) and bromochloroindolul phosphate (BCIP).

Acknowledgments

We thank Drs. N. Hernandez for the gift of TBP monoclonal antibodies, R. Tjian for the gift of anti-human TAF80 and TAF150 antibodies, and M. Green for the gift of Gal4–Pro fusion protein. We thank Drs. R. Tjian and S. Hahn for active discussions and the communication of results before publication. We are grateful to R. Drapkin and L. Zawel for reading the manuscript. This work was supported by grants from the National Institutes of Health (NIH) to D.R, and a grant-in-aid for Scientific Research on Priority Areas and from the Human Frontier Science Program (HFSP) research grant to H.H. F.M. was supported by a postdoctoral fellowship from the NIH, D.R. is a recipient of an American Cancer Society Faculty Research Award.

The publication costs of this article were defrayed in part by payment of page charges. This article must therefore be hereby marked "advertisement" in accordance with 18 USC section 1734 solely to indicate this fact.

Note added in proof

The sequence data for TFIIA-a have been submitted to the EMBL data library under accession number X75383.
