Nano urea effects on *Pleurotus ostreatus* nutritional value depending on the dose and timing of application

Youssef N. Sassine¹,², Layla Naim¹,³, Zeina El Sebaaly¹,⁴, Sami Abou Fayssal¹,³, Mohammed A. Alsanad⁴ & Milena H. Yordanova³

The work investigated the effect of Lithovit-Urea50 on the composition of *Pleurotus ostreatus* (Jacq. Ex Fr.) P. Kumm. (1871) cultivated on spent oyster substrate mixed with wheat straw (1:1, w/w mixture). The product was applied in different doses (C₁: 3 g kg⁻¹ and C₂: 5 g kg⁻¹) at three distinct timings (t₁: at spawning, t₂: after first harvest, t₃: at spawning and after first harvest). Protein and fiber contents increased respectively by 0.64 and 0.2% in C₁t₁ and by 0.46 and 0.8% in C₂t₂ compared to control (C₀t₀). Total carbohydrates increased by 0.48–3.76%. Sucrose and glucose contents decreased in the majority of treatments, while fructose increased in C₂t₁ (by 0.045%). Essential amino acids were the highest in C₁t₁, wherein respective improvement of 0.31, 0.10, 0.05, 0.21, 0.18, and 0.09% compared to C₀t₀. Similarly, C₁t₂ was superior in non-essential amino acids. Potassium, sodium, calcium, iron, and copper contents decreased in all treatments, with minor exceptions, zinc decreased in C₁t₁ and C₂t₁, while nickel and lead increased in all treatments. Conclusively, despite important ameliorations in the mushroom nutritional value, mostly in C₁t₁, the product should be further tested in lower doses (< 3 g kg⁻¹) to counteract its effect on heavy metal bioaccumulation.

*Pleurotus ostreatus*, commonly known as oyster mushroom, can grow in a wide range of temperatures using available lignocellulosic materials. It is the second most commercially produced mushroom worldwide. Oyster mushrooms are treasured for their low calorie, high protein, zinc, chitin, fiber, and vitamins (C, D, and B-complex) contents, as well as for their amino acid composition. Determining the nutritive content of oyster mushrooms could enhance their therapeutic value. It is known that mushroom composition and nutritional value are affected largely by the type and nutrient composition of the substrate. Effectively, the nutritional value of oyster mushrooms varied when they were cultivated on different substrates.

In mushroom producing areas, spent mushroom substrate (SMS) accumulates in huge quantities in collection centers of mushroom producing areas, as 5–6 kg of SMS is the result of the production of 1 kg of fresh mushroom. This leftover biomass derived from mushroom production gained special interest in early scientific reports for the cultivation of oyster mushroom. In fact, it is an abundant, cheap and easily available source of substrate, and is highly nutritive. It contains good amounts of cellulose, hemicellulose, calcium, magnesium, potassium, proteins, and carbohydrates. Oyster mushroom can degrade the lignocellulosic compounds of SMS, by producing hemicellulases, cellulases, and ligninases enzymes. The bioconversion of this waste material by the mushroom has been optimized through the addition of nutritional additives. Effectively supplementation of the spent substrate with commercial nutritional supplements, or other protein-rich additives has not only caused a remarkable increase in *P. ostreatus* yields, but it also ameliorated the mushroom nutritional value.

Overall, important aspects have to be considered during supplementation, including the type of nutrients required, the choice of supplement, and the most correct timing and methods for it to be applied. For instance, urea has been used as an organic source of nitrogen to improve oyster production, with a varying effect depending on the timing or dose of application to the growing substrate. Besides, it ameliorated the mushroom nutritional value...
nutritional value by increasing both their proteins and β-glucans contents. However, the use of nano-urea may be practically and economically more advantageous in mushroom farming compared to the conventional urea. The higher nitrogen content in the latter (46% N compared to 21% N in nano-urea) poses increasing risks of contamination of the substrate by competing fungi. On the other hand, nano-urea shows a slower releasing pattern of nitrogen into the substrate, providing a more efficient utilization of the applied nutrients, by applying a lesser amount of fertilizer.

Furthermore, knowing that the use of nano-urea as nutritional supplement to the spent oyster substrate (SOS) gave promising results regarding the productivity of oyster mushroom, the present work aimed to discuss the effect of nano-urea addition in different timing and doses on the nutritional value and amino acids composition of *P. ostreatus*.

**Material and methods**

**Experimental design.** *Pleurotus ostreatus* mushroom was cultivated on a half-half mixture of wheat-straw based spent oyster substrate (SOS) (obtained after one growing cycle of oyster mushroom at a local mushroom farm “Gourmet”; Mehrin, Jbeil, Byblos, Lebanon) and wheat straw (1:1, w/w mixture). The spent oyster substrate was initially sun-dried for 1 week, then chopped and mixed with wheat straw. The mixture was pasteurized at 60–65 °C, for 8 h, using hot water. Then, the mixture was cooled down to spawning temperature (25 °C). Spawning was performed at a 5% rate, corresponding to 50 g kg⁻¹ of substrate, using grain spawn of M2175 strain (Mycelia Company, Deinze, Belgium).

To evaluate the effect of supplementation on the mushroom nutritional value, Lithovit-Urea50 was tested in two separate doses: C1, 3 g kg⁻¹, C2, 5 g kg⁻¹, and three timings of application (t1, at spawning; t2, after first harvest; t3, at spawning and after first harvest). Therefore, six experimental treatments (C1t1, C1t2, C1t3, C2t1, C2t2 and C2t3) were arranged in a full factorial design with two factors (dose and timing of application) and ten replicates (bags) per treatment. The different treatments were compared to a non-treated substrate or control (C0t0).

Inoculated substrates were filled into perforated transparent polyethylene bags of 60 cm length and 40 cm width. Lithovit-Urea50 is a nitrogen fertilizer, suitable for use in organic farming (pursuant to Regulation (EC) No. 834/2007-European Community), sourced from Tribodyn AG Company, Northelm, Germany, and having the following composition: 33.0% calcium carbonate (CaCO₃), 21.0% total nitrogen (N), 18.5% calcium oxide (CaO), 6.5% silicon oxide (SiO₂), 1.2% magnesium oxide (MgO), 0.5% iron (Fe), and 0.01% manganese (Mn). The product was initially created by a process of tribodynamic activation and micronization of dolomite.

**Environmental conditions.** Inoculated bags were put in a cropping chamber in dark conditions at 23–25 °C until the end of the mycelia run stage. The cropping chamber was well-sealed and equipped with climate control facilities. During the mycelia run stage, the room was continuously moistened to keep relative humidity levels in the range of 80–90% (using Hotsale 7 L/h Ultrasonic Mist Maker). It was kept close to keep the CO₂ levels high for an adequate development of mycelium. At complete mycelia run (14 days after incubation), pin head formation was triggered by ventilation, reduction of the CO₂ levels to a range of 900–2300 ppm, lighting (200 lx light source), and reduction of the room temperature to around 15 °C. A high relative humidity (88–90%) was maintained during the fruiting stage. Continuous monitoring of the room temperature and relative humidity was performed using a humidity/temperature meter Lutron HT-3007SD.

**Analysis of substrate properties.** Properties of the initial substrate (Table 1) were analyzed as follows: moisture content (using Moisture Analyzer, Sartorius Instrument, Model MA37, Göttingen, Germany), organic matter (via loss of ignition method at 430 °C over 24 h, C/N ratio using CHN Analyzer with automatic sampler, Carlo-Erba elemental analyzer, Model 1106, Milan, Italy), and pH using a pH meter (UltraBasic-UB10; Denver Instrument, Bohemia, New York, USA). The determination of the total protein content followed the AOAC official methods of analysis, using Micro-Kjeldahl method (N x 6.25). Total carbohydrates were determined using Anthrone method. Furthermore, cellulose, hemicellulose, and lignin content were analyzed on dry samples (initial and residual substrate) using ANKOM technology method, filter bag technique, following AOAC official methods of analysis.

| Components | WS + SOS (1:1, w/w mixture) | WS | SOS |
|------------|-----------------------------|----|-----|
| Organic matter (%dw) | 82.8 | 92.7 | 82.6 |
| Total protein (%dw) | 7.50 | 6.5 | 8.0 |
| Total carbohydrates (%dw) | 30.54 | 35.2 | 28.2 |
| Cellulose (%dw) | 35.95 | 41.05 | 31.51 |
| Hemicellulose (%dw) | 13.14 | 21.38 | 10.6 |
| Lignin (%dw) | 6.59 | 7.27 | 6.05 |
| Moisture (%) | 85.6 | 80.6 | 83.5 |
| C/N ratio | 43:1 | 50:1 | 40:1 |
| pH (1:5, w/v) | 5.2 | 5.8 | 5.0 |

Table 1. Properties of the basic substrates (dw: dry weight).
Analysis of mushroom composition. Around one kilogram of complete (pileus and stipe) and mature fruiting bodies of each experimental treatment were needed to perform the different tests of composition. The different tests were performed on fresh samples, and then results were provided in percentage dry weight by conversion. Total protein content of samples was estimated by the macro-Kjeldahl method (N × 4.38)\(^41\). Determination of total carbohydrates content followed the Anthrone method\(^36\). Fat content was determined by extracting a known weight of powdered sample with ethyl ether, using a Soxhlet apparatus. The percentage of fiber was calculated, based on AOAC official method 962.09\(^41\) general method, after determining the ash content in mushrooms (2 g of mushrooms put in a crucible and set in a muffle furnace at 500 °C for 12 h, then the furnace removed, cooled in a desiccator and weighed). Thereafter, 0.5 g of dried sample were extracted using acetone in a 50 ml centrifuge tube, the extract containing fat was discarded, and 50 ml of H\(_2\)SO\(_4\) (1.25%) were added, the mixture was boiled at 100 °C for 15 min, then centrifuged at 1000 rpm, decanted and the solution discarded. This was followed by the addition of 50 ml NaOH (1.25%), boiling at 100 °C for 15 min, centrifugation at 1000 rpm, decantation, discarding again the solution, adding 25 ml H\(_2\)SO\(_4\) (1.25%), decanting solution, adding 50 ml H\(_2\)O, filtering the solution on a pre-weighed filter paper using Buchner, washing with 2 H\(_2\)O portions 50 ml each then using 25 ml ethanol portion. Therefore, the residue was dried for 2 h at 130 °C in oven; the remaining residue represented fiber and ash contents. The percentage of fiber was then calculated (Eq. 1). 

\[
%\text{fiber} = \frac{\text{weight (paper + residue)} - \text{weight (paper)}}{\text{weight (sample)}} \times \%\text{crude ash}
\]

The analysis of amino acid composition followed ISO standards (13903:2005)\(^42\). Free amino acids were extracted with hydrochloric acid. Co-extracted nitrogenous macromolecules were precipitated with sulfosalicylic acid and removed by filtration. The filtered solution was adjusted to a pH of 2.2. Amino acids were then separated by ion exchange chromatography and determined by reaction with ninhydrin with photometric detection at 570 nm.

For the measurements of ions (Ca, K, Mn, Fe, Na and Mg), 2.8 ml of HNO\(_3\) (65%) were added to 5–6 g of samples, digested at 150 °C for 1 h, then filtrated with 100 ml of distilled water. The filtrate was then subjected to Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Phosphorus content was determined by spectrophotometric method, wherein phosphorus reacts with molybdic acid to form phosphomolybdate complex, which was then reduced with amino naphthol sulfonic acid to complex molybdenum blue that was measured spectrophotometrically\(^43\).

Zinc, copper, nickel and lead were determined using Atomic Absorption Spectrophotometer (AAS) (Perkin Elmer, Model Analyst 400, Waltham, Massachusetts, USA); mushroom samples were digested using a mixture of HNO\(_3\), H\(_2\)SO\(_4\), and H\(_2\)O\(_2\) (4:1:1) (12 ml per 1 g of sample). The mixture was boiled to 150 °C for 4 h, and then deionized water was added to a volume of 25 ml. Same steps were followed to prepare a blank digest. Standard solutions for calibration were prepared by diluting a stock solution of 1000 mg/l (Sigma and Aldrich) of each tested element.

For the determination of soluble sugars, mushroom samples were heated in water at 100 °C for 30 min. The sample solution was filtered and 20 µl of filtrate were used then for normal phase extraction using High Performance Liquid Chromatography (HPLC) at 30 °C (normal phase extraction; column NH\(_2\) column: 250 × 4.5 mm ID, at a flow rate of 1.2 ml min\(^{-1}\)). Sugars were detected with a refractive index detector (RID) (mobile phase: mixture of polar-non-polar solution, calibration: using a 2 points concentration). Sugar identification was made by comparing with standards prepared from stock solution of sugars to get concentrations approximate to sample. For the different tests, each represented value is the mean of 3 replicates determination ± standard deviation.

Statistical analysis. One-way ANOVA (analysis of variance) and Duncan’s multiple range tests were applied using the program Statistical Package for Social Sciences “SPSS25”, at a 95% level of confidence.

Results and discussion
Mushrooms grow on agricultural wastes by secreting enzymes to digest the surrounding foodstuffs and get their nutrients from the substrate\(^44\). Therefore, their nutritional composition will largely depend on the chemical composition of the growing substrate\(^7–12\). In early studies, the changes in mushroom nutritional composition were mostly addressed when various nutrient additives were applied at spawning. In the present study, not only the dose of nano-urea, but also its timing of application had varying effects on the mushroom nutritional composition.

Mushroom composition. There was punctual improvement in the mushroom protein and fiber contents by 0.64% and 0.19% respectively when 3 g kg\(^{-1}\) nano-urea was applied at spawning (C\(_1\)t\(_1\)) and by 0.46% and 0.19% respectively when 5 g kg\(^{-1}\) nano-urea was applied after the first harvest (C\(_2\)t\(_2\)) (Table 2).

The nitrogen source is a major factor that affects the fungus’s enzyme production for biodegradation of a certain substrate\(^45\). Nitrogen can be transported into the fungus’s living cell in the form of amino acids\(^46\). Substrate proteins are degraded into amino acids by the extracellular enzymes secreted by the fungus mycelium. Amino acids are then assimilated for subsequent utilization for protein synthesis in the mushroom. The substrate composition and the harvest time of mushrooms may affect their protein content\(^47\). Values of protein content relative to the first timing of product application (at spawning) correspond to mushrooms of the first harvest, and were higher or comparable to control (3.56% and 3.00% in C\(_1\)t\(_1\) and C\(_1\)t\(_2\) respectively compared to 2.92% in control). A low protein dose applied at spawning (C\(_1\)t\(_1\)) may have enhanced the enzymatic accessibility of amino acids to the fungus, compared to control. Further, mushrooms consume the substrate’s nutrients as long as they grow.
Table 2. Composition of *P. ostreatus* mushrooms cultivated on supplemented substrates. C1, 3 g kg⁻¹, C2, 5 g kg⁻¹, t1 supplementation at spawning, t2 supplementation after the first harvest, t3 supplementation at spawning and after the first harvest. Values are means; means within the same column followed by the same letters are not significantly different at *P*<0.05 according to Duncan's multiple range test.
the treatment C2t1 (increase by 0.045%) compared to control. But, a double application of the highest product dose caused lower substrate degradation (higher average values of residual fibers), compared to control, maybe because of excess nitrogen, which may suppress the ligninolytic activity of *P. ostreatus*.

Overall, the decrease in sugar content of food is advantageous as excessive sugar intake is associated with adverse health conditions, including obesity, metabolic syndrome and inflammatory diseases.

Essential amino acids. Nutritionally, essential amino acids are defined as those amino acids that normally are insufficiently synthesized by the organism relative to its needs for maintenance, growth, development, and health, and which must be provided in the diet to meet requirements. They are signaling molecules and gene expression modulators. At the first timing of application (at spawning), it seems that a low dose of nano-urea (3 g kg⁻¹) was enough to enhance the assimilation of amino acids from the substrate, while the highest product dose (5 g kg⁻¹) has negatively affected it. In fact, the content of all essential amino acids was significantly improved in C1t1 compared to C2t1 and control (Table 3). Among all treatments, essential amino acids were the highest in mushrooms of the treatment C1t1, where threonine, valine, isoleucine, leucine, phenylalanine, histidine, lysine, and methionine contents increased by 0.31, 0.10, 0.05, 0.21, 0.18, 2.05, 0.27, and 0.09%, respectively compared to control. Another nano-supplement, rich in amino acids (Lithovit-Amino25) improved most of the essential amino acids in *P. ostreatus* mushroom when applied at spawning.

On the other hand, at the second timing of application (after the first harvest), both product doses have caused significant reduction in essential amino acids contents in mushrooms, compared to control, with few exceptions (respective increase of histidine content by 1.11 and 1.37% in C1t2 and C2t2, and of methionine content by 0.02% in C1t2). At this timing of application, essential amino acids were significantly higher in mushrooms of C2t2 than C1t2, except phenylalanine and methionine.

Furthermore, the product application twice during the production cycle (timing 3) caused a significant reduction in the majority of essential amino acids compared to control, with few exceptions; threonine, valine, and histidine contents increased by 0.12 and 0.14% in C1t3 and C2t3, respectively, while phenylalanine was comparable to control in both treatments. These findings suggest that the assimilation of these three amino acids (threonine, histidine, and phenylalanine) from the substrate is not counteracted by high nitrogen doses accumulating in the growing substrate. Instead, their assimilation mechanism may have required a stronger mycelia growth, thus higher enzyme secretion by the mushroom to degrade the substrate proteins. Overall, the most dominant essential amino acid was histidine, followed by leucine and threonine.

### Table 3. Sugar composition of *P. ostreatus* mushrooms cultivated on supplemented substrates. ### Non-essential amino acids.
Non-essential amino acids have a major role in regulating gene expression, cell signaling pathways, digestion and absorption of dietary nutrients. At the first timing of nano-urea application (at spawning), and similarly to the pattern observed for essential amino acids, the lowest product dose was enough to enhance the assimilation of all non-essential amino acids from the substrate, causing significant improvement of their contents in mushrooms compared to control (Table 6). In $C_{1t}$, contents of aspartic acid, serine, glutamic acid, proline, glycine, alanine, arginine, and cysteine increased by 0.67, 0.43, 0.95, 0.31, 0.22, 0.07, 0.89, and 0.06% compared to control. A higher product dose applied at this timing ($C_{2t}$) caused significantly lower values (for aspartic acid, serine, glutamic acid, glycine, alanine, and arginine), or values comparable to control (proline and cysteine). The higher content of both essential and non-essential amino acids caused higher protein content in mushrooms of $C_{2t}$ compared to $C_{1t}$. On the other hand, when nano-urea was applied at timing 2 (after the first harvest), a higher product dose was essential to ameliorate the assimilation of most non-essential amino acids (except arginine) from the substrate, improving their contents by a range of 0.02–0.68% in mushrooms of $C_{2t}$ compared to control.

Improvement in protein content in mushrooms of $C_{2t}$ compared to $C_{1t}$ is explained by higher contents of most essential and all non-essential amino acids in the former compared to the latter treatment. Besides, superior essential and non-essential amino acids contents caused the highest protein content in mushrooms of $C_{2t}$ compared to all tested treatments.
In contrast to the pattern observed for essential amino acids, the double application of nano-urea (timing 3) may have ameliorated the assimilation of most non-essential amino acids from the substrate, causing significant improvement of their contents in mushrooms. However, the double product application had negatively affected the mushroom content in glycine and arginine, independently from the dose applied, and in aspartic acid and proline, following the application of the highest dose. The mechanism of assimilation of these four amino acids may have been counteracted by the progressive accumulation of nitrogen in the substrate. However, a further investigation of the enzymatic activity as affected by nano-urea application may better confirm these findings.

The amino acids of mushrooms produced from nano-urea treated substrates were higher than values of amino acids of early studies. Glutamic acid was the most dominant non-essential amino acids in all treatments, followed by alanine, aspartic acid, and occasionally by arginine. In other reports, asparatic acid, glutamic acid and arginine were detected as three main amino acids in *P. ostreatus* mushrooms.

### Minerals and heavy metals

Results in Table 7 showed that nano-urea treatment decreased the mushroom phosphorus content by a range of 0.03–0.13% in comparison with control mushrooms. *P. ostreatus* is a phosphorus rich mushroom, which makes it a good contributor in human nutrition. However, high levels of phosphorus in food inhibit the intake of calcium causing bones weakness, itchy skin and bone or joints pain leading to chronic kidney disease-mineral bone disorder. On the other hand, nano-urea application had significantly increased the zinc content of mushrooms in all treatments (by a range of 8.3–43.2 ppm), except in *C*1t1 and *C*2t1 (reduction by 3.9 and 1.2 ppm, respectively). Mushrooms act as good zinc accumulators, this element is highly associated with protein- and carbohydrate- rich foods. Zinc content in mushrooms of *C*1t2, *C*1t3, and *C*2t3 was higher than the safe range 0.05–5 ppm reported for plant foods. Manganese content had safe zinc contents. In comparison with mushrooms obtained from control substrate, mushrooms of nano-urea treated substrates had higher nickel (increase by a range of 10.8–14.0 ppm) and lead (increase by a range of 10.1–21.01 ppm) contents. Contrarily, copper content decreased by a range of 3.6–10.7 ppm in all treatments, except in *C*1t2 (increase of 5.7 ppm) (Table 8). Copper content in mushrooms produced for this study was lower than in the range indicated in early studies and very far from the toxicity level (400–1000 ppm) indicated by WHO both in treated and non-treated cases. Manganese is an essential nutrient in human diet; it plays a major role in intracellular activities.

In contrast to the pattern observed for essential amino acids, the double application of nano-urea (timing 3) may have ameliorated the assimilation of most non-essential amino acids from the substrate, causing significant improvement of their contents in mushrooms. However, the double product application had negatively affected the mushroom content in glycine and arginine, independently from the dose applied, and in aspartic acid and proline, following the application of the highest dose. The mechanism of assimilation of these four amino acids may have been counteracted by the progressive accumulation of nitrogen in the substrate. However, a further investigation of the enzymatic activity as affected by nano-urea application may better confirm these findings.

The amino acids of mushrooms produced from nano-urea treated substrates were higher than values of amino acids of early studies. Glutamic acid was the most dominant non-essential amino acids in all treatments, followed by alanine, aspartic acid, and occasionally by arginine. In other reports, asparatic acid, glutamic acid and arginine were detected as three main amino acids in *P. ostreatus* mushrooms.

### Minerals and heavy metals

Results in Table 7 showed that nano-urea treatment decreased the mushroom phosphorus content by a range of 0.03–0.13% in comparison with control mushrooms. *P. ostreatus* is a phosphorus rich mushroom, which makes it a good contributor in human nutrition. However, high levels of phosphorus in food inhibit the intake of calcium causing bones weakness, itchy skin and bone or joints pain leading to chronic kidney disease-mineral bone disorder. On the other hand, nano-urea application had significantly increased the zinc content of mushrooms in all treatments (by a range of 8.3–43.2 ppm), except in *C*1t1 and *C*2t1 (reduction by 3.9 and 1.2 ppm, respectively). Mushrooms act as good zinc accumulators, this element is highly associated with protein- and carbohydrate- rich foods. Zinc content in mushrooms of *C*1t3, *C*2t3, and *C*3t3 was higher than the safe limit set by the WHO (60 ppm); while mushrooms of the remaining treatments had safe zinc contents.

Moreover, there was a statistically significant reduction in mushroom calcium content, by a range of 0.001–0.003%, in all nano-urea treatments. Likewise, mushroom potassium and sodium contents decreased significantly in mushrooms, except in *C*1t1, where both elements were comparable to control mushrooms. In general, in *Pleurotus* spp. the content of sodium is low, while the potassium content is high and this is beneficial from a nutritional point of view. Low sodium contents in food help in controlling the blood pressure problems.

Iron content decreased by a range of 4.4–8.0 ppm in all treatments, except in *C*2t1. The range of mushroom iron content obtained in all nano-urea treatments (16.8–20.0 ppm) was higher than the safe limit set by the FAO/WHO/CODEX standard safe limit (15 ppm), except in *C*3t1 (13.6 ppm). However, values of iron content obtained following nano-urea application got closer to the standard safe limit, compared to values obtained in control mushrooms. A diet rich in iron helps decreasing the incidence of anemia. On the other hand, nano-urea application did not significantly affect manganese and magnesium contents in mushroom. Manganese content obtained in mushrooms from this study was lower and in the range indicated in early studies and very far from the toxicity level (400–1000 ppm) indicated by WHO both in treated and non-treated cases. Manganese is an essential nutrient in human diet; it plays a major role in intracellular activities.

In contrast to the pattern observed for essential amino acids, the double application of nano-urea (timing 3) may have ameliorated the assimilation of most non-essential amino acids from the substrate, causing significant improvement of their contents in mushrooms. However, the double product application had negatively affected the mushroom content in glycine and arginine, independently from the dose applied, and in aspartic acid and proline, following the application of the highest dose. The mechanism of assimilation of these four amino acids may have been counteracted by the progressive accumulation of nitrogen in the substrate. However, a further investigation of the enzymatic activity as affected by nano-urea application may better confirm these findings.

The amino acids of mushrooms produced from nano-urea treated substrates were higher than values of amino acids of early studies. Glutamic acid was the most dominant non-essential amino acids in all treatments, followed by alanine, aspartic acid, and occasionally by arginine. In other reports, asparatic acid, glutamic acid and arginine were detected as three main amino acids in *P. ostreatus* mushrooms.
Mushrooms produced by the non-treated substrate showed a higher percentage of lead compared to that reported earlier (0.04 mg kg\(^{-1}\))\(^8\) and exceeding the permitted level stated by the EU commission\(^8\) (0.3 mg kg\(^{-1}\)) and WHO\(^7\) (2 mg kg\(^{-1}\)).

Like other mushrooms, Oyster mushroom has the ability to absorb heavy metals from substrates via spacious mycelium\(^8\). The mineral level of mushrooms is affected by the substrate\(^8\). Heavy metals bioaccumulation depends on metal concentration in the initial substrate, substrate pH, cation exchange capacity (CEC), and organic matter content\(^8\). Therefore, different factors may have caused higher accumulation of heavy metals, like Ni, Pb (in all cases), Zn and Fe (in some cases), and lower accumulation of almost all others tested minerals. First, some elements (like Ni, Pb, Fe, Zn, and Cu) were already more abundant in the initial growing substrate. Second, Lithovit-Urea\(^5\) is rich in calcium carbonate (33.0%), which may have caused a liming effect to the initially low substrate pH (5.2). Such an effect could have favored the absorption of some minerals over others. It was noted earlier that an excess of lime in the substrate reduces nutrients uptake ability of the fungus\(^8\), which may explain why a large proportion of minerals (P, Ca, K, Na, Mg, and Mn) were reduced in mushrooms following the product application. Elekes et al.\(^8\) reported a strong correlation between soil pH and zinc bioaccumulation in wild mushrooms, which may explain why mushroom zinc contents were higher in mushrooms produced from the substrates treated by nano-urea at later stages of the growing process, when the product effect on the substrate pH may have been more influential. Nevertheless, these assumptions require further investigation for the changes in the pH of nano-urea treated substrates during different stages of the growing process. Moreover, the addition of Lithovit-Urea\(^5\), containing silicon oxide (SiO\(_2\)), magnesium oxide (MgO), iron (Fe), and manganese (Mn), releasing many cations to the growing medium may have caused a direct effect on the substrate CEC, thus on the mechanism of metal absorption from the substrate, and its subsequent accumulation in mushrooms. One additional factor influencing the absorption of metals in mushrooms is the competition with other metal ions\(^8\), therefore, the decrease in certain metals in mushrooms of this study, like copper, for example, could be due to the competition caused by nickel, lead, and zinc, the bioaccumulation of which was in general higher under the present experimental conditions.

**Conclusion**

Among the different tested timing and doses of nano-urea application, a low product dose (3 g kg\(^{-1}\)) applied at spawning was enough to enhance many nutritional attributes of *P. ostreatus* mushroom, improving its proteins, essential and non-essential amino acids contents, and lowering its sugar content. Such a treatment resulted in a lower accumulation of zinc and copper in mushrooms compared to all nano-urea treated cases. However, keeping in mind that heavy metals accumulation in food products has many negative effects on human health, and that nano-urea application has generally activated the accumulation of nickel and lead in mushrooms, even with the lowest dose applied, it is recommended to investigate the product effect in lower doses (< 3 g kg\(^{-1}\)) in future investigations.

Acknowledgements

Authors would like to acknowledge Tribodyn AG Company, Northelm, Germany, for offering Lithovit-Urea50.

Author contributions

Y.N.S., M.H.Y., and Z.E.S., designed the experiment, L.N. and S.A.F. conducted the experiment, M.A.S. and S.A.F. performed data analysis, L.N. and Z.E.S. wrote the manuscript, M.A.S., Y.N.S., and M.H.Y. corrected the manuscript. All authors reviewed the manuscript.

Competing interests

The authors declare no competing interests.
