INTRODUCTION

Beta-lactam group of antibiotics is one of the most common antibacterial agents used to treat the mixed bacterial infections in both developed and developing countries including India [1]. The production of β-lactamases such as extended-spectrum β-lactamases (ESBLs), AmpC, and carbapenemase is the most common cause of bacterial resistance against beta-lactam antibiotics. In between the β-lactamase enzymes, ESBLs are rapidly growing group of β-lactamases that mediate resistance to extended-spectrum cephalosporins and monobactams but not affected by cephemycins (cefotaxin, cefotetan, and cefmetazole) and carbapenems (imipenem, meropenem, ertapenem, doripenem, etc.) [1,2].

ESBLs are showing resistance to penicillin and narrow-spectrum cephalosporin by hydrolyzing the beta-lactam ring and are inhibited by β-lactamase inhibitors such as clavulanic acid, sulbactam, and tazobactam [4-6]. These are commonly produced by members of the Enterobacteriaceae, namely, *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus* [7,8] other bacterial species in the families of Enterobacteriaceae and Pseudomonadaceae are also known to produce these enzymes [9]. These bacteria are a serious problem for infection control by practitioners. Hence, early detection and identification of these resistance enzymes will enable optimum antimicrobial therapy, and ensure the timely introduction of infection control procedures to prevent further spread as these infections [10,11].

ESBLs are often associated with plasmids harboring resistance genes to other antimicrobial classes, resulting in multidrug-resistant isolates thereby facilitating their transfer to different hosts [12,13]. The first ESBLs have evolved from native β-lactamases TEM and SHV by a genetic mutation. However, from the 2000s, a novel type of ESBL called CTX-M has emerged worldwide [14-16].

Control of infection by these microorganisms is a major challenge that requires accurate and fast ESBL detection in clinical microbiology laboratories. Hence, the rapid characterization of these isolates is very important in the treatment of hospitalized patients. The aim of this present study is to develop a standardized, inexpensive and simple approach that is able to detect ESBL-producing Enterobacteriaceae isolates in a routine clinical laboratory.

METHODS

This conceivable study was conducted at the Medical Microbiology Laboratory of Periyar University, Salem, Tamil Nadu, India. A total of 78 clinical samples was collected from the hospitals surrounding Salem. The clinical samples urine, swabs, sputum, blood, and body fluid were collected from patients presenting at the local hospitals between the periods of January 2017 and February 2017. The samples were inoculated onto blood agar (BA) and MacConkey agar plates and incubated plates were incubated at 37°C for 24 h. The isolates presenting at a significant number (colony counts ≥105 CFU/ml) were identified according to standard procedures.

Antimicrobial susceptibility tests

Antibiotic susceptibility of the clinical isolates was tested by the Kirby-Bauer disc diffusion method on Mueller Hinton Agar following CLSI guidelines using antibiotic discs containing penicillin (10 mcg), amoxicillin (30 mcg), ampicillin (10 mcg), ceftriaxone (30 mcg), cefazidime (30 mcg), cefotaxime (30 mcg), gentamycin (10 mcg), tetracycline (30 mcg), ciprofloxacin (5 mcg), and meropenem (10 mcg).

β-lactamases assay

This assay was done by plate and tube method to detect. The production of β-lactamases enzymes by the cephalosporins resistant isolates was tested by plate and tube method.
Plate method
The β-lactamase assay by plate method was done following the method of Kumar et al., 2013. A loopful culture of the test organism was spot inoculated on Mueller Hinton agar (MHA) containing 1% starch and penicillin (10,000 units). After incubation of plates at 37°C for 18–24 hrs, the plates were flooded with freshly prepared phosphate buffered saline (PBS) containing potassium iodide, iodine. The appearance of the clear, colorless zone around the bacterial growth is an indication of β-lactamase production. The β-lactamase converts penicillin to penicillin acid, which reduces iodine to iodide monitored through decolorization of the starch-iodine complex [17].

Tube method
The β-lactamase assay by tube method was done following the method of Alaa et al. The starch indicator was prepared by dissolving 1 g of starch powder in 100 ml of boiling water. The iodine reagent was prepared by dissolving 2 g of KI (potassium iodide), 1 g of iodine in 100 ml of distilled water (D.W). The solution was then stirred vigorously for 15 min and stored in brown bottles. A solution of 10 000 units of benzylpenicillin per ml was prepared in phosphate buffer pH 7 0. This was made by dissolving 0.6 g of penicillin G powder in 60 ml of PBS. The volume was made up to 100 ml with D.W and then sterilized by Millipore (0.22 µm) filters. The test was conducted by adding a loop full of overnight grown culture (of the tested bacteria) to 0.5–1 ml of the penicillin G solution. The tube was left at 37°C for 30 min. Thereafter, 2 drops of the starch solution were added, followed by 1 drop of iodine reagent. A color change from dark blue to colorless was noted over the next 10 min. The change of the black color to colorless solution indicated positive test [18].

ESBL detection
The clinical isolates showing reduced susceptibility to ceftazidime (zone diameter of <22 mm), ceftriaxone (zone diameter of <25 mm), or cefotaxime (zone diameter of <27 mm) as recommended by CLSI guidelines (2010), were screened for confirmation of ESBL production by following two different methods, namely, double disc synergy test (DDST) and combined disc synergy test (CDST).

DDST
Amoxicillin/clavulanic acid (20 µg/10 µg) and third generation cephalosporin discs were placed at a distance of 20 mm from center to center of the lawn cultures on Mueller Hinton agar plates. The plates were incubated at 37°C overnight. An enhancement in the zone of inhibition of cephalosporins toward the amoxicillin/clavulanic acid disc was considered a positive result for ESBL [19,20].

CDST
The phenotypic confirmation of ESBL producers was carried out by as per CLSI (2010) guidelines. A disc of ceftazidime (30 µg) alone and a disc of ceftazidime + clavulanic acid (30 µg/10 µg) were used in this study. Both the discs were placed at least 25 mm apart, center to center, on a lean culture of the test isolate on to MHA plate and incubated overnight at 37°C. Difference in zone diameters with and without clavulanic acid was measured. A ≥5 mm increase in the zone diameter of inhibition for any of the antimicrobial agents tested in combination with clavulanic acid compared to the zone diameter of inhibition when tested alone was considered as confirmatory for ESBL production [21-23].

To check the quality of these tests the ESBL negative strain of E. coli ATCC 25922 and ESBL positive strain K. pneumoniae ATCC 700603 were used as a standard control for both methods.

Genotypic detection of ESBL
The genotypic identification of ESBL producers was carried out by isolation of plasmid DNA. Isolation of plasmid DNA was carried out by alkaline lysis procedure (Sadasivam and Manickam, 2008) with some modification. 1 ml of an overnight culture was transferred into an eppendorf tube. The cells were sedimented by centrifuging briefly
(5000 RPM) in the microfuge and the supernatant was drained off. The pellet was resuspended by adding 100 µL of solution A and the contents were mixed by a vortex. Then, 100 µL solution B was added and mixed well by inverting the content (4-5 times). To the above viscous content, 100 µL of solution C was added, and the content was inverted 4-5 times to get mixed, the bulk of genomic DNA and other cell debris will precipitate into a viscous clump. It was centrifuged at 12000 RPM in a micro centrifuge, and the clump was removed. The clear lysate was transferred to another eppendorf tube. 150 µL of 100% isopropanol was added and mixed well and centrifuged the content at 12000 rpm for 30 min. The supernatant was drained off and 150 µL of absolute alcohol was added and centrifuged the content at 10000 rpm for 20 min. The supernatant was drained off and dissolved the DNA pellets with 20 µL TE buffer. The extracted Plasmid DNA was confirmed by running of agarose gel electrophoresis.

Isolates were screened for the resistance genes SHV, TEM, CTX-M, and OXA by a multiplex polymerase chain reaction (PCR) assay by following the protocol of Hong Fang et al, (2008) (Table 1). PCR amplification reactions were performed in a volume of 25 µL containing 12.5 µL of 2x Promega PCR Master Mix (USA), 0.2 µM concentrations of each primer, and 2 µL of DNA template. The cycling parameters were as follows: Initial denaturation at 95°C for 15 min; followed by 30 cycles of 94°C for 30 s, 62°C for 90 s, and 72°C for 60 s; and with a final extension at 72°C for 10 min. The amplified PCR products were subjected to electrophoresis at a 1.5% agarose gel in 1 XTBE buffer. A 100 bp ladder molecular weight marker (Helini, India) was used to measure the molecular weights of amplified products.

RESULTS

A total of 64 strains were isolated in significant numbers from collecting clinical samples. Antibiotic revealed that 54 (84%) isolates were resistant to penicillin, 52 (81%) isolates were resistant to ampicillin, and 30 (46%) isolates were resistant to amoxycillin. The resistance to ceftazidime, ceftriaxone, cepotaxime, and gentamycin was in between 40% and 60%, to tetracycline and ciprofloxacin was noted in between 30%. Minimal resistance of 18% was noted to the drug meropenen, 28 isolates were selected for the detection of ESBL production and β-lactamase production, which as they showed resistance to ceftazidime, ceftriaxone, and cefotaxime (Fig. 1).

ESBL detection

The result of plate and tube methods showed that all the 28 isolates were β-lactamase producers as confirmed by both the methods. The CDST was found to be the best method for the detection of ESBL when using the DDST. Out of 28 isolates, 23 were positive in CDST but in the DDST 18 were showing ESBL positive (Figs. 2 and 3, Chart 1).

Genotypic detection of ESBL isolates

Of the 28 cephalosporin resistant clinical isolates, 10 isolates were ESBL positive by both CDST and DDST as they produced β-lactamase enzyme. 2 isolates were subjected to genotypic characterization by multiplex PCR for the presence of TEM, SHV, OXA, and CTXm gene. Strain 806 contains TEM and SHV then the strain 7320 contains TEM only (Fig. 4).

DISCUSSION

The infections caused by cephalosporin-resistant Gram-negative bacteria that produce an extended spectrum of β-lactam enzymes have been reported with an increasing frequency in intensive care units and are associated with significant morbidity and mortality. Initially, this enzyme was produced by members of Enterobacteriaceae and some non-fermenters which hydrolyzed the most of β-lactam antibiotics.

Table 1: The forward and reverse primer sequence of SHV, TEM, CTXm, and OXA genes with amplification size

| Gene name | Primer sequence | Amplified size (bp) |
|-----------|-----------------|---------------------|
| SHV       | CTT TAT GGG CCC TCA CTC AA | 237 |
|           | AGG TGC TCA TCA TGG GAA AG | |

|           | AGT GTG TTT AGA ATG GTG ATC | |
| OXA       | ACA CAAG TAC ATA TCA ACT TCG C | 813 |

In our study out of the 64 isolates, about 50 isolates showed resistant to penicillin and ampicillin, and about 30 isolates showed resistance to ceftazidime, ceftriaxone, and cefotaxime. Only 12 isolates showed resistant to meropenem. β-lactamase assay was done by plate and tube method all the 28 isolates produced β-lactamase enzyme in both methods. Kumar et al, 2013 found similar results, among 180 MDR Acinetobacter spp. 147 were positive for beta-lactamase assay method.

In the study, 23 ESBL positive isolates from 28 isolates which showed resistant to ceftazidime, ceftriaxone, and cefotaxime. Only 12 isolates showed resistant to meropenem. β-lactamase assay was done by plate and tube method all the 28 isolates produced β-lactamase enzyme in both methods. Kumar et al, 2013 found similar results, among 180 MDR Acinetobacter spp. 147 were positive for beta-lactamase assay method.

ESBL detection

The result of plate and tube methods showed that all the 28 isolates were β-lactamase producers as confirmed by both the methods. The CDST was found to be the best method for the detection of ESBL when using the DDST. Out of 28 isolates, 23 were positive in CDST but in the DDST 18 were showing ESBL positive (Figs. 2 and 3, Chart 1).

Genotypic detection of ESBL isolates

Of the 28 cephalosporin resistant clinical isolates, 10 isolates were ESBL positive by both CDST and DDST as they produced β-lactamase enzyme. 2 isolates were subjected to genotypic characterization by multiplex PCR for the presence of TEM, SHV, OXA, and CTXm gene. Strain 806 contains TEM and SHV then the strain 7320 contains TEM only (Fig. 4).
In our study, 82% of the ESBL producing organisms were sensitive to meropenem.

Multiplex PCR results showed the presence of TEM gene in both 806 and 7320 isolates. In case of 806 TEM and SHV were present. In a previous study by Karimian in Iran, the frequency of blaTEM and blaCTX-M genes in the 83 ESBL producing E. coli isolates was 27 (32.5%) and 72 (86.7%), respectively. However, 24 isolates (28.9%) were indicated as having both genes. All E. coli strains harboring blaTEM were resistant to ceftazidime and cefotaxime, respectively, and ESBL production was observed in 59 (40.7%) strains, comprising blaCTX-M such as genes in 22 (37.3%) and blaTEM in 42 (71.2%) strains.

CONCLUSION

From the results of this study, it can be concluded that uncontrolled use of cephalosporin groups appears to be a potential risk factor for the emergence of ESBL producing strains of Enterobacteriaceae which poses a global challenge to microbiologist and clinicians. ESBL-producing bacteria have found their way out of the hospital, which could be considered as a risk factor in society. The monitoring and thoughtful usage of extended-spectrum cephalosporins, periodic observation of antibiotic resistance patterns will help to prevent the entry of ESBL producers into the environment. There is a need for the limitations and detected in the lab communication between microbiologist and physicians are the way control of the resistance.
