Diminishing fossil fuel resources and calls for sustainability are driving the urgent need for efficient valorization of renewable resources with high atom efficiency. Inspired from the natural goethite mineral with Mn paragenesis, we develop cost-effective MnO₂/goethite catalysts for the efficient valorization of dihydroxyacetone, an important biomass-based platform molecule, into value-added glycolic acid and formic acid with 83.2% and 93.4% yields. The DHA substrates first undergo C−C cleavage to selectively form glycolic acid and hydroxymethyl (−CH₂OH) radicals, which are further oxidized into formic acid. The kinetic and isotopic labeling experiments reveal that the catalase-like activity of MnO₂ turns the oxidative radicals into oxygen, which then switches towards a hydroxymethyl peroxide (HMOO) pathway for formic acid generation and prevents formic acid over-oxidation. This nature-inspired catalyst design not only significantly improves the carbon efficiency to 86.6%, but also enhances the oxygen atom utilization efficiency from 11.2% to 46.6%, indicating a promising biomass valorization process.
The global decline of fossil fuel resources and subsequent climate change issues have accelerated the need for renewable energy and sustainable resources. As a result, the co-production of chemicals with a high atom economy is being pursued with enthusiasm. Biodiesel is a renewable bio-derived fuel with steadily increasing production over the years but has led to the over-supply of crude glycerol with relatively low utilization efficiency. 1,3-dihydroxyacetone (DHA), which can be obtained via the catalytic oxidation or fermentation of glycerol and ketose, is listed as one of the most important C3 platform molecules. DHA can be converted to C2 and C1 chemicals via selective C−C cleavage, which enriches the product and value chain. For instance, selective C−C cleavage of DHA can simultaneously produce glycolic acid (GA) and formic acid (FA) with high atomic efficiency, in which GA is an important intermediate for the synthesis of personal care products and GA is often used in the food and leather industry as a source of formly groups and a hydrogen storage carrier. Al2O3 catalysts with isolated active sites were found to split H2O2 into HO· that selectively cleaves the C−C bond in alkane (83−90 kcal/mol), the C−C bond in DHA is relatively weak (~80 kcal/mol for acetone), but is subject to keto-enol tautomerism, which complicates the oxidative C−C cleavage of DHA. Under the attack of oxidative radicals, DHA could be oxidized to generate various organic radicals, making the controlled conversion to targeted chemicals difficult, while requiring a clear understanding of their precise fate and efficient regulation of radical pathways. For the present study, we were inspired from natural goethite minerals that are capable of cleaving the C−C bonds of organic compounds. We succeeded in synthesizing a MnO2-attached goethite catalyst that can co-produce GA and FA with high yields. This system decreases the H2O2 stoichiometric ratio by a factor of 3 to achieve high atom efficiency, particularly with the highest oxygen atom efficiency ever reported. We found that the introduction of MnO2 can not only promote HO· generation and C−C cleavage, but also mediate the chain reaction to inhibit FA oxidation. We are convinced that our strategy of using nature-inspired abundant Fe/Mn-based catalysts to selectively oxidize biomass-derived molecules into value-added products can boost the future development of biomass valorization technologies significantly.

**Results**

**Catalytic performance of iron-bearing minerals and natural goethite-inspired catalysts.** The typical iron-bearing minerals in the geochemical cycling of Fe, including hematite (α-Fe2O3), pyrite (FeS2), magnetite (Fe3O4), goethite (FeOOH) and lepidocrocite (γ-FeOOH), and the homogeneous Fenton catalysts (Fe2+ and Fe3+) were first screened for the selective oxidation of DHA. As shown in Fig. 1a, low DHA conversions of 20.0% and 47.1% were observed in the homogeneous Fe3+ and Fe2+ systems, respectively, indicating their weak activities of C−C bond cleavage. Although pyrite afforded the highest conversion of DHA (75.1%) among Fe-bearing minerals, it exhibited only moderate GA and FA yields and was almost completely dissolved after 24 h of reaction (the leaching ratio of Fe >90%, Supplementary Table 1). Taking into combined account of the DHA conversion and GA/FA yields, goethite outperformed other minerals with 71.9% DHA conversion, 68.5% GA yield, and 38.2% FA yield and was almost completely dissolved after 24 h (Fig. 1b). Meanwhile, the GA yield decreased, indicating the difficulty of the size regulation towards high-yield GA and FA production under high DHA conversion.

As the most thermodynamically stable and the most abundant Fe-bearing mineral, goethite is widely found in soils of the temperate climate, marine and lake sediments and can occur in variable structures, such as intergrown Fe-/Mn-oxides, calcite and

**Fig. 1 Catalytic performance screening of iron-based catalysts.** **a** Catalytic activity for DHA oxidation over Fe-based ions and different Fe-containing minerals. **b** Catalytic activity for DHA oxidation over different goethite and Fe-containing Mn-rich chemicals. The commercially available goethite (Sigma, 30−50 mesh) was used after grinding to more than 200 mesh. Reaction conditions: catalyst 30 μmol, DHA 1 mmol, H2O2 0.2 mL (30 wt% H2O2 aqueous), 25 °C, 400 rpm, 24 h. Error bars represent standard deviations from triplicate experiments.
clay minerals or other atoms such as isomorphous crystal elements and trace metals (Al, Mn and etc.) can substitute for the Fe atoms\textsuperscript{33–35}. To investigate these possible contributions of the unique natural structures, two natural goethite minerals, and a natural Mn-rich mineral were directly extracted from a mine and chosen for the selective oxidation of DHA. As shown in Fig. 1b, Goe-CZ, one of the natural goethites, showed a significant increase in GA and FA yield to 82.5 and 79.3% respectively (Fig. 1b). This serendipitous result impelled us to comprehensively characterize its composition and structure. Notably, the ICP analysis detected the presence of \( \sim 1.1 \) wt% of Mn in Goe-CZ, but not in any other goethites. In the natural environment, Mn can be substituted for Fe in the goethite structure by forming the isostructural goyite (\( \alpha \)-MnOOH), nussite (\( \gamma \)-MnO\(_2\)), or ramsdellite (\( \gamma \)-MnO\(_2\))\textsuperscript{34,36}. With the increase of the Mn/Fe ratio, new separate Mn/Fe- or Mn-bearing phases, such as jacobsite (MnFe\(_2\)O\(_4\)), hausmannite (MnO\(_2\)), or pyrolusite (\( \beta \)-MnO\(_2\)), may appear together with goethite\textsuperscript{36}. The Mn distribution in the Goe-CZ was further investigated due to its possible contribution to catalytic performance. No perceptible diffraction peaks of Mn-containing phases were observed in XRD patterns (Fig. 2a), but the nanocrystalline hausmannite and pyrolusite phases were successfully identified in the HRTEM images of the Goe-CZ sample (Supplementary Fig. 3). The XPS peaks at 641.5 eV can be attributed to Mn 2\( p\)\(_{3/2}\) signal of Mn(IV) species (Fig. 2b). The microscopic morphological analysis provided direct visual evidence for the proposed Mn distributions. SEM images revealed that the mineral is composed of 0.1–0.3 mm flake-like macroparticles, but microscopically forms a stacking of \( < 1 \) \( \mu \)m rod-like microparticles (Supplementary Fig. 4). According to the EPMA analysis with high spatial resolution (Fig. 2d), Mn was largely absent on most Goe-CZ surfaces, while a high Mn content was detected on some micron-sized particles, confirming the intergrowth of Mn-bearing phases with goethite. Besides, the Mn substitution into the goethite lattice was also observed in some particles, as indicating the overlap of Fe and Mn EDS signals at the rod edges (Fig. 2e).

As illustrated in Fig. 2f, the above characterizations clearly showed the two forms of Mn in the natural goethite (Goe-CZ), which inspired us to mimic the natural structure of Goe-CZ. We directly added the Mn nitrate salt to the precursors of goethite (Fe(NO\(_3\))\(_3\)) in the synthesis of goethite to mimic the substitution (Supplementary Fig. 7). The intergrowth of Mn/Fe-bearing phases was successfully characterized by mechanical mixing the as-prepared jacobsite, commercial hausmannite, or pyrolusite with as-synthesized goethite microrods, denoted as jacobsite-attached goethite (jacobsite/Goe), hausmannite-attached goethite (hausmannite/Goe), and pyrolusite-attached goethite (pyrolusite/Goe), respectively. Similar to the Goe-CZ, there are no diffraction peaks assigned to Mn/Fe-bearing phases in any of the three samples (Supplementary Fig. 8), which should be ascribed to their low contents and high dispersion. Based on these results, we can conclude that the Mn distributions in natural Goe-CZ were largely reproduced by the doped and mixed samples, although there are still differences in the relative intensities of the diffraction peaks and the Mn valence states.

Selective oxidation of DHA was performed with the natural goethite-inspired mimicked catalysts. Obviously, these catalysts with different Mn distributions showed significant differences in the catalytic activity. As shown in Fig. 2g, Mn/Goe showed only slightly improved yields compared to the pure goethite, while the three MnO\(_2\)-attached goethites showed significant improvement in the catalytic performance, in which the GA/FA yields (84.3% for GA and 90.8% for FA) in MnO\(_2\)/Goe even surpassed natural Goe-CZ. This indicates that the reaction benefits from \( \beta \)-MnO\(_2\) as a separate crystal phase. The control experiments without goethite exhibited lower GA and FA yields (Supplementary Fig. 9), which demonstrated the critical synergy between goethite and \( \beta \)-MnO\(_2\). By screening reaction parameters like reaction time and H\(_2\)O\(_2\) concentration, we pinned down an optimal condition of 2 mmol of H\(_2\)O\(_2\) for 24 h for the highest activity and selectivity (Supplementary Fig. 10). No obvious increase in GA and FA yields was observed under prolonged reaction time, and the GA and FA yields rose under relatively low H\(_2\)O\(_2\) dosage but started to stagnate and even gradually decrease at high concentrations (>2.0 mmol) due to the over-oxidation of products. However, under O\(_2\)-rich conditions (O\(_2\)/H\(_2\)O\(_2\) = 1.2 MPa), the amount of H\(_2\)O\(_2\) dosage could be further reduced to 1.8 mmol without a noticeable decrease in the GA and FA yield (Supplementary Fig. 11).

MnO\(_2\) particles profoundly impact on the DHA conversion, and their effect was then studied and optimized. The introduction of MnO\(_2\) (0.1 wt% of Mn in goethite) significantly improved the H\(_2\)O\(_2\) decomposition and catalytic DHA conversion, but the reactivity remained nearly unchanged as the MnO\(_2\) ratio varied from 0.1 wt% to 5.0 wt% (Fig. 3a). The highest yield of GA and FA could reach 83.2 and 93.4% (Mn = 1.0 wt%), which outperformed the reported Cu/Al\(_2\)O\(_3\) system by 52.4% with respect to FA yield\textsuperscript{13}. The improved FA yield could lead to a carbon atom efficiency of 86.6–10.2% higher than the Cu/Al\(_2\)O\(_3\) system—while the CO\(_2\) yield was drastically reduced from 18.2% in Cu/Al\(_2\)O\(_3\) to 1.3% by avoiding the excessive oxidation of FA (Fig. 3b). This atom efficiency could be even higher due to a small percentage of unbalanced products (2.2–7.8%). In addition to carbon efficiency, the utilization of H\(_2\)O\(_2\) was also drastically improved by using less than a third of the H\(_2\)O\(_2\), reaching an overall atom efficiency of 67.2% compared to 19.4% in Cu/Al\(_2\)O\(_3\) system. In particular, oxygen atom utilization of this catalyst impressively reached 44.2%, and could further increase to 46.6% when the amount of H\(_2\)O\(_2\) dosage was reduced to 1.8 mmol under O\(_2\)-rich conditions, which is at least two-fold higher than the highest heterogeneous oxidation processes using H\(_2\)O\(_2\) as the oxidant (Fig. 3c and Supplementary Table 2)\textsuperscript{13,26,37–46}. In industrial-scale chemical production that uses H\(_2\)O\(_2\) as an oxidant, H\(_2\)O\(_2\) cost is usually one of the main economic factors. Therefore, these chemical production processes are generally coupled with H\(_2\)O\(_2\) synthesis plants, which are generally less expensive when considering the high production and transportation costs of commercial H\(_2\)O\(_2\) (USD 0.43–2.87 kg\(^{-1}\) for production (27.5–50 wt% H\(_2\)O\(_2\)) and USD 2.87 km\(^{-1}\) for transportation)\textsuperscript{47–49}. The significant reduction of H\(_2\)O\(_2\) consumption in this system can indisputably save the cost of H\(_2\)O\(_2\) plant construction and its corresponding maintenance, thereby increasing the overall economic efficiency of the process. In addition, our biomass-based process also includes carbon emission reduction potential, which is also may be economically advantageous from a sustainability point of view. When the percentage of MnO\(_2\) reached >5%, H\(_2\)O\(_2\) decomposition dominated over the DHA conversion, decreasing yields of GA and FA. We also examined the effect of MnO\(_2\) on the homogeneous Fenton systems for DHA oxidation. However, the Fe\(^{2+}\) and Fe\(^{3+}\) systems only showed slightly higher DHA conversion and FA yield upon the addition of different MnO\(_2\) amounts, indicating that the homogeneous Fenton activity cannot be easily promoted by MnO\(_2\) (Supplementary Fig. 12). Further, we extended this...
system from DHA to other biomass-based platform molecules classified as: lignocellulose-derived compounds (glucose and xylose), lignin-based model compounds (β-O-4 ketone: 2-phenoxyacetophenone), and glycerol-based compounds (glycerol and 1,2-propanediol). Compared to the pure goethite, the MnO2/Goe catalyst showed improved conversion of the five substrates, especially for xylose, and achieved 16.39–37.78% enhancement in total carbon atom selectivity (Supplementary Fig. 13 and Supplementary Table 3). This result adequately demonstrates that this nature-inspired catalyst is effective not only for the selective oxidation of DHA but also for enhancing the C–C cleavage and suppressing the excessive product oxidation for other biomass-based substrates.

Although the reaction formed strongly acidic products, the rod-like morphology of the goethite composition in the catalyst remained intact after the catalytic reaction (Supplementary Fig. 14). During the reuse cycling experiments (Supplementary Table 4), the GA and FA yields decreased slightly from 83.2, 93.4 to 78.7%, 84.0% during the first cycle but remained nearly unchanged as the number of reuse cycles increased, indicating the satisfactory reusability of the MnO2/Goe catalyst. The leached Fe was lower than 0.14% in all five cycles and the leached Mn was in the range of 1.08–1.91% in the last four cycles, not including the first cycle. In order to investigate the activity and durability of the catalyst for practical industrial applications, we further tested its catalytic performance using scaled-up continuous (0.36 mol DHA/day) and batch (2.5 mol DHA, 2500-times scale-up) reactors. Within the 10-day continuous operation, the catalytic activity stabilized after the first day with similar GA and FA selectivity and slightly decreased DHA conversion due to the dilution of H2O2 required for safe operation under scaled-up conditions (Fig. 3 d and Supplementary Fig. 15). The 2500×

Error bars represent standard deviations from triplicate experiments.](https://doi.org/10.1038/s41467-021-27240-5)
A scaled-up batch system could also achieve a similar performance as that of the small-sized reactor system (Supplementary Table 5). As shown in Supplementary Table 6, the productivity \( \frac{g_{\text{product}}}{g_{\text{catalyst}} \cdot h^{-1}} \) of our scaled-up continuous and batch systems is much higher than that of the reported Cu/Al2O3 system, even comparable with some of the glycerol-based systems requiring high temperatures. These results clearly highlight the promising potentials of this catalyst for industrial applications.

**Understanding and improving the C–C cleavage of DHA.** Activation of C–C bonds can be achieved in a variety of pathways including radical transfer, nucleophilic attack, and transition-metal insertion. Since goethite can activate H2O2 to form radicals in a Fenton-like manner, we first used electron paramagnetic resonance (EPR) and the spin trap 5,5-Dimethyl-1-pyrroline N-oxide (DMPO) to monitor the formation of radicals during DHA selective oxidation. Typical EPR signals belonging to DMPO-OH and DMPO-OOH adducts were clearly resolved.
suggesting the formation of HO• and HOO• radicals (Fig. 4a). According to the optimized structure and electrostatic potential distribution of DHA, the hydroxyl oxygen atoms are oriented towards ketyl oxygen atoms, which makes the DHA molecule polarized and the attack of HO• more favorable along the opposite direction of oxygen atoms (Fig. 4b). There are mainly two routes of reacting DHA with HO• radicals: (1) hydrogen abstraction of the α-carbon by a HO• radical to form a DHA-based radical; (2) the addition of a HO• radical to the carbonyl group to form a carbonyl-centered radical, which can be then decomposed into GA and a hydroxymethyl radical (Fig. 4b). Although the formation of GA and FA implied that the latter pathway dominated the DHA oxidation in our system, we probed the radical intermediates with the aid of EPR. In addition to DMPO-OH and DMPO-OOH adducts, a new signal with hyperfine splitting parameters of $A_{\text{N}} = 15.9$ G and $A_{\text{H}} = 22.7$ G could be assigned to the DMPO-hydroxymethyl radical adduct (DMPO-CH$_2$OH), which indicated the DHA molecule was activated by the addition of HO• to carbonyl group. There was no signal of any other radicals observed, completely ruling out the hydrogen abstraction pathway. The relative amount of fitted DMPO-CH$_2$OH adducts over time showed a negative correlation with that of DMPO-OH, suggesting a cause-and-effect relationship between the two radicals (Fig. 4a). The DMPO-CH$_2$OH adduct increased rapidly at the early stage and reached a peak at 4 h (30%), indicating that the C–C cleavage took place mainly in the early stages.

Moreover, the 1%-MnO$_2$/Goe catalyst exhibited a HO• generation rate of 0.164 M•h$^{-1}$ at the first hour, more than twice as high as that of goethite (0.071 M•h$^{-1}$) (Fig. 4c). This enhancement progressively decayed over time, which agrees with the early-stage C–C cleavage processes. Unlike iron (hydro) oxides, MnO$_2$ cannot activate H$_2$O$_2$ to generate HO•, but rather catalyzes the decomposition of H$_2$O$_2$ via a two-electron transfer reaction (Eq. 5)$.^57$ Therefore, the HO• enhancement is likely caused by the MnO$_2$/Goe synergy. As we observed how leaching of Mn$^{2+}$ and the acidic environment prohibited the cycling of reduced Mn$^{2+}$ back to MnO$_2$, we anticipated that the Mn$^{2+}$ accumulation near the interface could potentially reduce the number of Fe(III) sites for promoting HO• generation due to the proximity of the two redox couples (Mn$^{3+}$/Mn$^{2+} = 0.9$–1.5 V, goethite/Fe(II) = −1.0 V at pH = 1) (Eq. 4)$.^54$ Such Mn$^{2+}$ effect was then surveyed by the pyrophosphate (P$_2$O$_7^{4−}$) complexing experiment. The presence of P$_2$O$_7^{4−}$ ligand traps Mn$^{2+}$ and prevents redox shuttling to goethite, which in turn greatly inhibits the conversion of DHA at 10 mM P$_2$O$_7^{4−}$ (Supplementary Fig. 16a)$^{55,56}$. Consistently, when Mn$^{2+}$ ions were directly added to the pure goethite system, an activity increase was also observed (Supplementary Fig. 16b). Such redox cycle effect was also supported by the higher fraction of Fe(II) in the Fe $2p_{3/2}$ XPS for MnO$_2$/Goe (Supplementary Fig. 16c and Supplementary Table 7).

During the Mn$^{2+}$-promoted reduction of Fe(III), the generated Mn$^{3+}$ returns to MnO$_2$ via rapid disproportionation under the strongly acidic condition (Eq. 5)$^{57}$, which was further verified by Auger mapping. As shown in Fig. 4e, Mn signals appeared on the surface of goethite and were distributed along the rod-like structure after the reaction compared to the fresh MnO$_2$/Goe catalyst, which indicates that the Mn$^{2+}$ oxidation and the following Mn$^{3+}$ disproportionation had occurred on the goethite surface, forming MnO$_2$ particles via Eqs. 4, 5$^{55}$. Based on these results, we proposed the mechanism for the HO• generation catalyzed by the MnO$_2$/Goe catalyst (Fig. 4f). The reductively
released Mn$^{2+}$ reacts with Fe(III) sites on the goethite surface to form Fe(II) sites. The formed Fe(II) sites can activate H$_2$O$_2$ via a single-electron transfer pathway to produce HO$^-$ that cleave the C–C bonds of DHA (Eq. 6). Simultaneously, Mn$^{2+}$ is oxidized to Mn$^{3+}$ and then disproportionates back into MnO$_2$ to recycle the catalyst.

\[

\]

Regulating the -CH$_2$OH transformation to FA. To explore the chain propagation induced by the C–C cleavage, we first investigated the kinetics of GA and FA formation on the MnO$_2$/Goe catalyst (Fig. 5a). The selectivity of GA remained essentially unchanged and only slightly decreased after 12 h due to the possible consecutive oxidation of GA. Notably, the selectivity of FA was relatively low at the early stage but exhibited an unusual trend of higher selectivity under longer reaction time. These results are consistent with the evolution of -CH$_2$OH species (Eq. 7), impelling us to investigate their reaction pathway.

\[
\text{CH}_2\text{OHCOH}_2\text{OH} + \text{HO}^{-} \rightarrow \text{CH}_2\text{OHCOOH} + \text{-CH}_2\text{OH} \\
\]

As a radical, -CH$_2$OH can inevitably self-couple to form ethylene glycol. In our system, only traces of ethylene glycol were detected with very small production values (<0.1% DHA conversion) (Supplementary Fig. 18), indicating that the self-coupling of -CH$_2$OH radicals is not kinetically dominant. Alternatively, in the HO$^-$-enriched Fenton system, -CH$_2$OH radicals can first combine with HO$^-$ to form hydrated formaldehyde (CH$_2$OH$_2$OH) (Eq. 8) and then be oxidized to -CH(OH)$_2$ radicals and FA (Eqs. 9–11) [58]. The schematic diagram based on elementary reactions provided a clear stoichiometric analysis (Fig. 5b), which turned out that converting 1 mole of DHA to FA via the HO$^-$-enriched pathway requires 4 or 6 equivalents of H$_2$O$_2$. However, in our system, only 2 equivalents of H$_2$O$_2$ were added, indicating that other species rather than HO$^-$ should act as the oxidant of -CH$_2$OH radicals. In addition to HO$^-$, O$_2$ generated through H$_2$O$_2$ decomposition (Eq. 5) may also react with -CH$_2$OH radicals as another oxygen source.

Hydroxymethyl peroxy radicals (-OOC$_2$OH, HMOO) can be generated under oxygen-rich environment (Eq. 12) and can subsequently undergo decomposition to form FA (Eq. 13) [59,60]. The stoichiometric analysis of this process in Fig. 5b suggests that the conversion of 1 mole of DHA to FA only requires 1.5 molar equivalents of H$_2$O$_2$, much lower than that of the non-HMOO pathway.

\[
\text{-CH}_2\text{OH} + \text{HO}^{-} \rightarrow \text{CH}_2\text{OH}_2\text{OH} \\

\text{-CH}_2\text{OH} + \text{H}_2\text{O} \rightarrow \text{HOCH}_2\text{OOH} \\
\text{2HOCH}_2\text{OOH} \rightarrow \text{[HOCH}_2\text{OO} - \text{OOC}_2\text{OH}] \rightarrow \text{2CHOOH} + \text{H}_2\text{O}_2 \\
\]

Due to the catalase-like activity of MnO$_2$, we discovered that the dissolved oxygen concentration was significantly higher in our MnO$_2$/Goe system than in the pure Goe system (Supplementary Fig. 19), especially in the first few hours (31.8 ppm vs. 11.0 ppm). When we continuously bubbled N$_2$ to remove dissolved oxygen during the reaction, the FA yield remarkably decreased (Fig. 6a), while the DHA conversion and GA yield were only slightly inhibited. Correspondingly, for the pure goethite system under O$_2$ pressure, the FA yield increased significantly with increasing O$_2$ pressure (Supplementary Fig. 20). These results suggested that O$_2$ greatly contributed to the FA production as a reactant, implying the dominance of the HMOO path during -CH$_2$OH conversion. Since the presence of various radicals in the system hindered the identification of HMOO radicals, we designed $^{18}$O isotope experiments to validate their presence in our MnO$_2$/Goe system. Once $^{18}$O$_2$ molecules react with -CH$_2$OH radicals, $^{18}$O-labeled FA (HC$_{18}$O$_2$OH, m/z = 47) should be generated, while only HC$^{16}$O$_2$H (m/z = 45) should be generated otherwise (Supplementary Fig. 21). As shown in Fig. 6b, the relative abundance of detected $^{18}$O-labeled FA and its fragments is enhanced by bubbling $^{18}$O$_2$ into the reaction solution, confirming the existence of HMOO and its contribution to FA formation. These results indicate that the HMOO pathway provides an easily-accessed route to fix and utilize the O$_2$ without involving the difficult O–O activation by spin inversion [61].

Unlike short-lived HO$^-$ radicals ($t_{1/2} = 10^{-9}$ s), HMOO radicals have longer life-time ($t_{1/2} = 7 \times 10^{-3}$ s) and tend to self-couple or couple with HOO$^-$ to form stable intermediates at low pHs [60,62]. As shown in Fig. 6c, Operando ATR-IR spectra provided insight
into the generation and decomposition of products and intermediates of the DHA oxidation, particularly for ·CH2OH conversion. The bands at 1724 and 1704 cm$^{-1}$ are assigned to the $\nu$(C=O) vibration region of GA and FA (Fig. 6d)$^{13}$, and the evolution of the FA vibration band significantly lagged behind that of GA. Although the organic peroxidic vibration region (700–900 cm$^{-1}$) was more disturbed by the O–H vibration of goethite, two weak bands at ~750 and ~850 cm$^{-1}$ could still be observed during 4 h to 12 h, demonstrating the presence of peroxidic intermediates at this stage$^{63}$. Correspondingly, it was found that about 30% of C1 products (FA, formaldehyde and hydrated formaldehyde) were lost during the first 2 h in our MnO$_2$/Goe system. While this amount gradually decreased to close to zero after 12 h (Supplementary Fig. 22), the loss of unknown products might be attributed to the coupling intermediates of HMOO.

We further compared the kinetics of the HMOO and non-HMOO pathways (Supplementary Table 8). The persistent HMOO radicals and their coupling peroxidic intermediates confirmed the domination of the O$_2$-rich step described in Eq.12, which reflects the slower kinetics of the HMOO pathway than that of the non-HMOO pathway. The slow transformation of ·CH$_2$OH radicals to FA in the MnO$_2$/Goe system bypasses the early-stage Fenton-like activity to avoid the excessive oxidation of FA. In addition, due to the continuous accumulation of FA, the pH of our MnO$_2$/Goe system was maintained at a low range (0.9–1.6) throughout the reaction compared to that of the Cu/Al$_2$O$_3$ system (1.3–2.2) with low FA yield (Fig. 6e). The pH of the systems significantly affected the degree of protonation/deprotonation of FA, which changed the intrinsic rate constant of HO· with FA ($k_{\text{HCO}_2\text{H}:\text{HO}} = 3.2 \times 10^8$ M$^{-1}$s$^{-1}$ vs. $k_{\text{HCO}_2\text{H}:\text{HO}} = 1.3 \times 10^8$ M$^{-1}$s$^{-1}$)$^{64}$. We calculated the ratio of protonated/deprotonated FA in the two systems and further determined the average intrinsic rate constants. The reaction rate in our MnO$_2$/Goe system was always lower than that in the Cu/Al$_2$O$_3$ system; specifically, it was lower than one-fourth ($2.0 \times 10^8$ M$^{-1}$s$^{-1}$ vs. $8.7 \times 10^8$ M$^{-1}$s$^{-1}$) in the early stage, which—in turn—greatly inhibited FA degradation (Fig. 6f). Based on these, a schematic comparison of the non-HMOO/HMOO pathways is shown in Fig. 7. Although the formed FA is inevitably degraded by HO· attack, the process is kinetically determined by two factors: the HO· concentration and the intrinsic rate constant of HO· with FA (Eq. 14). FA was rapidly generated but deeply oxidized in the early stage of the reaction under HO·-enriched environment. In contrast, the transformation of ·CH$_2$OH to FA mediated by HMOO is a slow process, and, at low pH, is accompanied by the gradual release of FA to reduce the average intrinsic rate for FA oxidation. Consequently, this all together inhibits the FA

**Fig. 6 FA formation investigations.** a Effect of bubbling N$_2$ on the activity of MnO$_2$/Goe catalyst. Error bars represent standard deviations from triplicate experiments. b MS signals of FA and its fragments during conversion of DHA with/without bubbling $^{18}$O$_2$. c d Operando ATR-FTIR spectra during conversion of DHA in D$_2$O and the corresponding carbonyl bond and organic peroxide bond vibration regions. e f Variation in pH during the reaction process using 1%-MnO$_2$/Goe and Cu/Al$_2$O$_3$ catalysts and the corresponding protonated/unprotonated FA ratio with the change of pH value and the calculated average intrinsic rate constants of FA with HO·. The calculation of the ratio and average intrinsic rate constants were described in SI. The preparation and reaction conditions of Cu/Al$_2$O$_3$ were the same as that in the literature$^{13}$. 

### Table 8: Protonated Unprotonated FA ratio (%)

| pH | HCOOH or HCOO- ratio (%) |
|----|--------------------------|
| 0  | 100                      |
| 0.9 | 90                       |
| 1.3 | 80                       |
| 1.6 | 70                       |

### Equation 12

$$\text{FA} \rightarrow \text{HCOOH} + \text{HCOO}^-$$

### Equation 14

$$k_{\text{HCO}_2\text{H}:\text{HO}} = 3.2 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$$

degradation kinetics and regulates the CH₂OH transformation toward high FA selectivity.

\[-\frac{d[FA]}{dt} = k_{\text{ins}} \times [\text{HO}^\cdot] \times [FA] \quad (14)\]

Discussion

Heterogeneous Fenton chemistry has shown increasing promise in industrial oxidation processes targeting high selectivity. However, one of the major obstacles for Fenton-based chemicals production is inefficient HO· generation. Inspired by natural goethite, we have successfully developed mimic MnO₂/Goe catalyst via simple mechanical mixing for the co-production of GA and FA from DHA. The reactions proceed efficiently and selectively under room temperature and atmospheric pressure, with high carbon atom efficiency and high H₂O₂ utilization. EPR studied HO· generation kinetic and AEM images indicated that the incorporation of separate β-MnO₂ phase can readily induce the acceleration of the Fe(III)/Fe(II) cycle on goethite surface to activate H₂O₂, which provides a tractable strategy for promoting Fenton-like activity without relying on sophisticated regulation in Fe active sites at the atomic level.

Understanding and regulating the evolution intermediates and radical is a more demanding challenge, which has rarely been achieved in heterogeneous catalysis. In this contribution, the stoichiometric analysis and kinetic experiments supported the switch of elemental steps towards FA formation with high H₂O₂ utilization efficiency, implying the contribution of the released O₂ catalyzed by MnO₂. Further, 18O isotopic labeling experiments and operando IR measurements confirmed the presence of hydroxymethyl peroxide (HMOO) radical that is an important indicator species for the proposed pathway and formed over O₂-rich environment. These characterization and mechanistic studies depict an overall scenario of the C−C cleavage of DHA and the conversion from generated CH₂OH radicals to FA, which demonstrates that—at least for HO−dominated C−C cleavage—O₂ can directly react with radical intermediates as a key oxygen donor to change the resulting product distribution.

In summary, this work not only develops a MnO₂/Goe catalyst that can selectively oxidize DHA to co-produce GA/FA in excellent carbon/oxygen efficiency, but also provides a typical example of how to control the radical pathway during C−C cleavage. This system exhibits general feasibility for other biomass-based platforms although the detailed reaction mechanism needs to be elucidated, which highlights the great potential of Fenton chemistry as a powerful tool for the C−C cleavage and reveals an alternative route for the synthesis of various fine chemicals. It can also serve as a starting point for further studies on the interfacial reaction mechanism of radical-mediated C−C activation.

Methods

Chemicals and reagents. Fe(NO₃)₃·9H₂O, Mn(NO₃)₂·4H₂O, sodium bicarbonate (NaHCO₃), and NaOH were purchased from Aladdin Chemical Inc. (Shanghai, China). DHA, GA, and FA, and 30 wt% H₂O₂ were obtained from Shanghai Titan Scientific Co., Ltd. (Shanghai, China). 18O (97 atom%) was purchased from Beijing InnoChem Scientific Co., Ltd. (Beijing, China). DMPO was purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). The chemicals used to synthesize goethite (α-FeOOH) are ACS grade and other chemicals are analytical grade. All chemicals were used without further purification. Milli-Q water was used throughout this study.

Iron and manganese-containing minerals. Goethite, hematite (α-Fe₂O₃), magnetite (Fe₃O₄) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Lepidocrocite (γ-FeOOH) was purchased from Alfa-Aesar (Haverhill, MA, USA). Hausmannite (Mn₃O₄) and pyrolusite (β-MnO₂) were purchased from Shanghai Macklin Biochemical Co., Ltd. (Shanghai, China). Micronodors, nanorods, Mn-doped goethite, and jacsite (MnFe₂O₄) were synthesized according to procedures previously described (Supplementary Methods). Pyrite used in the study was obtained by directly mining from the commercial pyrite deposits located in Lin-cang County, Yunnan Province, China. Mn-rich mineral used in the study was obtained by directly mining from the commercial Mn oxides deposits located in Shijiazhuang City, Hebei Province, China, and has been identified as consisting of SiO₂ and three Mn-containing phases (Todorokite, Groutite, and Birnesite) (Supplementary Fig. 23), but also contains a small amount of Fe (7.4 wt%). Two natural goethite minerals used in the study were obtained by directly mining from the commercial massive sulfide lead-zinc deposits located in Chenzhou (CZ) County, Hunan Province, China, and Wenshan (WS) County, Yunnan Province, China, were labeled as Goe-CZ and Goe-WS, respectively, in which they were both formed in the unsaturated oxidation zone of the deposits as the secondary mineral phases prepared by mechanical and chemical methods using a tube roller mixer (MSK-MIX-T8, HF-Kejing, China) under the scroll mode (30 rpm) for 1 h. The commercially available goethite (30−50 mesh), natural goethite (>10 cm), and natural pyrite (1−5 cm) were ground and sieved manually to above 200 mesh for the activity test, while other catalyst powders (>200 mesh) were directly used in the reaction. The structural information of all Fe/Mn-containing minerals is listed in Supplementary Table 9.

Characterization methods. The morphology of the catalyst was characterized by scanning electron microscopy (SEM, ZEISS GeminiSEM 500, German). The manganese distribution in natural goethite was identified using electron probe micro analyzer (EPMA, JEOL JXA-8530F, Japan) and transmission electron microscopy (TEM, Thermo Scientific Tals F200X, USA) equipped with high angle annular dark field (HAADF) and energy dispersive X-ray (EDX) analysis detectors. X-ray diffraction (XRD) patterns were collected on a Bruker D8 advance X-ray diffractometer (Bruker, USA) with a Cu Kα radiation (=1.5406 Å). The BET surface area was measured by N₂ adsorption isotherms at 77 K using ASAP 2020 automated surface area analyzer (Micrometrics, USA). X-ray photoelectron spectroscopy (XPS) was collected on an ESCALAB 250Xi spectrometer (Thermo Scientific, USA) with a monochromatic Al Kα source (1486.6 eV, passing energy 20 eV), and all binding energies were calibrated with the C 1 s peak at 284.8 eV. Scanning Auger mapping (SAM) analysis was carried out using a PHI-710 Auger microprobe (Physical Electronics, Inc., USA). Operando infrared absorption spectroscopy in the attenuated total reflection mode (ATR-IR) was collected on a ReactIR15 IR spectrometer (Mettler Toledo, USA). The formation of free radicals was examined by electron paramagnetic resonance spectroscopy (EPR, Bruker ELEXYS 500-10/12, USA) using DMPO as a spin trap agent. The detailed ATR-IR measurements and DMPO-trapping procedures are described in Supplementary Methods.

Computational methods. All computational procedure was carried out using Gaussian 09 and Gaussian view 6.0 programs (99). The optimization structure and electrostatic potential calculation of DHA have been performed using the B3LYP functional and the 6−31 g* basis set.

Selective C−C bond cleavage of DHA. The selective C−C bond cleavage of DHA was studied by batch experiments. In a typical experiment, 30.0 μmol iron (hydrd oxide, 1.0 mmol DHA, and 2 mmol H₂O₂ (30 wt% H₂O₂ aqueous solution) were added to a 5 mL glass reactor and reacted under a stirring speed of 400 rpm at 25 °C for 24 h. For the N₂/18O₂ bubbling experiment, the glass reactor was replaced with a modified HPLC sample vial containing a micro insert tube (300 μL) to reduce the FA loss and total evaporation loss. At a set time interval, the suspension sample was withdrawn and immediately filtered (0.22 μm PES) to remove the solids. The concentrations of DHA, GA, and FA were analyzed using a high-performance liquid chromatography (HPLC, Waters 2695, USA) equipped with a diode array detector (DAD, Waters 2996, USA). The total concentrations of formaldehyde and hydrated formaldehyde (methanal) were analyzed by HPLC after 2,4-dinitrophenylhydrazone (2,4-DNPH) derivatization (100). H₂O₂ concentration was analyzed spectrophoto metrically using the titanium sulfate method (101). The amount of generated CO₂ was determined by GC-MS (Agilent 7890B, USA) with...
N₂ in air as an internal standard. Dissolved oxygen (DO) was determined by a DO meter (INESA JPB-667A, China) in an enlarged system (10 mmol DHA, reaction solution volume of ~2 mL) due to the large size of the electrode head (1 cm in diameter). During the test, the DO electrode was first immersed 0.5 cm below the surface of the solution, and then the DO value was recorded after 30 s of stabilization. The relative abundance of FA, H₂O₂-labeled FA, and their fragments were detected by gas chromatography–mass spectrometry (GC-MS, Shimadzu GCMS-QP2010Plus, Japan) with DR-FFAP column. The concentration of HO₂ was quantified by a chemical probe method using formic acid as the probe molecule[36]. More details are presented in Supplementary Methods.

**Reusability of MnO₂/GOe catalyst.** The catalyst after reaction were filtered using 0.22 μm PES membrane, washed with deionized water and dried overnight at 60 °C in a vacuum oven for the next use. To offset the unavoidable catalyst mass loss during the recovery (~20–40% for each run), we performed 10 sets of parallel experiments at the first cycle to recover enough catalyst for subsequent cycles. The leaching percent is defined as the molar ratio between the loss of metal and initially, added metal component.

**Scale-up of catalytic processes.** For the continuous activity test, the reaction was carried out in a double-jacket tubular packed bed having dimensions of 100 × 1.5 cm (height × diameter) (Supplementary Fig. 24), with the up-flow rate of liquid through the packed layer of particles (mixture of 16 mesh silicon carbide with 2.0 g 1%–MnO₂/GOe catalyst). The mixture of 1 mmol DHA in 2 mmol H₂O₂ aqueous solution diluted to 10 wt% was pumped to the packed bed with a flow rate of 0.15 mL/min (360 mmol DHA/day) and the reaction temperature was maintained at 25 °C. The batch reaction was scaled up 2500 times in equal condition of the original system and was carried out in a 1 L double-jacket kettle (catalyst 75 mol, DHA 2.5 mol, 500 mL 30 wt% H₂O₂ aqueous, 25 °C, 400 rpm, 24 h) (Supplementary Fig. 25).
