Coherent States for 3d Deformed Special Relativity: 
semi-classical points in a quantum flat spacetime

ABSTRACT

We analyse the quantum geometry of 3-dimensional deformed special relativity (DSR) and the notion of spacetime points in such a context, identified with coherent states that minimize the uncertainty relations among spacetime coordinates operators. We construct this system of coherent states in both the Riemannian and Lorentzian case, and study their properties and their geometric interpretation.

I. INTRODUCTION

Motivated mainly by the possibility of Quantum Gravity phenomenology [1], Deformed (or Doubly) Special Relativity [2] has emerged recently as a possible description of the kinematics of Quantum Gravity, in the flat space approximation. The precise relation with the full theory, still to be constructed, is not yet fully understood [3]; however, in the 3d case solid arguments have been obtained for this to be the case [4, 5], and even a rigorous derivation of some characterizing DSR features from a specific quantum gravity model has been obtained [6], and in the 4d case, although the situation is much less clear, interesting arguments have been found [5, 7], confirming the reasons for the current interest in this model.

The basic motivation for constructing such a model is the attempt to incorporate the presence of a non-zero invariant minimal length (thought of as a remnant at the kinematical level of the underlying quantum gravity theory, and therefore usually identified with the Planck length) into the kinematical setting of Special Relativity, where the other invariant quantity, the speed of light, is present. The outcome of this deformation of Special Relativity to accommodate two invariant scales is first of all a modification of the symmetry group of the theory, that becomes the \( \kappa \)-Poincaré group [16], and a consequent modification of dispersion relations for moving particles, of reaction thresholds of scattering processes, and a vast arena of new possibilities for testing quantum gravity models [8].

A deformed symmetry group for spacetime can be equivalently seen [9] as a non trivial metric on momentum space, that becomes curved and, more precisely, in the DSR case endowed with a De Sitter (or Anti-DeSitter) geometry. This has important consequences for the geometry of spacetime. Defining spacetime “coordinates” \( X_\mu \) as Lie derivatives over this curved momentum space, in other words “by duality” with respect to momenta, they turn out to be non-commutative, being defined (at least in one particular choice of basis [10]) by the Cartan decomposition of the de Sitter algebra into its Lorentz subalgebra and the remnant (the spacetime coordinates themselves). Also, they have a non-trivial action on momentum space, characterized by a deformation parameter \( \kappa = 1/l_p \), where \( l_p \) is the Planck length, i.e. the same deformation parameter appearing in the \( \kappa \)-Poincaré algebra. Spacetime acquires then, also in this approximately flat effective description, a quantum nature, and its geometry must be dealt with accordingly. Indeed, the quantities \( X_\mu \) are quantum operators, first of all, and their representations must be studied in order to study the properties of spacetime in this model, and are best understood not as “coordinates” but as basic distance operators in spacetime (with respect to a given origin), due also to their transformation properties under Lorentz transformations (they transform as 4-vectors). The study of their properties (eigenstates, spectra, etc), and more generally of the quantum spacetime geometry of DSR, has been started in [11], using tools from the representation theory of the Lorentz group in various dimensions. Another issue that was discussed in [11] is the notion of “spacetime point” in a quantum spacetime, with its quantum nature reflected in the non-commutativity of the distance operators \( X_\mu \) that we would use to localize points. The best definition available of a spacetime point in this quantum setting is that of a coherent state in the Hilbert space of quantum states of geometry, being the representation space of the distance operators \( X_\mu \), which minimizes the uncertainty in all the \( X_\mu \) themselves. Indeed, we take this as a definition of a ‘point’ in a quantum spacetime.

In general one would expect a minimal simultaneous uncertainty, i.e. an uncertainty in the measurement of several spacetime coordinate, as for measuring a spacetime distance \( l \), of the form:

\[
\delta l \geq l_p \times \left( \frac{l}{l_p} \right)^\alpha
\]

with \( \alpha = 1/2 \) in 3d and \( \alpha = 1/3 \) in 4d assuming the validity of the holographic principle, or \( \alpha = 1/3 \) in 3d and \( \alpha = 1/4 \) in 4d, not making this assumption (the argument for this was reviewed in [11]).

The exact form of the uncertainty relations is basis dependent in DSR, i.e. it depends on the precise definition of the \( X_\mu \) operators [12] one chooses. In the so-called \( \kappa \)-Minkowski basis, in which the \( X_\mu \) form a Lie algebra, the notion of coherent state and minimal uncertainty is straightforward to implement and was indeed obtained in [11]; however, in this basis the interpretation of the \( X_\mu \) as distance operators is not immediate and the geometric meaning of the is more obscure. On the other hand, in the Snyder basis, to which we were referring above, obtained by Cartan decomposition, this interpretation is clear, but the construction of coherent states, i.e. the identification of what is a spacetime point, is more technically involved and the framework of generalized coherent states on Lie groups [13] has to be used.

The procedure for constructing a system of coherent states is (briefly) the following: given a Lie Group \( G \) and a representation \( T \) of it acting on the Hilbert space \( \mathcal{H} \), with a fixed vector \( |\Psi_0\rangle \) in it, the system of states \( \{ |\Psi_g\rangle = T(g) |\Psi_0\rangle \} \)
is a system of coherent states. The point is then to identify which are the states $\Psi_0$ that are closest to classical, in the sense that they minimize the invariant dispersion or variance $\Delta = \Delta C = \langle \Psi_0 | C | \Psi_0 \rangle - g^{ij} \langle \Psi_0 | X_i | \Psi_0 \rangle \langle \Psi_0 | X_j | \Psi_0 \rangle$, where $C = g^{ij} X_i X_j$ is the invariant quadratic Casimir of the group $G$. The general requirement is the following: call $g$ the algebra of $G$, $g^c$ its complexification, $\mathfrak{b}$ the isotropy subalgebra of the state $|\Psi_0\rangle$, i.e. the set of elements $b$ in $g^c$ such that $T_b |\Psi_0\rangle = \lambda_b |\Psi_0\rangle$, with $\lambda_b$ a complex number, and $\mathfrak{b}$ the subalgebra of $g^c$ conjugate to $\mathfrak{b}$; then the state $|\Psi_0\rangle$ is closest to the classical states if it is most symmetrical, that is if $b \oplus b = g^c$, i.e. if the isotropy subalgebra $\mathfrak{b}$ is maximal.

In this paper, we tackle exactly the problem of defining points in a quantum spacetime with the formalism of coherent states using these general techniques. In the first part of the paper we construct coherent states minimizing the spacetime uncertainty relations (thus representing semi-classical points) for 3d DSR, first in the Euclidean setting and then in the Minkowskian one, our construction being based on the fact that the momentum space in 3d DSR is given by the SU(2) group manifold in the Minkowskian, that gives similar results and represents in a slightly simplified context the same construction that one would perform for 4d DSR. We confine ourselves to the 3-dimensional case purely for greater simplicity of the relevant calculations, which become much more involved in higher dimensions; however we stress that no major conceptual or technical difference is expected in the more realistic case of 4 spacetime dimensions, or in higher ones for what matters; these cases can be in principle handled using the same tools and with the same procedure.

II. COHERENT STATES: THE EUCLIDEAN 3D SPACE

In 3d deformed special relativity (DSR), the momentum space $\mathcal{M}$ is simply the group manifold SU(2). The Hilbert space of wave functions (say, for a point particle living in the DSR spacetime) in the momentum polarization is then the space of $L^2$ functions over SU(2) equipped with the Haar measure: $\mathcal{H} = L^2(\text{SU}(2), dg)$. In the framework of spin foam quantization, it has been shown that this curved momentum space structure can be derived directly from 3d (Riemannian) quantum gravity coupled to matter [6]. More precisely, the effective theory describing the matter propagation, after integration over the gravity degrees of freedom, is a DSR theory invariant under a $\kappa$-deformation of the Poincaré algebra, where the deformation parameter $\kappa$ is simply related to the Newton constant for gravity and therefore to the Planck length.

In this context, the curved momentum space naturally leads to a deformation of the rule of addition of momenta. Indeed the addition of momenta will not be the simple $\mathbb{R}^3$ addition anymore, but will be defined by the multiplication on the SU(2) group. More technically, the standard convention is to define the 3-momentum $\vec{p}$ from the SU(2) group element as follow:

$$g(\vec{p}) \equiv \sqrt{1 - \frac{\vec{p}^2}{\kappa^2}} \text{Id} + i \frac{\vec{p}}{\kappa} \vec{\sigma},$$

(2)

where $\vec{\sigma}$ are the usual Pauli matrices and $\kappa$ the Planck mass. Then the deformed addition of momenta $\oplus$ is given by:

$$g(\vec{p}_1 \oplus \vec{p}_2) \equiv g(\vec{p}_1) g(\vec{p}_2),$$

(3)

or more explicitly:

$$\vec{p}_1 \oplus \vec{p}_2 = \vec{p}_1 \sqrt{1 - \frac{\vec{p}_1^2}{\kappa^2}} + \vec{p}_2 \sqrt{1 - \frac{\vec{p}_2^2}{\kappa^2}} - \frac{1}{\kappa} \vec{p}_1 \wedge \vec{p}_2.$$ 

This leads to a deformation of the law of conservation of energy-momentum, which is interpreted as due to the gravitational interaction.

In the present work, we are interested by the dual structure to the momentum space, and we would like to describe the space-(time) structure of the 3d DSR theory. Given the SU(2) group structure of momentum space, there is a preferred choice for the coordinates, that in a sense combines the virtues of the Snyder basis and of the $\kappa$-Minkowski basis for 4d DSR. The coordinates $X_i$ are now operators acting on the Hilbert space $\mathcal{H}$ and more precisely, they are the translation operators on the group manifold SU(2), as in the Snyder basis: $X_i \equiv l_x J_i$, are the standard $\mathfrak{su}(2)$ algebra
generators, which are represented by the Pauli matrices $\sigma^i$ in the fundamental two-dimensional representation, and $l_P = \hbar/\kappa$ is the 3d Planck length.

The spacetime coordinates are now non-commutative:

$$[X_i, X_j] = il_P \epsilon_{ijk} X_k,$$

and obviously form a Lie algebra, just as in the $\kappa$-Minkowski basis of 4d DSR, and also the bracket between positions and momenta is deformed:

$$[X_i, p_j] = -i\hbar \sqrt{1 - \frac{p^2}{\kappa^2}} \delta_{ij} + il_P \epsilon_{ijk} p_k.$$

The (squared) spacetime length operator $L^2 \equiv X_i X_i$ is actually the Casimir operator of SU(2). It is invariant under SU(2) and commutes with the coordinates $X_i$. Its spectrum is of course $l_P^2 \times j(j + 1)$, with $j \in \mathbb{Z}$, while the spectrum of the $X_i$ coordinate operators is simply $l_P \mathbb{Z}$. This way, one can view this non-commutative spacetime as implementing a minimal length $l_P$ and a discrete structure of spacetime. Note also that this quantum spacetime structure is analogous to the one discovered in 3d loop quantum gravity and spin foam models, and was indeed studied as a simplified version of it, with its Lorentz invariance analysed in detail, in [11].

Because the spacetime coordinates do not commute with each other anymore, we can not simultaneously diagonalize the $X_i$’s and localize the three coordinates of a point/particle perfectly at the same time. So we face the issue of how to define a point. In order to be able to talk about a spacetime point, as it was proposed in [11], we need to introduce coherent states minimizing the uncertainty in the $X_i$’s, which will define a notion of semi-classical points in a non-commutative geometry. Actually, coherent states for Lie groups, and especially SU(2), are well-known and we will review the material presented by Perelomov [13] from our own perspective; coherent states for the algebra generated by the $X_i$ operators, named “the fuzzy sphere” and considered as a paradigmatic example of a non-commutative spacetime, were constructed using a different approach in [14].

A. A first length uncertainty estimate

Starting with the $su(2)$ algebra $[X_i, X_j] = il_P \epsilon_{ijk} X_k$, we get the following uncertainty relations for $i \neq j$:

$$(\delta X_i)^2(\delta X_j)^2 \geq \frac{l_P^2}{4}(\epsilon_{ijk} X_k)^2.$$  

(6)

Summing all these uncertainty relations over $i$ and $j$ (possibly equal), we obtain$^1$:

$$(\delta l)^4 \geq 2\frac{l_P^2}{4} l^2 + \sum_i (\delta X_i)^4 \geq \frac{l_P^2}{4} 2l^2,$$

where we have introduced the distance $l^2 \equiv \sum_i (X_i)^2$ and the uncertainty $(\delta l)^2 \equiv \sum_i (\delta X_i)^2$. Finally, we have derived the following uncertainty relation:

$$(\delta l)^2 \geq \frac{1}{\sqrt{2}} l_P l.$$  

(7)

This provides us with a first bound on the uncertainty, which suggests a generic feature of the localization of spacetime points: we can not localize a space point at a distance $L$ from us with an uncertainty smaller than of the order of $\sqrt{l_P} L$. Actually, computing the uncertainty exactly over the quantum states, we will find in the following that the true minimal spread is simply $(\delta L)^2 \geq l_P L$. This is simply due to the term $\sum_i (\delta X_i)^4 > 0$.

$^1$ We would like to thank Laurent Freidel for pointing out this simple fact to us.
B. SU(2) coherent states and the minimal uncertainty

States diagonalizing $Z \equiv X_3$ are the usual $|j, m\rangle$, where $j$ is the spin label and $m$ the angular momentum projection over the $X_3$ direction. It is easy to check the expectation values of the coordinate operators on such states:

$$
\langle X_1 \rangle_{j,m} = \langle X_2 \rangle_{j,m} = 0, \quad \langle X_3 \rangle_{j,m} = ml_p.
$$

(8)

Therefore such states correspond geometrically to points located along the $X_3$ axis at (non-invariant) distance $lp|m|$. The spread of the state or its uncertainty (which determines the precision of its localization) is defined as:

$$
\delta L = \sqrt{\langle X_i X_i \rangle - \langle X_i \rangle \langle X_i \rangle}.
$$

(9)

Then we easily compute:

$$
(\delta L)_{j,m} = lp \sqrt{j(j+1) - m^2},
$$

(10)

which is minimal for $m = j$ (and for $m = -j$). In other words, the maximal (or minimal) weight states $|j, j\rangle$ (or $|j, -j\rangle$) are the coherent states for SU(2) minimizing the uncertainties in the positions and thus are the semi-classical states for 3d Euclidean DSR, i.e. the best definition of spacetime points in the corresponding quantum spacetime. Of course, these correspond to “some” of the points of this quantum spacetime, those at the location mentioned above. On such states, we have:

$$
\langle L \rangle = \sqrt{\langle X_i X_i \rangle} = lp \sqrt{j(j+1)}, \quad \text{and} \quad \delta L = lp \sqrt{j} = lp \left( \sqrt{\frac{L^2}{l_p^2} + \frac{1}{4} - \frac{1}{2}} \right),
$$

which confirms the fact that these quantum points are approximately localized at a spacetime distance $lp|j|$ from the origin, i.e. from the location of the observer, and we derive the relation for large distance$^2$:

$$
\delta L \sim \sqrt{Ll_p}.
$$

(11)

This relation is exactly the one expected from the holographic principle in 3d, as mentioned in the introduction. We stress that the uncertainty is actually substantially larger than the Planck length $l_p$, as expected from several arguments about quantum measurements in the context of general relativity [19].

Now we want to define all the other points of our quantum spacetime, i.e. construct all the other coherent states minimizing the spacetime uncertainty relations, following the Perelomov construction, according to which the full coherent states system is obtained from the vector invariant under the maximal subalgebra by the action of a group transformation. More technically, we define the (coherent) states:

$$
|j, \hat{n} \rangle \in S^2 \equiv e^{\alpha J_+ - \bar{\alpha} J_-} |j, j\rangle = \sum_{m=-j}^{+j} \frac{(2j)!}{(j+m)!(j-m)!} \frac{1}{(1 + |z|^2)^{j-m}} |j, m\rangle,
$$

(12)

with the following notations:

$$
\hat{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta), \quad \alpha = \frac{\theta}{2} e^{-i\phi}, \quad z = \tan \frac{\theta}{2} e^{-i\phi}.
$$

$^2$ We could have defined the average distance from the origin through Pythagoras formula as $\langle L \rangle = \sqrt{\langle X_i \rangle \langle X_i \rangle}$ which would lead to $\langle L \rangle = j lp$. In this case, the relation between the distance and the uncertainty simplifies to:

$$
\delta L = lp \sqrt{j} = \sqrt{L l_p},
$$

and we recover exactly the bound set by the holographic principle.
Using the explicit expression, one can check that:

\[ \langle X_1 \rangle_{j, \hat{n}} = 2j \frac{\text{Re}(z)}{1 + |z|^2}, \quad \langle X_2 \rangle_{j, \hat{n}} = 2j \frac{\text{Im}(z)}{1 + |z|^2}, \quad \langle X_3 \rangle_{j, \hat{n}} = j \frac{1 - |z|^2}{1 + |z|^2}, \]

or more simply:

\[ \langle \hat{X} \rangle_{j, \hat{n}} = j \hat{n} l_P. \]  

(13)

This means that the above states corresponds to the points located at a distance \( l_P j \) in the direction \( \hat{n} \) from the origin, and the set of all these states spans the 2-sphere of radius \( l_P j \) centered in the origin. We can compute the overlap between two coherent states and we obtain:

\[ \langle j, \hat{n}_1 | j, \hat{n}_2 \rangle = e^{i\Phi(\hat{n}_1, \hat{n}_2)} \left( \frac{1 + \hat{n}_1 \cdot \hat{n}_2}{2} \right)^j, \]

(14)

where the phase is

\[ \Phi(\hat{n}_1, \hat{n}_2) = j A(\hat{n}_0, \hat{n}_1, \hat{n}_2) = \frac{j}{2l} \ln \left( \frac{1 + \alpha_1 \alpha_2}{1 + \alpha_1 \alpha_3} \right), \]

with \( A(\hat{n}_0, \hat{n}_1, \hat{n}_2) \) the area of the geodesic triangle on the sphere \( S^2 \) with vertices given by \( \hat{n}_0 = (0, 0, 1) \), \( \hat{n}_1 \) and \( \hat{n}_2 \).

These states are truly the SU(2) semiclassical coherent states, meaning that they saturate (minimize) the uncertainty relation

\[ (\delta X_1)(\delta X_2) \geq \frac{l_P}{2} \langle X_3 \rangle, \]

induced by the commutation relation \( [X_1, X_2] = il_P X_3 \), as well as the others obtained by cyclic permutations of these coordinate operators. And finally, they form a resolution of unity\(^3\):

\[ \frac{2j + 1}{4\pi} \int d^2\hat{n} \langle j, \hat{n} \rangle \langle j, \hat{n} \rangle = \text{Id}_j, \]

(15)

where \( \text{Id}_j \) is the identity on the Hilbert space \( \mathcal{H}_j \) of the spin-\( j \) representation (whose basis vectors are the \( |j, m\rangle \), \(-j \leq m \leq +j\)). This confirms (it is the algebraic characterization of this) that they exhaust all the points of the 2-sphere of radius \( l_P j \) around the origin of our quantum spacetime. From this one can prove that the set of all states of this form, for all values of \( j \), span the whole quantum spacetime under consideration; in other words, one can prove, using the Peter-Weyl measure for weighting each representation \( j \), that this system of coherent states provides us with a resolution of unity on the full Hilbert space \( \mathcal{H} \):

\[ \text{Id} = \frac{1}{4\pi} \sum_j (2j + 1) \int d^2\hat{n} \langle j, \hat{n} \rangle \langle j, \hat{n} \rangle. \]

This is actually a positive-operator-valued-measure (POVM). Indeed the projection operator \( |j, \hat{n}\rangle \langle j, \hat{n} | \) allows the simultaneous measurement of the three spacetime coordinates \( X_1, X_2, X_3 \), even though this measurement is not sharp since the states \( |j, \hat{n} \rangle \) have a non-vanishing overlap. These operators allow us to localize a spacetime point with an uncertainty \( \delta L \sim \sqrt{L} \) depending on the distance \( L \) to the origin. This gives a special role to the observer, who is located at the origin. We also note that a similar analysis of the (quantum) point structure of a non-commutative spacetime in terms of POVMs was performed by Toller in [15].

\[ ^3 \text{The measure on the sphere is given by:} \]

\[ d^2\hat{n} \equiv \sin d\theta d\phi = \frac{4d^2\theta}{(1 + |z|^2)^2}. \]
We would like to end this section on the remark that to go from one ‘point’ \(|j, \tilde{n}_1\) of our non-commutative spacetime to another point \(|j, \tilde{n}_2\), we actually simply do a SU(2) rotation \(g\), which takes \(\tilde{n}_1\) to \(\tilde{n}_2\) i.e. we use the position operators \(X_i = \lambda P J_i\) themselves to generate a spacetime translation. This let us move along the 2-sphere of radius \(\lambda P\). Nevertheless, we see that these special translations do not allow us to change the value of the distance \(j\) and to go from one state at \(j_1\) to another at \(j_2\): for this we would need the momentum operators \(p_i\). We discuss briefly below why the action of the momentum operators on these states is not easy to analyze.

Let us sum up the situation for this Euclidean 3d deformed special relativity. The momentum space is SU(2) and the Hilbert space \(\mathcal{H}\) of wave functions of the theory is \(L^2(\text{SU}(2))\). An orthogonal basis of \(\mathcal{H}\) is provided by the matrix elements of the group elements in all the representations of SU(2), we note them \(D_{ab}^j(g) ≡ \langle j, a|g|j, b\rangle\):

\[
\langle D^k_{cd}|D^j_{ab} \rangle ≡ \int dg D^j_{ab}(g)D^k_{cd}(g) = \frac{\delta_{jk}}{2j+1}\delta_{ac}\delta_{bd}.
\]

To normalize this states, we multiply them by a factor \(\sqrt{2j+1}\). Functions of the momentum \(g\) (or \(\vec{p}\)) acts by multiplication

\[
\varphi(\vec{p}).D^j_{ab}(g) ≡ \varphi(\vec{p}(g))D^j_{ab}(g),
\]

while the position operators \(\hat{X}\) act as derivations

\[
\hat{X}_i.D^j_{ab}(g) ≡ D^j_{ab}(\lambda \hat{p} J_i \cdot g) = \lambda \hat{p} \langle j, a|J_i g|j, b\rangle,
\]

or equivalently

\[
e^{i\vec{v} \cdot \hat{X}}.D^j_{ab}(g) ≡ D^j_{ab}(e^{i\lambda \hat{p} \cdot \vec{v}} g).
\]

As the operator \(\hat{X}_i\) acts on the left, it acts only on \(a\) and leaves \(b\) invariant. Therefore, keeping \(b\) fixed, the whole previous analysis of SU(2) coherent states applies to the vector \(|j, a\): states having a minimal spacetime spread are \(|D^j_{ab}\) ≡ \(|j, \tilde{n}|g|j, b\). Now, an important remark is that the standard translations \(e^{i\vec{p} \cdot \vec{v}}\) do not map a coherent state to another coherent state, or that the system of coherent states is not invariant under the action of the standard translations. In a sense we can thus say that the system of coherent states \(\{|j, \tilde{n}|, j ∈ \mathbb{N}/2, \tilde{n} ∈ \mathbb{S}^2\}\) is relative to a given observer (located at the origin). More precisely, \(e^{i\vec{p} \cdot \vec{v}}\) acts simply by multiplication on the matrix elements:

\[
e^{i\vec{v} \cdot \hat{X}}.D^j_{ab}(g) = e^{iv\cdot \hat{p}(g)} D^j_{ab}(g) = e^{\hat{p}(g)\cdot \hat{X}}.D^j_{ab}(g),
\]

where we take the trace in the fundamental two-dimensional representation, but the function \(\exp(i\vec{v} \cdot \text{Tr}(g\vec{\sigma}))\) decomposes into matrix elements of all possible representations of SU(2). On the other hand, we can introduce the simpler operators given by multiplication by the matrix elements themselves \(D^j_{ab}(g)\). However we can not interpret them as translation operators in a straightforward way. Overall, it appears that it is not straightforward at all to define translation operators that have a simple action on the coherent states.

C. About plane waves in non-commutative geometry

Coherent states for this Euclidean spacetime based on the \(\mathfrak{su}(2)\) algebra representing semi-classical points were actually already proposed in [14] (although the authors did not recognize them as the highest weight vectors \(|j, j\rangle\) as written by Perelomov), where the authors also investigate the possibility of writing a Poincaré covariant differential calculus. A topic of special interest is the plane waves. More precisely, from the perspective of measuring the difference between a plane wave in flat commutative spacetime from a plane wave in non-commutative space, it is interesting to compare the expectation value \(\langle \exp(i\vec{p} \cdot \hat{X}) \rangle\) for fixed momentum \(\vec{p}\) on a coherent state to its classical value \(\exp(i\vec{p} \cdot \langle \hat{X} \rangle)\).

Explicitly computing these expectation values on a semi-classical state \(|j, \tilde{n}\rangle\) satisfying \(\langle \hat{X} \rangle = j\tilde{n}\), we find:

\[
e^{i\vec{p} \cdot \langle \hat{X} \rangle} = e^{ij\lambda \vec{p} \cdot \tilde{n}} = (\cos(l_p \vec{p} \cdot \tilde{n}) + i \sin(l_p \vec{p} \cdot \tilde{n}))^j,
\]
\[ \langle \exp(i \vec{P} \cdot \vec{X}) \rangle = \left( \cos \left( \frac{l_P |\vec{P}|}{2} \right) + i \frac{\vec{P} \cdot \hat{n}}{|\vec{P}|} \sin \left( \frac{l_P |\vec{P}|}{2} \right) \right)^2. \]  

It is straightforward to check that in the classical limit \( l_P \to 0 \), the two expressions have the same asymptotical behavior as \( 1 + i j l_P \frac{\vec{P} \cdot \hat{n}}{|\vec{P}|} \). Noting \( k \equiv l_P |\vec{P}| \) and \( \cos \theta \equiv \frac{-\vec{P} \cdot \hat{n}}{|\vec{P}|} \), we can write:

\[ \langle \exp(i \vec{P} \cdot \vec{X}) \rangle = \left( \cos k + \sin^2 \theta \sin^2 \frac{k}{2} + i \cos \theta \sin k \right)^j = \left( 1 - \sin^2 \theta \sin^2 \frac{k}{2} \right)^j e^{2ij\varphi}, \]

with \( \tan \varphi \equiv \cos \theta \tan \frac{k}{2} \). This is to be compared to \( \exp(i \vec{P} \cdot \langle \vec{X} \rangle) = \exp(i jk \cos \theta) = (\cos(k \cos \theta) + i \sin(k \cos \theta))^j \). The first difference is the intensity i.e. the modulus of \( \langle \exp(i \vec{P} \cdot \vec{X}) \rangle \) is not one: it presents an anisotropy centered around the direction set by the momentum \( \vec{P} \) and increases with its norm. The modulus being always inferior to 1, it will go to 0 as the distance \( j \) grows: we will have a damping of the plane wave as the distance from the origin grows, which should be a visible effect of the non-commutative geometry. The difference in the phases \( 2\varphi \) and \( k \cos \theta \) is rather small, but will eventually blow up (linearly) as the distance \( j \) gets large.

![Plot of \( |\langle \exp(i\vec{P} \cdot \vec{X}) \rangle| \) for \( j = 100 \) and \( k = 1/10 \) then \( k = 1/2 \) as a function of the angle \( \theta \) between \( \vec{P} \) and \( \langle \vec{X} \rangle \).](image)

**FIG. 1: Plot of \(|\langle \exp(i\vec{P} \cdot \vec{X}) \rangle|\) for \( j = 100 \) and \( k = 1/10 \) then \( k = 1/2 \) as a function of the angle \( \theta \) between \( \vec{P} \) and \( \langle \vec{X} \rangle \).**

### III. COHERENT STATES: THE LORENTZIAN 3D SPACE-TIME

Lorentzian 3d deformed special relativity is very similar to the Euclidean one. It is now the non-compact group manifold SU(1, 1) that is identified as momentum space, and again one can select a preferred set of spacetime coordinate operators given by the Lie derivatives acting on this group manifold. We introduce the rotation generator \( J_z \) and the two boost generators \( K_x, K_y \), which satisfy the \( su(1, 1) \) algebra:

\[ [J_z, K_\pm] = \pm K_\pm, \quad [K_+, K_-] = -2J_z, \]

\[ 4 \text{ We explicitly compute} \]

\[ \langle \exp(i \vec{P} \cdot \vec{X}) \rangle = \langle j, j | g^{-1} \exp(il_P \vec{P} \cdot \vec{T}) g | j, j \rangle = \langle j, j | \exp(il_P (g^{-1} \cdot \vec{T}) \cdot \vec{T}) | j, j \rangle = \left( \cos \left( \frac{l_P |\vec{P}|}{2} \right) + \frac{(g^{-1} \cdot \vec{P}) \cdot \hat{n}}{|\vec{P}|} \sin \left( \frac{l_P |\vec{P}|}{2} \right) \right)^2, \]

with \( (g^{-1} \cdot \vec{P}) \cdot \vec{T} = \vec{P} \cdot \hat{n} \).
where $K_\pm = K_x \pm i K_y$. In the following, we choose to work with the \((+-)\) signature. Noting $\sigma$, the Lorentzian Pauli matrices representing the algebra $su(1,1)$ in the fundamental two-dimensional representation, the group element are defined as $g = \exp(i \tilde{u}.\sigma)$ and can always be expanded as $g = \pm \sqrt{1 - \kappa^2} |\vec{p}|^2 + i \kappa \cdot \vec{p} \cdot \sigma$. We distinguish two cases according to $\tilde{u}$ and $\vec{p}$ being time-like or space-like:

- $\vec{p}$ is time-like, $|\vec{p}|^2 \geq 0$, and $g$ is a rotation of axis $\vec{p}$ and angle $\theta$ such that $\sin \theta = \kappa |\vec{p}|$. The sign $\pm$ can be absorbed in the definition of $\theta$.

- $\vec{p}$ is space-like, $|\vec{p}|^2 \leq 0$, and $g$ is a boost of axis $\vec{p}$ and angle $\eta$ such that $\sinh \eta = \kappa \sqrt{-|\vec{p}|^2}$.

This defines the link between the momentum $\vec{p}$ living in $\mathbb{R}^{2,1}$ and the group element $g$ living in the group manifold $SU(1,1)$. The addition of momenta is defined by the group multiplication: $g(\vec{p}_1 \oplus \vec{p}_2) = g(\vec{p}_1)g(\vec{p}_2)$ and leads to the same deformation as the Euclidean theory in the case of time-like momenta.

The spacetime coordinates are once more defined as the Lie algebra generators (see also [11]), which produce the translations on $SU(1,1)$:

$$T \equiv l_P J_z, \quad X \equiv l_P K_x, \quad Y \equiv l_P K_y.$$

The (spacetime) (squared) length operator is $L^2 \equiv T^2 - X^2 - Y^2$ and is actually the Casimir operator of $SU(1,1)$. The spectrum of $T$ is discrete $l_P \mathbb{Z}$ while the the spectra of the space coordinate remains continuous $l_P \mathbb{R}$. The spectrum of $L^2$ is more involved and consists of two distinct series:

- positive discrete eigenvalues: states $|j,m\rangle$ with $j \geq 1$ correspond to the discrete principal series of irreducible representations of $SU(1,1)$. There are two such series. The positive series have $J_z$-eigenvalues $m$ larger than $j$ while the negative series have $m \leq -j$. The value of the Casimir operator is $j(j-1)$; accordingly, the eigenstates belonging to this series have the geometric interpretation of defining timelike spacetime points with respect to the origin, with the positive series corresponding to points in the future half of the lightcone, and the negative series to points in the past half of it;

- negative continuous eigenvalues: states $|s,m\rangle$ with $s \in \mathbb{R}$ correspond to the continuous principal series of irreducible representations of $SU(1,1)$. $J_z$-eigenvalues $m$ takes all values in $\mathbb{Z}$. The value of the Casimir operator is $-(s^2 + 1/4)$, and accordingly the the corresponding eigenstates are interpreted as spacelike spacetime points.

We have therefore a quantum spacetime with a discrete time-like structure; moreover, while we have a minimal spacelike space-time distance $L^2 = -1/4$, the space coordinates $X$ and $Y$ can take any value in $\mathbb{R}$. This situation is thus exactly the same as that related to the length operator in (2+1)-d Loop Quantum Gravity [21], as to be expected since the quantum geometric structure is based on the group $SU(1,1)$ also in that case.

Now we are interested in constructing states with minimal spread. We define the uncertainty as previously:

$$\delta L = \sqrt{\langle (L^2) - \langle T \rangle^2 + \langle X \rangle^2 + \langle Y \rangle^2 \rangle}.$$  \hspace{1cm} (19)

We consider the time-like case first. We can easily evaluate the distance and uncertainty on the basis states $|j,m\rangle$, $m \geq j$:

$$L_{j,m} = l_P \sqrt{j(j-1)}, \quad (\delta L)_{j,m} = l_P \sqrt{j(j-1) - m^2}.$$  

Therefore we reach the minimal spread for the lowest weight vector $m = j$ in the positive discrete series of representations. It would be the maximal weight $m = -j$ for the negative discrete series of representations. For time-like distances, we can conclude that:

$$(\delta L)_{\text{min}} = (\delta L)_{j,j} = l_P \sqrt{j} \sim \sqrt{l_P L},$$  \hspace{1cm} (20)

which reproduces the result from the Euclidean theory. For space-like vectors, the basis vectors $|s,m\rangle$ give:

$$|L_{s,m}| = l_P \sqrt{s^2 + \frac{1}{4}}, \quad |(\delta L)_{s,m}| = l_P \sqrt{s^2 + \frac{1}{4} + m^2},$$
where $\Gamma$ is the Euler $\Gamma$-function. Then we have the resolution of identity: 

$$\delta L$$

uncertainty relation similar to the Euclidean theory with classical quantum points for the Lorentzian DSR theory for time-like separations. We obtain a spacetime distance interpretation proposed above.

In this context, we have reviewed the construction of coherent states for SU(1,1) group element which maps the vector $\hat{n}_0 = (1,0,0)$, pointing to the origin of the hyperboloid, to the vector $\hat{n}$. There is a U(1) ambiguity in defining this group element, corresponding to the group transformations leaving the vectors on the hyperboloid invariant, so that the relevant group transformations are the boosts only; this gives a phase ambiguity in the definition of $|j, \hat{n}\rangle$. The sign $\pm$ corresponds to the choice of sign of the discrete representation we use. These states have all the nice properties of the SU(2) coherent states, including the resolution of unity. We can write explicitly these coherent states as:

$$|z\rangle = (1 - |z|^2)^j \sum_{m=0}^{2j} \left( \frac{\Gamma(m + 2j)}{m! \Gamma(2j)} \right)^{\frac{1}{2}} z^m |j, j + m\rangle,$$

where $\Gamma$ is the Euler $\Gamma$-function. Then we have the resolution of identity:

$$\frac{2j - 1}{\pi} \int \frac{d^2z}{(1 - |z|^2)^2} |z\rangle \langle z| = 1d_j,$$

meaning that we exhaust the set of points at timelike spacetime distance $l_\mu \sqrt{j(j - 1)}$, with the notation:

$$\hat{n} = (\cosh \eta, \sinh \eta \cos \phi, \sinh \eta \sin \phi), \quad z = \tanh \frac{\eta}{2} e^{-i\phi}.$$

Of course we have also a full resolution of unity for all timelike distances, meaning that these system of coherent states spans geometrically the whole lightcone centered at the origin. In addition, one can compute the overlap between two such states:

$$|\langle j, \hat{n}_1 | j, \hat{n}_2 \rangle|^2 = \left( \frac{1 + \hat{n}_1 \cdot \hat{n}_2}{2} \right)^{-2j}.$$

We see that the whole construction and its results are the exact analogue of those of the Euclidean theory, for these discrete timelike quantum points. More details can be found in [13], where it is also described how to build a system coherent states for the continuous representations using functions over the Lobachevsky plane SU(1,1)/U(1), using a different basis of states, i.e. eigenstates of different spacetime coordinate operators, in agreement with the geometric interpretation proposed above.

To sum up, the quantum spacetime of Lorentzian DSR is a non-commutative spacetime with a discrete time structure. In this context, we have reviewed the construction of coherent states for SU(1,1) and established a notion of semi-classical quantum points for the Lorentzian DSR theory for time-like separations. We obtain a spacetime distance uncertainty relation similar to the Euclidean theory with $\delta L \sim \sqrt{L}$. This is in agreement with the expectation from the holographic principle.

**IV. COHERENT STATES FOR THE SNYDER THEORY: TOWARDS FOUR DIMENSIONS**

Now, we would like to extend the 3d results to the 4d DSR theory. Also in this case we would like to define a notion of semi-classical quantum points in terms of appropriate coherent states and check whether we obtain again an uncertainty relation of the type $\delta L \sim \sqrt{L}$ similarly to the 3d theory (actually a generic feature of Lie algebra constructions) or
something of the type \( \delta L \sim L^{1/3} \) as expected from various arguments in 4d (including the holographic principle) or something completely different. The Snyder construction\[10\], that gives a version of DSR in 4d, is based on the definition of momentum space as the quotient space \( SO(4,1)/SO(3,1) \), i.e. a manifold with a de Sitter geometry\(^5\). It is not obvious that the framework of coherent states for Lie groups can be straightforwardly applied to this case. As a start, we propose here to study using such framework the 3d Snyder theory defined from the quotient space \( SO(4)/SO(3) \) in the Riemannian context and \( SO(3,1)/SO(2,1) \) in the Lorentzian context, and compare the results so obtained to those that come from using instead the \( SU(2) \) group structure, that have been described in the previous sections and that can be independently confirmed as trustworthy by more fundamental quantum gravity approaches, as we have discussed above.

### A. The Euclidean theory

We now work with a momentum space defined as the homogeneous space \( SO(4)/SO(3) \sim S_3 \) and we define configuration space by duality with respect to it. More precisely, starting with the Lie algebra \( so(4) \), we identify the "boost" generators \( K_i \) with the spacetime coordinates \( x_i/l_P \), which now truly become operators \( \hat{x}_i \) acting on the Hilbert space of wave functions given by square integrable functions on momentum space. The \( SO(3) \) generators \( J_i \) act as usual on \( \vec{x} \) which still behaves as a vector. As previously, the coordinates are the generators of the translations on \( SO(4)/SO(3) \) -or equivalently basis of vectors on the tangent space- and are non-commutative:

\[
[x_i, x_j] = i l_P^2 \epsilon_{ijk} J_k,
\]

although they do not form a closed Lie algebra anymore. They have a discrete spectrum \( \mathbb{Z} l_P \).

As said above, the Hilbert space of our theory is the space of \( L^2 \) functions over the momentum space \( SO(4)/SO(3) \sim S_3 \). Through harmonic analysis, such functions can be decomposed in \( SO(4) \) representations and more precisely in simple representations of \( SO(4) \) due to the required \( SO(3) \)-invariance. A basis of functions is given by the matrix elements:

\[
f_{n,j,m}(g \in SO(4)) = \langle n, j, m | g | n, 0 \rangle,
\]

where \( n \) is the label of a simple representation (for details, see the appendix A) and \( j, m \) are the labels of the canonical \( SO(3) \) basis of the considered \( SO(4) \) representation. The vector \( | n, 0 \rangle = | n, j = m = 0 \rangle \) is the \( SO(3) \)-invariant vector of the simple representation \( n \) and ensures that \( f_{n,j,m} \) is truly a function on the coset \( SO(4)/SO(3) \). We can sum up this in a compact way, writing our Hilbert space as the direct sum of all \( SO(4) \) simple representations \( R^n \):

\[
\mathcal{H} = \bigoplus_{n \in \mathbb{N}} R^n_{SO(4)}, \quad R^n_{SO(4)} = \bigoplus_{j=0}^{2n} V^j_{SO(3)}.
\]

In this setting, we define the spacetime (square) length operator:

\[
\hat{L}^2 = x_i x_i = l_P^2 \hat{K}^2.
\]

Writing \( \hat{K}^2 = (\hat{J}^2 + \hat{R}^2) - \hat{J}^2 \), this operator \( \hat{L} \) is obviously diagonalized in the \( | n, j, m \rangle \) basis and its spectrum is:

\[
L^2 | n, j, m \rangle = l_P^2 \left( 4n(n + 1) - j(j + 1) \right) | n, j, m \rangle.
\]

As \( 0 \leq j \leq 2n \), the eigenvalues of \( L^2 \) are always positive as expected.

---

\(^5\) One can also work with the AdS geometry given by the homogeneous space \( SO(3,2)/SO(3,1) \).
1. Coherent states around the origin

We would like to identify states localized around some classical spacetime coordinates \((x_0, x_1, x_2)\) and to compute their spread or uncertainty. We can start by calculating the mean value of \(\hat{x}_i\) on the states \(|n, j, m\rangle\). In the following, we choose a particular value \(n\) and keep it fixed. First, one can check that (see the appendix A for details):

\[
\langle j, m|\hat{x}_i|j, m\rangle = l_p \langle j, m|\hat{K}|j, m\rangle = 0,
\]

which in fact results from that we are only using simple representations. Therefore these states \(|j, m\rangle\) are centered around the origin \((0, 0, 0)\). It is also easy to get:

\[
\langle j, m|J_3|j, m\rangle = m, \quad \langle j, m|J_{1,2}|j, m\rangle = 0.
\]

We can define an invariant uncertainty, which is the Lie algebra uncertainty[13]:

\[
\Delta = \langle \hat{J}^2 + \hat{K}^2 \rangle - \langle \hat{J} \rangle^2 - \langle \hat{K} \rangle^2,
\]

which gives:

\[
\Delta_{j,m} = 4n(n + 1) - m^2.
\]

This uncertainty is minimal when for the highest weight \(m = j = 2n\), for which we have \(\Delta_{\text{min}} = 4n\). Nevertheless, it is not exactly the uncertainty which interests us. Physically, we are more interested into the position uncertainty:

\[
(\delta x)^2 = \langle \hat{x}^2 \rangle - \langle \hat{x} \rangle^2 = l_p^2 (\langle \hat{K}^2 \rangle - \langle \hat{K} \rangle^2).
\]

On the states \(|j, m\rangle\), the mean value of the position vanishes so that \((\delta x)^2 = L^2:

\[
(\delta x)^2_{j,m} = l_p^2 (4n(n + 1) - j(j + 1)),
\]

which is minimal for the largest representation \(j = 2n\), for which we have:

\[
(\delta x)^2_{\text{min}} = 2nl_p^2.
\]

From these results, it appears that the length spectrum is quite misleading. All the length eigenvectors \(|n, j, m\rangle\) are centered around the spacetime origin and the value of \(\hat{L}^2\) gives the (square of the) uncertainty/spread of the state.

2. Localizing arbitrary points

We have just seen that states in the canonical basis for simple representations of \(SO(4)\) can be interpreted as giving a definition of a quantum point defining the origin of our non-commutative spacetime. The next task is to identify coherent states that correspond to arbitrary (quantum) points in spacetime, localized with greater or lesser degree of uncertainty. The idea is to consider arbitrary combinations of basis states, and more precisely states that can be obtained from these by acting with generic group elements (in the appropriate representation, of course). In other words we will be considering states of the type: \(U^{(n)}(g)\ |n, j, m\rangle\) and consider the mean value of the coordinate distance operators on them, in order to check that they correspond indeed to points distinguished from the origin, and then the corresponding dispersion in these operators to check their degree of localization.

In this Riemannian setting, we consider group elements \(U^{(n)}(g)\) corresponding to the exponentiation of a given Lie algebra element \(K_i\). For \(K_1\), we can compute:

\[
e^{-i\theta K_1}K_1e^{+i\theta K_1} = K_1, \quad e^{-i\theta K_1}K_2e^{+i\theta K_1} = \cos \theta K_2 + \sin \theta J_3, \quad e^{-i\theta K_1}K_3e^{+i\theta K_1} = \cos \theta K_3 - \sin \theta J_2,
\]

which allows us to derive explicitly the exact expression of the average position and spread of the state \(|\theta n jm\rangle \equiv e^{+i\theta K_1} |n jm\rangle\):

\[
\langle K_1\rangle_{\theta n jm} = 0, \quad \langle K_2\rangle_{\theta n jm} = m \sin \theta, \quad \langle K_3\rangle_{\theta n jm} = 0, \quad \langle \vec{K} \rangle^2 = m^2 \sin^2 \theta,
\]

\[\tag{32}\]

\[
\langle K_1\rangle_{\theta n jm} = 0, \quad \langle K_2\rangle_{\theta n jm} = m \sin \theta, \quad \langle K_3\rangle_{\theta n jm} = 0, \quad \langle \vec{K} \rangle^2 = m^2 \sin^2 \theta,
\]

\[\tag{32}\]
\( (\delta K_1)_{nmj}^2 = \frac{1}{2} \left[ \gamma_j^2(j^2 - j + m^2) + \gamma_{j+1}^2(j^2 + 3j + m^2 + 2) \right], \)

\( (\delta K_2)_{nmj}^2 = \frac{\cos^2 \theta}{2} \left[ \gamma_j^2(j^2 - j + m^2) + \gamma_{j+1}^2(j^2 + 3j + m^2 + 2) \right], \)

\( (\delta K_3)_{nmj}^2 = \frac{\sin^2 \theta}{2} \left( j(j + 1) - m^2 \right) + \cos^2 \theta \left[ \gamma_j^2(j^2 - m^2) + \gamma_{j+1}^2((j + 1)^2 - m^2) \right], \)

\( (\delta K_4)_{nmj}^2 = (\delta K_1)^2 + \frac{\sin^2 \theta}{2} \left( j(j + 1) - m^2 \right) + \frac{\cos^2 \theta}{2} \left[ \gamma_j^2(3j^2 - j - m^2) + \gamma_{j+1}^2(3j^2 + 7j + 4 - m^2) \right], \)

(33)

with the factors \( \gamma_j, \gamma_{j+1} \) given in appendix. Therefore, our state \( |\theta nmj \rangle = e^{+i\varphi K_1} |nmj \rangle \) corresponds to a point localized around the \( X_2 \) axis at distance \( m \sin \theta \) from the origin (remember that the labels \( j \) and \( m \) refer to the choice of canonical basis with respect to the operator \( J_3 \)). An analogous calculation for the state \( e^{i\varphi K_2} |nmj \rangle \) would of course show that it corresponds to a point localized around the \( X_1 \) axis at the same distance, and one could of course define states located at non-zero distance along the \( X_3 \) axis. Let us have a closer look at the uncertainty of these states.

Taking as angle \( \theta = \pi/2 \), the expressions simplify:

\[ \langle \delta x \rangle = \frac{m l_P (0, 1, 0)}{2}, \quad (\delta x_2) = 0, \]

\[ (\delta x_1)^2 = \frac{l_P^2}{2} \left[ \gamma_j^2(j^2 - j + m^2) + \gamma_{j+1}^2(j^2 + 3j + m^2 + 2) \right], \]

\[ (\delta x_3)^2 = \frac{l_P^2}{2} \left( j(j + 1) - m^2 \right). \]

As far as \( x_3 \) is concerned, we have the same formulas as in the case of SU(2) coherent states. This is rather natural since \( e^{+i\varphi K_1} \) rotates \( K_2 \) into \( K_3 \). And we reach a minimal uncertainty in \( x_3 \) when \( m \) is set to its maximal value \( j \).

We then have:

\[ \langle \delta x \rangle = j l_P (0, 1, 0), \quad (\delta x) = l_P \sqrt{\frac{j^2}{2} + (\delta x_1)^2}_{m,j,m=j}. \]

(34)

We get a spread \( \delta x \) of \( \sqrt{x l_P}/2 \) outset by \( \delta x_1 \). Then the minimal value of \( \delta x_1 \) is obtained for the maximal values of the labels \( m = j = 2n \), in which case we get:

\[ \langle \delta x \rangle = 2n l_P (0, 1, 0), \quad (\delta x) = l_P \sqrt{n + \frac{n}{4}} = \frac{1}{2} \sqrt{2n} x l_P, \]

(35)

with the same square-root law dependence of the uncertainty \( \delta x \) that we had found in the 3d DSR case on the (average) distance \( x \) from the origin.

A more careful analysis, allowing \( \theta \) to vary and using the explicit formula for \( \gamma_j \), shows that again the minimal uncertainty \( (\delta x)^2 \) for a fixed angle \( \theta \) is again obtained for the maximal values of the labels \( m = j = 2n \). In this case it is straightforward to get:

\[ \langle \delta x \rangle = 2n l_P (0, 1, 0), \quad \left( \frac{\delta x}{\langle \delta x \rangle} \right)^2 = \frac{1}{4n} \left( 1 + \frac{\cos^2 \theta}{4 \sin^2 \theta} \right). \]

(36)

\[ e^{-i\varphi K_1} K_2 e^{+i\varphi K_1} = e^{-i\theta (J_2 L - J_2 R)} (J_2 L - J_2 R) e^{i\theta (J_2 L - J_2 R)} = \cos \theta J_2^L + \sin \theta J_2^R - \cos \theta J_2^R + \sin \theta J_2^L = \cos \theta K_2 + \sin \theta J_3. \]

To compute the action of the boosts on the Lie algebra elements, we can make use of the splitting of the \( so(4) \) algebra into left and right \( su(2) \) algebras. For example, we write:

\( e^{-i\varphi K_1} K_2 e^{+i\varphi K_1} = e^{-i\theta (J_2^L - J_2^R)} (J_2^L - J_2^R) e^{i\theta (J_2^L - J_2^R)} = \cos \theta J_2^L + \sin \theta J_2^R - \cos \theta J_2^R + \sin \theta J_2^L = \cos \theta K_2 + \sin \theta J_3. \)
The minimal relative uncertainty is obviously obtained when $\cos \theta = 0$, i.e. when $\theta = \pi/2 \text{[mod}\pi]\). Using the same techniques one can study coherent states defining arbitrary points (not located around any specific coordinate axis) in this quantum flat spacetime. This concludes our analysis of coherent states in this Euclidean Snyder model for a non-commutative flat geometry in a 3d spacetime. We have constructed coherent states minimizing the position uncertainty around arbitrary spacetime positions and we derived a square-root law relating the (minimal) spread of localization of spacetime points to their (average) distance from the origin. At the end of the day, this seems to be a generic feature of these non-commutative 3d geometries.

3. Relating the Snyder model to the DSR Theory

A natural question, that the reader might ask, is the link between the earlier DSR theory using the group $SU(2)$ as momentum space and the present Snyder theory based on the homogeneous space $SO(4)/SO(3) \sim S^3$. Indeed as manifold, the two momentum spaces are isomorphic. So what is the precise difference? In fact, the Snyder formalism allows a great freedom in what one can call coordinate operators. Indeed we can choose any set of three generators $X_i$ of the translations on $S^3$. The standard Snyder coordinates are the boosts:

$$X_i^{\text{Snyder}} \equiv l_p K_i.$$ 

Nevertheless, one can also define some $su(2)$ coordinates, which we call here the DSR coordinates:

$$X_i^{\text{DSR}} \equiv l_p (K_i + J_i).$$

These are the generators of the translations on $S^3$ identified with the group manifold $SU(2)$ given by the generators of the right $SU(2)$ subgroup of the initial $SO(4)$ symmetry group. Note that we could have also chosen the left $su(2)$ generators $K_i - J_i$. The coherent states we have defined for 3d DSR refer indeed to this particular choice of spacetime coordinates operators.

Once the spacetime coordinate operators are chosen, we then have a freedom in the precise definition of the momentum, more exactly in the choice of mapping between points in $S^3$ and the standard (measurable) momentum $\vec{p} \in \mathbb{R}^3$; this is the well-known ambiguity in the choice of basis for a DSR theory (see [12, 22] for a discussion of this feature of DSR theories and for possible resolutions of this ambiguity).

B. Localizing Points in 3d Lorentzian DSR spacetime

1. States centered around the origin

Let us move on to the Lorentzian case and repeat the same steps as in the previous Riemannian case. The momentum space is now defined as the one-sheet Lorentzian hyperboloid $H_3 \sim SO(3,1)/SO(2,1)$ and the position are defined as the “boost” generators:

$$x_0 \equiv J_{03}, \quad x_1 \equiv J_{13}, \quad x_2 \equiv J_{23}. \quad (36)$$

The (squared) length $\hat{L}^2 \equiv J_{13}^2 + J_{23}^2 - J_{03}^2$ is invariant under the 3d Lorentz group $SO(2,1)$ and is equal to the difference of the $SO(3,1)$ second Casimir operator and the $SO(2,1)$ Casimir operator. Thus its spectrum is obtained by decomposing the $SO(3,1)$ representations involved in the harmonic analysis over the hyperboloid $H_3$ into $SO(2,1)$ representations. As explained in appendix, such simple $SO(3,1)$ representations are of two kinds: we have a continuous series labeled by a real parameter $\rho \in \mathbb{R}_+$ and a discrete series labeled by a half-integer $n \geq 2$. Following the decomposition of the simple representations into $SO(2,1)$ representations given in appendix, the spectrum associated to the continuous series is:

$$\hat{L}^2 |\rho, s, m\rangle = - (\rho^2 + 1) + \left( s^2 + \frac{1}{4} \right) = s^2 - \rho^2 - \frac{3}{4}, \quad (37)$$
where $s$ runs in $\mathbb{R}_+$ and $m \in \mathbb{Z}$ is the half-integer ($U(1)$ weight) labeling the basis of the SO$(2, 1)$ representations. The discrete simple representations give:

$$\hat{L}^2 |n, s, m\rangle = (n^2 - 1) + \left(s^2 + \frac{1}{4}\right) = n^2 + s^2 - \frac{3}{4},$$

with $s \in \mathbb{R}_+$ and $m \in \mathbb{Z}$, and:

$$\hat{L}^2 |n, j\pm, m\rangle = (n^2 - 1) + \left(-j^2 + \frac{1}{4}\right) = n^2 - j^2 - \frac{3}{4},$$

with $j \leq n - 1/2$ and $\pm m \geq (j + 1/2)$. Let us point out the important fact that the discrete simple representations always carry positive $L^2$ eigenvalues which correspond to spacelike distances. The simple continuous representations are more subtle to interpret.

Just as in the Euclidean case, such length eigenvector can be proved to be centered around the origin. More precisely, one can check that:

$$\langle I_3, I_2, m | x_\mu | I_3, I_2, m \rangle = 0 = \langle m | J_{01} | m \rangle = \langle m | J_{02} | m \rangle, \quad \langle m | J_{12} | m \rangle = m,$$

where $I_d$ denotes the considered representation SO$(d, 1)$.

The uncertainty/spread$^7$ of these states is thus entirely exactly given by the length operator: $(\delta x)^2_{I_3, I_2, m} = \langle I_3, I_2, m | \hat{L}^2 | I_3, I_2, m \rangle$. Taking into account only the spacelike sector defined by the discrete simple representations, we get that, once the SO$(3, 1)$ representation is fixed to a given $I_3 = n$, the minimal uncertainty is obtained for the maximal value $I_2 = j = n - 1/2$ for which we have:

$$(\delta x)_{min} = \sqrt{n^2 - j^2 - \frac{3}{4}} = \sqrt{n - 1} \geq 1.$$

2. **Localize arbitrary points**

As in the Riemannian case, quantum states to be identified with arbitrary points in the non-commutative Lorentzian spacetime of DSR can be obtained considering combinations of basis states defined by applying a generic group transformation to them $U^{I_3}(g) | I_3, I_2, m \rangle$. Again, the SO$(2, 1)$ subgroup of the SO$(3, 1)$ symmetry group of momentum space acts trivially (in the sense that it will not change the expectation values of the coordinates $x_\mu$) and the non-trivial action is only that of transformations generated by the operators $X_0 = J_{03}, X_1 = J_{13}$ and $X_2 = J_{23}$ and their linear combinations.

Let us start by having a look at vectors of the type $\exp(+i\theta J_{13}) | I_3, I_2, m \rangle$. Then we can compute:

$$\exp(-i\theta J_{13})X_0 \exp(+i\theta J_{13}) = \cos \theta X_0 - \sin \theta J_{01},$$

$$\exp(-i\theta J_{13})X_1 \exp(+i\theta J_{13}) = X_1,$$

$$\exp(-i\theta J_{13})X_2 \exp(+i\theta J_{13}) = \cos \theta X_2 + \sin \theta J_{12}.$$

On basis states $| I_3, I_2, m \rangle$ of simple representations, only the (diagonalized) rotation $J_{12}$ have a non-zero expectation value. Therefore, similarly to the Riemannian case, we realize that a rotation $\exp(+i\theta J_{13}) = \exp(+i\theta X_1)$ will generate states located around the spacetime point $(0, 0, m \sin \theta)$ on the $X_2$ axis.

Let us look at the spread of these states. We will only do the explicit calculation for an angle $\theta = \pi/2$. $(\delta X_2)$ obviously vanishes. Then we obtain:

$$(\delta X_0)^2_{\pi/2, I_3, I_2, m} = |\langle I_3, I_2, m | J_{01} | I_3, I_2, m \rangle| = \frac{1}{2} |Q(I_2) + m^2|,$$

$^7$ The Lie algebra "invariant" uncertainty $\Delta$ is computed as in the Riemannian case and is either $\Delta = -(\rho^2 + m^2 + 1) < 0$ or $\Delta = n^2 - m^2 - 1$ with arbitrary sign.
where \( Q(\mathcal{I}_2 = s) = s^2 + 1/4 \) and \( Q(\mathcal{I}_2 = j \pm) = -j^2 + 1/4 \). Computing \( (\delta X) \) is more complicated and requires the exact action of the \( \text{SO}(3,1) \) boost operators in the representation \( \mathcal{I}_3 \). Focusing on \( (\delta X_0) \), we see that the continuous \( \text{SO}(2,1) \) representations \( \mathcal{I}_2 = s \) do not lead to any interesting uncertainty result, while the discrete \( \text{SO}(2,1) \) representations \( \mathcal{I}_2 = j \pm \) give a minimal uncertainty when \( m \) reaches its minimal value \( j + 1/2 \). Then we obtain:

\[
\langle \tilde{X} \rangle_{\pi/2, \mathcal{I}_3, \mathcal{I}_2} = l_P \left( 0, 0, j + \frac{1}{2} \right), \quad (\delta X_2) = 0, \quad (\delta X_0) = l_P \frac{1}{\sqrt{2}} \sqrt{j + \frac{1}{2}} = \frac{1}{\sqrt{2}} l_P X.
\]

And we recover a square-root law for the spread in time of a spacetime point localized at a spacelike separation from the origin. It would be interesting to finally compute the spread \( \delta X_1 \) to close the analysis.

Had we rotated the basis states using \( \exp(i\theta X_2) \), we would have found a state localized around a point on the \( X_1 \) axis, and the analysis would have proceeded analogously. Finally, if we want to construct a state localized around a point on the timelike axis \( X_0 \), we would need to start with a state which is not an eigenstate of \( J_{12} \). For example, we can first do a \( \exp(i\eta J_{02}) \) and then a \( \exp(i\theta J_{13}) \) (or vice-versa). Calculating the effect of such a transformation on \( X_0 = J_{03} \), we would get a contribution from the action of \( J_{12} \), which has a non-vanishing expectation value. We leave the study of the details of this construction and of the properties of such states for future investigation.

3. A remark on the space uncertainty

Looking more closely at the states centered around the origin \(| \mathcal{I}_3, \mathcal{I}_2, m \rangle \), we remind that the covariant spread of a state labeled with representations of the continuous series \( (\mathcal{I}_3, \mathcal{I}_2, s) \) reads:

\[
(\delta x)^2 = -l_P^2 (\rho^2 + 1) + \left( s^2 + \frac{1}{4} \right) = l_P^2 \left( s^2 - \rho^2 - \frac{3}{4} \right).
\]

This squared uncertainty on the position can be positive, or negative or even zero. Let us remind that we are in a Lorentzian metric, and that \( (\delta x)^2 = \delta x_\mu \delta x^\mu \) is thus positive when spacelike, negative when timelike and vanishes when null-like. We would like to insist on the fact that \( (\delta x)^2 = 0 \) does not mean that we have perfectly localized the spacetime point and that we should look at the individual uncertainties for each coordinate to have a proper geometric interpretation of the state under consideration.

Moreover, looking at the above expression of the uncertainty \( (\delta x)^2 \), it is not obvious that the Planck length \( l_P \) is a minimal scale for spacetime localization measurements. For this purpose, we can introduce a notion of space uncertainty:

\[
(\delta x)^2_{sp} \equiv (\delta x_1)^2 + (\delta x_2)^2.
\]

This uncertainty is obviously not a Lorentz invariant. Nevertheless, its minimum is of course invariant.

Now the commutation relation of \( x_1 \) and \( x_2 \) is simply \([x_1, x_2] = il_P J_{12} = il_P J_3\); this means that \( x_1/l_P, x_2/l_P \) and \( J_{12} \) form an \( \text{su}(2) \) algebra. We can therefore perform with identical results our analysis of \( \text{SU}(2) \) coherent states: the state minimizing the uncertainty relation induced by \([x_1, x_2] = il_P J_{12} \) are the coherent states \( g|J, M = J \rangle \), where \( J \) labels the \( \text{SU}(2) \) representation, \(|J, J \rangle \) the maximal weight vector and \( g \) an arbitrary \( \text{SU}(2) \) transformation. Computing \( (\delta x)^2_{sp} \) on such states, we thus obtain:

\[
(\delta x)^2_{sp} = J l_P^2.
\]

The minimum is reached for \( J = \frac{1}{2} \) if working with \( \text{SU}(2) \) (or \( J = 1 \) if working with \( \text{SO}(3) \)). In the end this means that there exists a non-contractible minimal uncertainty for the localization of a point in space given by:

\[
[(\delta x)_{sp}]_{\text{min}} = \frac{1}{\sqrt{2}} l_P.
\]

And we conclude that the Planck length \( l_P \) effectively appears as a minimal length scale in space; we can not resolve the space coordinates of any event in spacetime with a better accuracy than \( l_P/\sqrt{2} \).
V. CONCLUSIONS AND OUTLOOK

In this work we have analyzed some properties of the quantum geometry corresponding to 3-dimensional DSR (deformed or doubly special relativity) in both the Riemannian and Lorentzian setting, and in particular we tackled the issue of defining a suitable notion of “quantum points” in the relevant quantum spacetime, out of the appropriate definition of distance and coordinate operators. DSR models are presently understood as (candidates for) effective descriptions of quantum gravity in the weak-gravity limit, that take nevertheless into account the presence of an invariant distance or energy scale (the Planck scale) coming from the full theory. Being based on a curved momentum space and on a deformed symmetry group for spacetime, the configuration space of such models, i.e. the spacetime they describe, is naturally quantum and non-commutative. A careful analysis of such quantum flat spacetime and of its quantum geometry is needed and important for basically three reasons: 1) any proper understanding of physical processes in a DSR setting that might have phenomenological interest, and thus tell us something about the underlying fundamental quantum gravity theory, requires a clear spacetime description, as all the processes we are interested in from a physical perspective are understood as happening in spacetime; 2) the role of the Lorentz group and the way Lorentz invariance is realized, or modified to be compatible with the Planck scale, in quantum gravity is best studied in spacetime terms, since our most intuitive notion of Lorentz transformations is as spacetime symmetries; 3) the properties of the DSR quantum spacetime and of the DSR quantum geometry can be compared with those unveiled by more fundamental theories of quantum gravity and with more general features of a quantum spacetime as suggested by other approaches (such as loop quantum gravity or spin foam models or string theory); on the one hand this can suggest us which of these approaches is on the right track (by giving us means to analyze in a simplified context and then test experimentally some of their predictions) or which features of a quantum spacetime we should hope to describe with a more fundamental theory; on the other hand this can help us to understand how a DSR effective description may arise from any of these more fundamental theories in a rigorous way.

The second issue, regarding the role and implementation of Lorentz invariance, was studied in [11], together with the geometric interpretation and some properties of spacetime coordinate operators in DSR, thus starting off the analysis of its quantum spacetime geometry. In this paper we have carried this analysis further by studying the basic ingredient of a spacetime: points. The starting point was the idea that in quantum spacetime, such as the DSR one, the only notion of a “point” is that of a coherent state corresponding to a given non-zero values of the distance (spacetime coordinate) operators, and which is semi-classical in the sense that it minimizes the uncertainty in the simultaneous determination (measurement) of such operators. Therefore we proceeded to construct these states and to study their properties looking for a consistent geometric interpretation of them.

In the case of Riemannian 3d DSR the construction is based on the fact that the DSR momentum space is an $S^3$ manifold endowed with and SU(2) group structure, so that the corresponding Hilbert space of wave functions is $L^2(S^3)$ endowed with an appropriate action of SU(2); using the harmonic analysis on $S^3$ and the representation theory of SU(2) we have constructed the system of coherent states for this Hilbert space and identified the semiclassical ones, and we have discussed in detail the geometric meaning of their properties. The same construction was performed in the slightly more involved case of Lorentzian 3d DSR, based instead on the SU(1,1) group structure; here a careful distinction of timelike and spacelike structures and points is needed and to see how this is realized at the quantum level is very interesting: we have indeed performed again the whole construction of coherent states and studied with the same tools as in the Riemannian case their quantum geometric properties, and again uncovered the “point structure” of the DSR quantum spacetime, this time revealing also its quantum causality in terms of lightcones.

Both in the Riemannian and Lorentzian case we have pointed out an interesting square-root dependence of the quantum localization uncertainty, i.e. of the spread of coordinate operators for semiclassical coherent states (quantum points) around their mean values (classical points), on the distance itself. This is what one would have expected from arguments based holographic principle and may thus be a hint of a kind of intrinsic fundamental holography of a quantum spacetime.

As a preliminary step towards analyzing the quantum spacetime geometry of 4d DSR, we have then considered coherent states for the Hilbert spaces given by $L^2(SO(4)/SO(3))$ and $L^2(SO(3,1)/SO(2,1))$, where the relevant group actions are represented by $SO(4)$ and $SO(3,1)$ respectively; this is because in 4d DSR momentum space is indeed given by 4d De Sitter space (or the 4-sphere in the Riemannian case) with the De Sitter (or $SO(5)$) group structure. In this context we have again constructed the system of coherent states and analyzed their properties and their geometric interpretation, comparing the results with those obtained previously; we have shown how the construction proceeds...
in the so-called Snyder coordinates (the construction of coherent states in $\kappa$-Minkowski coordinates was performed in the 4-dimensional case in [11]). The extension of this construction and these results to the 4-dimensional case is more technically and computationally involved but would proceed in complete analogy.

Our analysis and results nicely complement, we think, previous work on the quantum geometry of non-commutative spacetimes, and on the notion of points in such a context. In particular we have in mind the important work of Majid [14] for the fuzzy sphere and that of Toller [15] for the Snyder spacetime. In fact, we have constructed the same spacetimes, and on the notion of points in such a context. In particular we have in mind the important work of Majid technically and computationally involved but would proceed in complete analogy.

APPENDIX A: SIMPLE REPRESENTATIONS OF $\text{SO}(4)$

$\mathfrak{so}(4) \sim \text{spin}(4)$ is isomorphic to two copies of $\mathfrak{su}(2)$, $\mathfrak{su}(2)_L \oplus \mathfrak{su}(2)_R$, as a Lie algebra. Its representation are labeled by two spin $(j_L, j_R)$. If we call $\vec{J}_L$ and $\vec{J}_R$ the standard generators of the left and right $\text{SU}(2)$ groups, the generators of the space rotation group $\text{SU}(2)$ are $\vec{J} = \vec{J}_L + \vec{J}_R$ while the "boosts" generators are $\vec{K} = \vec{J}_L - \vec{J}_R$. The two Casimir operators are:

$$C_1 = \vec{J}^2 + \vec{K}^2 = 2\vec{J}_L^2 + 2\vec{J}_R^2 = 2j_L(j_L + 1) + 2j_R(j_R + 1),$$

and

$$C_2 = \vec{J} \cdot \vec{K} = \vec{J}_L^2 - \vec{J}_R^2 = j_L(j_L + 1) - j_R(j_R + 1).$$

The so-called simple representations are equivalently defined as the irreducible representations which contain a $\text{SU}(2)$-invariant vector or such that $C_2 = \vec{J} \cdot \vec{K} = 0$. Therefore, they are such that $j_L = j_R$ and we label them by a single half-integer $n = j_L = j_R$. For a given $n$, the action of the generators in the standard $\text{SU}(2)$ basis is:

\begin{align*}
J_3|j, m\rangle &= m|j, m\rangle \\
J_+|j, m\rangle &= \sqrt{(j-m)(j+m+1)}|j, m+1\rangle \\
J_-|j, m\rangle &= \sqrt{(j+m)(j-m+1)}|j, m-1\rangle \\
K_3|j, m\rangle &= \gamma_j\sqrt{j^2 - m^2}|j-1, m\rangle + \gamma_{j+1}\sqrt{(j+1)^2 - m^2}|j+1, m\rangle \\
K_+|j, m\rangle &= \gamma_j\sqrt{(j-m)(j-m+1)}|j-1, m+1\rangle + \gamma_{j+1}\sqrt{(j+m+1)(j+m+2)}|j+1, m+1\rangle \\
K_-|j, m\rangle &= \gamma_j\sqrt{(j+m)(j+m+1)}|j-1, m-1\rangle + \gamma_{j+1}\sqrt{(j-m+1)(j-m+2)}|j+1, m-1\rangle,
\end{align*}

with

$$\gamma_j = \frac{1}{2} \sqrt{\frac{n(n+1) - \frac{1}{4}(j-1)(j+1)}{(j-\frac{1}{2})(j+\frac{1}{2})}}.$$ 

As $\gamma_j = 2n+1 = 0$, the $\text{SU}(2)$ spin $j$ runs from 0 to $2n$. Then it is straightforward to check that $C_1 = J^2 + K^2 = 4n(n+1)$.

APPENDIX B: SIMPLE REPRESENTATIONS OF THE LORENTZ GROUP $\text{SO}(3, 1)$

An irreducible representation of the Lorentz group is characterized by two numbers $(n, \mu)$, where $n \in \mathbb{N}/2$ and $\mu \in \mathbb{C}$. The unitary representations correspond to two cases:

1. the principal series: $(n, \mu) = (n, ip), \quad n \in \mathbb{N}/2, \quad \rho \in \mathbb{R}$.

2. the supplementary series: $(n, \mu) = (0, \rho), \quad |\rho| < 1, \quad \rho \in \mathbb{R}$. 

2.
The principal series representations are the ones intervening in the Plancherel decomposition formula for $L^2$ functions over $\text{SL}(2, \mathbb{C})$. The Casimirs are then:

$$C_1 = \tilde{K}^2 - \tilde{J}^2 = \rho^2 - n^2 + 1, \quad C_2 = \tilde{J} \cdot \tilde{K} = 2\rho.$$ 

Simple representations are defined as the representations of the principal series with the vanishing Casimir $C_2(\mathfrak{sl}(2, \mathbb{C}))$. There are clearly two types of such representations: a discrete series $(n, 0)$ and a continuous series $(0, i\rho)$.

Let us decompose these simple representations on $\text{SU}(2)$ representations. In general, a $(n, i\rho)$ representations will decompose onto spins $j \geq n$. Then we have:

$$J_3|j, m\rangle = m|j, m\rangle$$
$$J_+|j, m\rangle = \sqrt{(j-m)(j+m+1)}|j, m+1\rangle$$
$$J_-|j, m\rangle = \sqrt{(j+m)(j-m+1)}|j, m-1\rangle$$
$$K_3|j, m\rangle = \gamma_j \sqrt{j^2 - m^2}|j-1, m\rangle - \gamma_{j+1} \sqrt{(j+1)^2 - m^2}|j+1, m\rangle$$
$$K_+|j, m\rangle = \gamma_j \sqrt{(j-m)(j-m+1)}|j-1, m+1\rangle + \gamma_{j+1} \sqrt{(j+m+1)(j+m+2)}|j+1, m+1\rangle$$
$$K_-|j, m\rangle = -\gamma_j \sqrt{(j+m)(j+m-1)}|j-1, m-1\rangle - \gamma_{j+1} \sqrt{(j-m+1)(j-m+2)}|j-1, m+1\rangle,$$  \hspace{1cm} (B1)

with

$$\gamma(j) = \frac{i}{2} \sqrt{\frac{j^2 - m^2}{(j-\frac{1}{2})(j+\frac{1}{2})}} \quad \text{or} \quad \gamma(j) = \frac{i}{2} \sqrt{\frac{j^2 + \rho^2}{(j-\frac{1}{2})(j+\frac{1}{2})}}.$$ 

Irreducible $\text{SL}(2, \mathbb{C})$ representations containing a vector invariant under the compact subgroup $\text{SU}(2)$ or under the non-compact subgroup $\text{SU}(1, 1)$ are very naturally simple representations. Looking at the harmonic analysis over the hyperboloid $\text{SL}(2, \mathbb{C})/\text{SU}(2) \sim \text{SO}(3, 1)/\text{SO}(3)$, $L^2$ functions decompose onto simple representations from the continuous series $(0, i\rho)$. On the other hand, looking at the harmonic analysis over the hyperboloid $\text{SL}(2, \mathbb{C})/\text{SU}(1, 1) \sim \text{SO}(3, 1)/\text{SO}(2, 1)$, we need all the simple representations both from the continuous and discrete series. This latter case is the one relevant for the study of the Lorentzian 3d DSR theory.

Let them look at the decomposition of simple representations into $\text{SO}(2, 1)$ representations. To start with, $\text{SO}(2, 1)$ irreducible unitary representations are of two kinds (at least dealing wit the principal series):

1. the (principal) continuous series labeled by a real parameter $s \in \mathbb{R}_+$: the Casimir $C(\mathfrak{so}(2, 1)) = J_{01}^2 + J_{02}^2 - J_{12}^2$ is simply $s^2 + 1/4$, and the representations have $U(1)$ weights $m \in \mathbb{Z}$.

2. the (principal) positive and negative series labeled by an integer parameter $j \in \mathbb{N}$, $j \geq 1$ (and a sign $\pm$): the Casimir is then $C(\mathfrak{so}(2, 1)) = -j^2 + 1/4$, positive representations have $U(1)$ weights $m$ running from $j + 1/2$ to $+\infty$ while negative representations have weights running from $-(j + 1/2)$ to $-\infty$.

Simple $\text{SO}(3, 1)$ representations of the continuous series decompose only onto the continuous series of $\text{SO}(2, 1)$ representations:

$$R^n = 2 \int_0^\infty ds \, V^s,$$  \hspace{1cm} (B2)

while simple representations from the discrete series decompose over all $\text{SO}(2, 1)$ representations:

$$R^n = \bigoplus_{j=1}^{n-1/2} (V^{j+} \oplus V^{j-}) \oplus \int_0^\infty ds \, V^s.$$  \hspace{1cm} (B3)
