Emergent Momentum-Space Skyrmion Texture on the Surface of Topological Insulators

Narayan Mohanta, Arno P. Kampf & Thilo Kopp

The quantum anomalous Hall effect has been theoretically predicted and experimentally verified in magnetic topological insulators. In addition, the surface states of these materials exhibit a hedgehog-like “spin” texture in momentum space. Here, we apply the previously formulated low-energy model for Bi$_2$Se$_3$, a parent compound for magnetic topological insulators, to a slab geometry in which an exchange field acts only within one of the surface layers. In this sample setup, the hedgehog transforms into a skyrmion texture beyond a critical exchange field. This critical field marks a transition between two topologically distinct phases. The topological phase transition takes place without energy gap closing at the Fermi level and leaves the transverse Hall conductance unchanged and quantized to $e^2/2h$. The momentum-space skyrmion texture persists in a finite field range. It may find its realization in hybrid heterostructures with an interface between a three-dimensional topological insulator and a ferromagnetic insulator.

Breaking of time-reversal symmetry (TRS) in three-dimensional (3D) topological insulators (TIs) has led to fascinating new topological phenomena. Among them are the quantum anomalous Hall effect (QAHE), the inverse spin-galvanic effect, axion electrodynamics, and the half-quantum Hall effect on the surface with conductance $\sigma_{xy} = e^2/2h$. In TIs, strong spin-orbit coupling locks the electron's spin to its momentum and forces the surface states to form a helical spin texture in momentum space. Advances in angle-resolved photoemission spectroscopy (ARPES) have facilitated observing these textures in spin-resolved spectra. The two routes to break the TRS and to gap the surface state of a 3D TI are either the doping with transition-metal ions as magnetic impurities or the magnetic proximity effect of a magnetic insulator (MI) adlayer or substrate. In magnetically doped TIs, Dirac semi-metallic surface states acquire a gap and reveal a hedgehog-like spin texture; their Hall conductance is quantized in units of $e^2/h$.

The isostructural tetradymite compounds Bi$_2$Se$_3$, Bi$_2$Te$_3$, and Sb$_2$Te$_3$ belong to the class of strong TIs with an odd number of massless Dirac cones at selected surfaces. Bi$_2$Se$_3$ has a band gap of 0.3 eV and only one massless Dirac cone in the surface-band dispersion, if the crystal is cleaved along the (111) direction. Ab initio GW calculations have challenged the results of earlier band structure calculations and concluded that the band gap is direct. Experimentally, ARPES or scanning tunneling microscopy leave this issue still unsettled. Typically, Se vacancies at the surface shift the Fermi level towards the conduction band, but further doping by Ca counteracts this shift and can move the Fermi level back to the Dirac point. The real-space structure of Bi$_2$Se$_3$ consists of stacked layers. In this stacking, Bi and Se alternate to form five-layer blocks which are coupled via van der Waals interactions; it is therefore well suited for preparing thin films or heterostructures. A structure of five such layers, typically referred to as the ‘quintuple’ layer, repeats along the (111) direction.

Here, we focus on a slab geometry for a 3D TI, in which the exchange field acts on only one of the surface layers. This choice naturally applies to a geometry, in which a TI slab is attached to a ferromagnetic insulator. We adopt a previously-developed strategy to describe a slab of Bi$_2$Se$_3$, stacked with $N$ quintuple layers along the $z$-direction. The formalism, as outlined in the Method section, straightforwardly allows to examine the layer-resolved electronic dispersion of the slab with respect to the transverse momenta. The low-energy bands of Bi$_2$Se$_3$ result from four bonding and anti-bonding $P_z$ orbitals with total angular momenta $J_z = \pm 1/2$. Below, we will refer to the $J_z$ eigenvalues in short as "spin". If one of its surfaces is exposed to a magnetic field or exchange

coupled to a ferromagnetic insulator, such a slab has the same hedgehog spin-texture in momentum space as in magnetically doped TIs. However, at a critical field strength, the hedgehog texture transforms into a skyrmion texture. This topological transition is signalled by a discrete change in the skyrmion counting number. It originates from a field-induced degeneracy point of a surface and a bulk band which, thereafter, interchange their spatial characters. Remarkably, the spin-texture transition leaves the Hall conductance unchanged. The skyrmion "spin" texture remains stable over a finite range of exchange fields similar to the real-space skyrmion lattices in chiral magnets in an external magnetic field.

Results

"Spin" texture. In the absence of a magnetic or an exchange field, two degenerate Dirac cones appear in the spectrum near the center of the surface Brillouin zone, the Γ point; the corresponding states are spatially confined to the top or the bottom surface. With the Bi₂Se₃ specific parameter set adopted from ref. 40, the Dirac point is not precisely located at the Fermi energy, but this has no influence on the results presented below. Once the TRS is broken by a finite field of strength \( h_z \), in one of the two surfaces of the slab, the two-fold degeneracy is lifted in all the bands and the surface state, which experiences the exchange field, acquires a gap. In Fig. 1, we plot the momentum-space "spin" texture \( \mathbf{S}(k) \) and the \( z \)-component of the "spin" expectation value \( S_z(k) \) projected into the surface layer (enumerated as \( l_z = 1 \)), which is subject to the exchange field, in the vicinity of the Dirac point in the 2D surface Brillouin zone. \( S(k) \) is evaluated as the sum of the \( l_z = 1 \) contributions from the two surface-centered bands, top and bottom (marked in red and green in Fig. 2(a,b)). The resultant of the two bands is taken here, because the surface bands hybridize away from the Brillouin zone center (see below and the Supplementary Information). The "spin" texture in the selected surface layer changes qualitatively upon increasing the exchange field. The texture in Fig. 1(a) for \( h_z = 0.1 \) eV is "hedgehog"-like. A similar pattern was detected in the spin-resolved ARPES experiments on Mn doped Bi₂Se₃. For larger field strength, the momentum-space "spin" structure transforms into a skyrmion-like texture as shown in Fig. 1(c). Most noticeable is the sign change of \( S_z \) in the near vicinity of the surface Brillouin zone center, the Γ point (\( |k| = 0 \)). Increasing \( h_z \) further leads to yet another qualitative change of the "spin" texture. At first sight, the texture in Fig. 1(d) appears to have changed only quantitatively in comparison with Fig. 1(c). But as the analysis below will reveal, the topological character of these textures is indeed qualitatively different.

Skyrmion number. In order to decisively identify the topological character of the "spin" textures in Fig. 1, we calculate the skyrmion number \( N = \frac{1}{4\pi} \int d^2k \mathbf{S} \cdot \left( \frac{\partial \mathbf{S}}{\partial k_x} \times \frac{\partial \mathbf{S}}{\partial k_y} \right) \) in the exchange-split occupied surface band (the green band in Fig. 2(c)) at the top surface (\( l_z = 1 \)) of the slab, where the integral is extended to the hexagonal surface Brillouin zone. \( \mathbf{S} \) is the normalized "spin" expectation value which ensures the quantization of the skyrmion number. \( N \) as a function of the exchange field strength \( h_z \) is shown in Fig. 3(a). Indeed, \( N = 1/2 \) for exchange fields below the critical value \( h_{z,1} = 0.273 \) eV, identifying more precisely that the hedgehog phase has the "spin" texture of a half-skyrmion (or meron). At \( h_{z,1} \), the skyrmion number switches to \(-1\), indicating the (anti-)skyrmion character of the texture for \( h_{z,1} < h_z \leq h_{z,2} = 0.31 \) eV, and \( N = 0 \) beyond \( h_{z,2} \). The discontinuous changes of \( N \)
decisively display the signals for topological phase transitions. $N$ takes a finite value ($1/2$ or $-1$) in the exchange-split surface band (green band in Fig. 2(a–c)) only and is zero in the unsplit surface band (red band in Fig. 2(a–c)). $N$ changes sign upon reversal of the magnetic-field direction. Two types of skyrmion lattices commonly appear in chiral magnets. They are either classified as Néel-type or Bloch-type skyrmion (see e.g. refs 42–44); both have the same skyrmion number, but they differ in their spin-winding pattern. A closer inspection of Fig. 1(a) reveals that the momentum-space texture emerging here is a Bloch-type skyrmion.

**Hall conductance.** The obvious question arises whether the topological “spin” texture transitions are accompanied by a change in the Chern number and the associated Hall conductance. To address this question, we calculate $\sigma_{xy}$ for the full slab via the Kubo formula:

$$\sigma_{xy} = e^2 \hbar \sum_{m,n,k} \frac{\text{Im} \langle n|\hat{V}_x|n\rangle \langle m|\hat{V}_y|m\rangle}{(E_{mk} - E_{nk})^2} \times (n_j(E_{mk}) - n_j(E_{nk})).$$

where $m$ and $n$ are the band indices, $\hat{V}_x, \hat{V}_y$ are the velocity operators and $n_j$ denotes the Fermi-Dirac distribution function. The energy gap in thin slabs of 3D TIs is not truly closed at the Dirac point due to a finite size effect even

*Figure 2. Electronic structure across the topological transition.* (a,b) Band dispersions of the Bi$_2$Se$_3$ slab near the $\overline{\Gamma}$ point. The unsplit and exchange-split surface bands are marked in red and green, respectively, for field strengths (a) $h_z = 0.2$ eV (hedgehog phase), and (b) $h_z = 0.273$ eV at the transition. The arrow indicates the special radius $R_k = 0.3/a$ for the avoided level crossing of the two-surface bands. (c) Expanded view of the spectrum in (b) near $R_k = R_{ks}$. (d) The energy gaps $\Delta E_{\overline{\Gamma}}$ at the $\overline{\Gamma}$ point of the exchange-split surface band (green) and between the occupied part of this band and the top occupied bulk band (brown). The squared amplitude of the wave function $\Psi_{\overline{\Gamma}}$ for the green and orange bands in (a,b) as a function of the layer index $l_z$ for (e) $h_z = 0.2$ eV (hedgehog phase) and (f) $h_z = 0.3$ eV (skyrmion phase).
in the absence of a TRS breaking magnetic field. \( \sigma_{xy} \) takes a finite value even for \( h_z = 0 \) due to the tiny energy gap at the \( \Gamma \) point. Therefore, to isolate the effect of the TRS breaking exchange field, we evaluate and plot \( \sigma_{xy} = -\frac{\sigma_{xy}(0)}{h_{zz}} \) throughout the finite-field range. (b) The \( z \)-component of the "spin" expectation value \( S_z \) (in units of \( \hbar/2 \)) and (c) the polar angle \( \Theta = -S_z \cos{z} \) versus the distance \( R_k = \sqrt{k_x^2 + k_y^2} \) from the \( \Gamma \) point for different values of \( h_z \). The symbols and colors used in (c) refer to the same parameters as in (b). (d) The variation of the characteristic radii \( R_H \) (blue circles) and \( R_S \) (red squares) of the hedgehog and the skyrmion "spin" textures, respectively.

**Figure 3. Analysis of the "spin" textures.** (a) The skyrmion number \( N \) as a function of the exchange-field strength \( h_z \). The dashed vertical lines at the critical fields \( h_{zc1} \) and \( h_{zc2} \) bound the field range in which the skyrmion "spin" texture appears. Inset: Hall conductance \( \sigma_{xy} = \sigma_{xy}(h_z) - \sigma_{xy}(h_z = 0) \) versus \( h_z \). \( \sigma_{xy} = e^2/2h \) throughout the finite-field range. (b) The \( z \)-component of the "spin" expectation value \( S_z \) (in units of \( \hbar/2 \)) and (c) the polar angle \( \Theta = -S_z \cos{z} \) versus the distance \( R_k = \sqrt{k_x^2 + k_y^2} \) from the \( \Gamma \) point for different values of \( h_z \). The symbols and colors used in (c) refer to the same parameters as in (b). (d) The variation of the characteristic radii \( R_H \) (blue circles) and \( R_S \) (red squares) of the hedgehog and the skyrmion "spin" textures, respectively.
field range $0 < h_z < h_{zc1}$, while the radius $R_S$ for the skyrmion texture increases rapidly within the field range $h_{zc1} < h_z < h_{zc2}$ as shown in Fig. 3(d). $R_{H}$ and $R_S$ even exceed further out than the special radius $R_K$. Beyond $h_{zc2}$, $\Theta$ stops at a finite angle and the “spins” no longer sweep to the opposite direction indicating the loss of the texture’s skyrmion character.

**Electronic spectra across the transition.** To get more insight into the origin of the topological phase transition, we analyze the changes in the electronic structure across the transition. In Figs 2(a,b), the band dispersions of the slab are plotted in the hedgehog phase ($h_z = 0.2$ eV) and at the critical field $h_{zc1} = 0.273$ eV, respectively, along the $\Gamma \rightarrow \Gamma \rightarrow M$ direction in the hexagonal surface Brillouin zone. Upon increasing $h_z$, the top occupied bulk band (orange) rises up in energy and touches the exchange-split surface band (green) at the $\Gamma$ point for $h_z = h_{zc1}$, as depicted in Fig. 2(b). The former turns back towards the lower-energy bulk bands upon further increasing $h_z$.

The exchange-split and unsplit surface bands have an avoided level crossing at $R_K$ ($\simeq 0.3/\alpha_z$, as visible in Fig. 2(c). This observation clarifies the role of the special radius $R_K$ within which the hedgehog and skyrmion textures form. The hybridization between the two (top and bottom) surface bands of the slab is possible, because their corresponding wave functions extend towards the interior of the slab at momenta away from the $\Gamma$ point and therefore allow for a finite overlap (see also the Supplementary Information).

Figure 2(d) shows the variation of the energy gap at the $\Gamma$ point of the exchange-split surface band and the gap between the occupied part of this band and the top occupied bulk band. When the exchange field reaches $h_z = h_{zc1}$, a bulk and a surface states become degenerate at the $\Gamma$ point. Figure 2(e,f) show the squared amplitude of the wave functions at the $\Psi_{\alpha_z}$s calculated for the occupied exchange-split surface band and the top occupied bulk band, as a function of the layer index $l_z$ for $h_z = 0.2$ eV (hedgehog phase) and $h_z = 0.3$ eV (skyrmion phase). Evidently, these states interchange their spatial character across the transition.

**Discussion**

An experimental detection of the skyrmion texture will be challenging using spin-resolved ARPES techniques. The real obstacle, however, to induce the topological transition is the required large exchange splitting. For the Bi$_2$Se$_3$, specific parameter set which we have used in our calculations, the required exchange field is more than four times larger than the so far observed splitting of $\sim 50$ meV in Bi$_2$Se$_3$ samples which are homogeneously doped with magnetic impurities$^{24}$. At the TI/MI heterointerface of Bi$_2$Se$_3$/MnSe(111), the exchange splitting is only $7 \text{meV}^{24,51}$. Yet, the extraordinarily large g-factor of $\sim 50$ observed for the Dirac electrons in the Bi$_2$Se$_3$ surface states may render it possible to achieve unusually large exchange splittings$^{25,53}$. We have verified that the critical field can be reduced by applying an electric field along $z$-direction (up to $\sim 15\%$ by a bias voltage of 0.1 V between the two open surfaces). The phenomenon of the topological transition is expected to be generic to other strong TIs as well. Therefore, the selection of a TI with a band gap, narrower than Bi$_2$Se$_3$, is another possible route to realize the anticipated topological transition or the “spin”-skyrmion texture in momentum space itself. Explicit calculations confirm the expectation that temperature effects are negligibly small for the observed phase transition because of the material’s sizeable energy gap of 0.3 eV. Hence, the transitions should robustly occur at room temperature and even beyond. For these temperatures, orbital effects arising from the magnetization of the surface will not be relevant, justifying a posteriori the ansatz that the exchange field couples only to the electron’s spin. Furthermore, the typical cyclotron frequencies $\omega_c$ in semiconductors are of the order $\omega_c \sim 10^{11} \text{Hz}$. Specifically, for Bi$_2$Se$_3$, an inverse scattering rate $\tau \sim 5.1 \times 10^{-14} \text{s}$ was inferred from de-Haas-van Alphen experiments$^{24}$. So $\omega_c \tau < 1$ even for magnetic fields near 100T, indicating that the effects of orbital magnetic-field are unlikely to influence the surface electrons in Bi$_2$Se$_3$.

The encountered topological phase transition provides a new example where the energy gap at the Fermi level does not close across the transition. Remarkably, while the skyrmion counting number changes, the Hall conductance remains constant. The hedgehog to skyrmion phase transition in the momentum-space “spin” texture is yet another striking phenomenon to occur in three dimensional topological insulators.

**Method**

The Hamiltonian for a slab of Bi$_2$Se$_3$ is given by [ref. 40, Supplementary Information]

$$H_{\text{slab}} = \frac{1}{N_z} \sum_{\mathbf{k}} \sum_{\alpha} \left( \sum_{l_z=1}^{4} \sum_{\alpha} c_{\mathbf{k}l_z}^\dagger H_0(\mathbf{k}) c_{\mathbf{k}l_z} + \sum_{l_z=1}^{4} c_{\mathbf{k}l_z}^\dagger H_{\text{ex}} c_{\mathbf{k}l_z+1} + H.c. \right),$$

(2)

where $\mathbf{k} \equiv (k_x, k_y, l_z)$, index $\alpha$ labels the four bonding and antibonding states of $P_z$ orbitals in the following order: $|1^+P_z\rangle, |1^-P_z\rangle, |2^+P_z\rangle, |2^-P_z\rangle$; these orbitals form the low-energy bands of Bi$_2$Se$_3$. The superscripts denote the parity$^{24}$, $l_z$ is the layer index, and the arrows represent the total angular momentum eigenvalues $J_z = \pm 1/2$ which result from spin-orbit coupling$^{22}$.

A single quintuple layer, in the presence of a perpendicular exchange (or Zeeman) field, is effectively described by the Hamiltonian$^{15}$.
\[
H^Z_0(k) = H_0(k) + H_z = \\
\begin{bmatrix}
\varepsilon_+ + h_z & 0 & 0 & A_0 k_- \\
0 & \varepsilon_- + h_z & A_0 k_+ & 0 \\
0 & 0 & \varepsilon_+ - h_z & 0 \\
A_0 k_+ & 0 & 0 & \varepsilon_- - h_z \\
\end{bmatrix}
\]

with \(\varepsilon_{\pm} = \varepsilon_0(k) \pm M(k)\), \(\varepsilon_0(k) = C_0 + 2C_2(2 - \cos k_y a - \cos k_y a)\), \(M(k) = M_0 + M_1 + 2M_2(2 - \cos k_y a - \cos k_y a)\), \(k_- = \sin k_x a \pm i \sin k_x a\) is the lattice constant in a layer, \(h_z\) is the strength of the exchange field, and \(H_z\) describes the exchange coupling via the \(h_z\) entries on the matrix diagonal. \(H_1\) accounts for the coupling between two neighboring layers and is expressed as

\[
H_1 = \begin{pmatrix}
-M_1 - C_1 & iB_0/2 & 0 & 0 \\
iB_0/2 & M_1 - C_1 & 0 & 0 \\
0 & 0 & -M_1 - C_1 & -iB_0/2 \\
0 & 0 & -iB_0/2 & M_1 - C_1 \\
\end{pmatrix}
\]

The parameters in \(H_0\) and \(H_1\) are taken from ref. 40: \(A_0 = 0.8\) eV, \(B_0 = 0.32\) eV, \(C_0 = -0.0083\) eV, \(C_1 = 0.204\) eV, \(C_2 = 1.77\) eV, \(M_0 = -0.28\) eV, \(M_1 = 0.216\) eV, \(M_2 = 2.6\) eV and \(a = 4.14\) Å.

The exchange field is subsequently chosen to act only on the top surface layer of the slab with layer index \(l = 1\).

The total Hamiltonian matrix for the slab, of dimension \(4N_x \times 4N_y\), therefore, has the tridiagonal structure

\[
H(k) = \begin{pmatrix}
H_0^Z & H_1 \\
H_1^\dagger & H_0 \\
\end{pmatrix}
\]

The band dispersion \(E_b\) of the slab is obtained by solving the eigenvalue equation \(H(k)\Psi_b = E_b\Psi_b\), where \(\Psi_b\) and \(E_b\) are the eigenvectors and eigenvalues of \(H(k)\), respectively. The “spin” expectation values, at the surface layer with exchange coupling, are computed using

\[
\hat{s}_j(k) = \frac{h}{2} \sum_n C_n \begin{pmatrix} \sigma_{\xi} & 0 \\ 0 & \sigma_{\xi} \end{pmatrix} \Psi_n(k)
\]

where \(C_n = (|\Psi_n_{l=1,\xi}|, |\Psi_n_{l=1,\xi}|^*)\) with \(l = 1\), \(n\) labels the eigenenergies corresponding to the two surface bands, \(\sigma_\xi\) \((\xi = x, y, z)\) are the Pauli matrices, and \(h\) is the Planck’s constant. The results presented above are obtained for a slab of 15 quintuple layers.

Acknowledgements
The authors gratefully acknowledge discussions with Daniel Braak. This work was supported by the DFG through TRR 80.

Author Contributions
N.M. performed the calculations. N.M., A.P.K., and T.K. discussed the results and wrote the manuscript.
