Generalized Sparse Covariance-based Estimation

Johan Swärd, Student member, IEEE, Stefan Ingi Adalbjörnsson, Member, IEEE, and Andreas Jakobsson, Senior Member, IEEE

Abstract—In this work, we extend the sparse iterative covariance-based estimator (SPICE), by generalizing the formulation to allow for different norm constraints on the signal and noise parameters in the covariance model. For a given norm, the resulting extended SPICE method enjoys the same benefits as the regular SPICE method, including being hyper-parameter free, although the choice of norms are shown to govern the sparsity in the resulting solution. Furthermore, we show that solving the extended SPICE method is equivalent to solving a penalized regression problem, which provides an alternative interpretation of the proposed method and a deeper insight on the differences in sparsity between the extended and the original SPICE formulation. We examine the performance of the method for different choices of norms, and compare the results to the original SPICE method, showing the benefits of using the extended formulation. We also provide two ways of solving the extended SPICE method; one grid-based method, for which an efficient implementation is given, and a gridless method for the sinusoidal case, which results in a semi-definite programming problem.

I. INTRODUCTION

Many problems in signal processing may be well described using a linear model, such that

$$y = Bx + e$$

where $y \in \mathbb{C}^N$ is a vector of measurements, $B$ a matrix of regressors, $x$ the parameter vector, and $e$ denotes an additive (complex-valued) noise term, typically assumed to have zero mean and covariance matrix $\Sigma$. This model occurs in a wide range of applications, such as in, e.g., audio and speech processing [1,2] and spectroscopy [3].

Historically, there have been two main principles available for solving these kinds of problems: parametric and non-parametric methods. The latter approach does not rely on any a-priori information about the signal, including assumptions on the model structure or order, and such techniques are therefore more robust to uncertainties in such model assumptions than the former. However, this robustness comes with the downside that the non-parametric methods are, in general, not able to yield as good performance as the parametric approaches, which typically in turn are less robust [8]. Recently, notable efforts have been made to combine these two approaches, developing so-called semi-parametric approaches, which typically only make some weak model structure assumptions, such that assuming that the solution is sparse, although restrain from making any stronger model order assumptions. This implies that although the dictionary, $B \in \mathbb{C}^{N \times M}$, is formed using $M \gg N$ signal candidates, only a few of these candidates are assumed present in the signal. The problem is thus transformed into finding the subset of these $M$ candidates best approximating the measured signal $y$. Many sparse methods do this by enforcing sparsity on the vector $x$, creating a trade-off between the model fit and the level of sparsity. In [9], this was done by introducing the LASSO optimization problem

$$\text{minimize} \quad \frac{1}{2} \|y - Bx\|^2 + \mu \|x\|_1 \quad (2)$$

where the first term penalizes the $\ell_2$-norm distance between the model and the signal, and the second term enforces sparsity upon the vector $x$, with $\mu$ being a user parameter that governs the trade-off between the two terms. Recently, many other sparse methods have been proposed (see, e.g., [10]–[15] and the references therein). One potential drawback of these methods is the requirement of selecting the user parameter, which is often a non-trivial task. Sometimes there are physical aspects that may aid in the choice of this parameter, whereas, in other, some kind of rule of thumb on how to choose it may be found [16]. Other ideas include solving the problem for all different values of the parameter [15,17], or to use some iterative process for aiding in the choice [10,18,19]. Another common way is to use cross-validation to find a suitable regularization parameter (see, e.g., [15]).

In [20], a novel approach to form a sparse solution was proposed based on a covariance fitting criteria, and was shown to overcome the drawback of selecting the

This work was supported in part by the Swedish Research Council and the Crafoord’s and Carl Trygger’s foundations. This work has been presented in part at the ICASSP conference 2017.

user parameter (see also [21]–[25]). The minimization
criteria that was proposed was
\begin{equation}
\min_{\hat{p} \geq 0} \| R^{1/2}(\hat{p})(R(\hat{p}) - y y^*) \|_F^2
\end{equation}
where \( \| \cdot \|_F \) denotes the Frobenius norm, \((\cdot)^*\) the
conjugate transpose, and where
\begin{align*}
R(\hat{p}) &= A \hat{p}^* \\
A &= [\ B \ I \ ] \\
p &= [p_1 \ldots p_M]^T \\
\sigma &= [\sigma_1 \ldots \sigma_N]^T \\
\hat{p} &= [p^T \sigma^T]^T \\
P &= \text{diag} (\hat{p})
\end{align*}
with \( I \) denoting the \( N \times N \) identity matrix, \((\cdot)^T\) the
transpose, \( \sigma_k \) the noise standard deviation for sample \( k \),
and \( \text{diag}(z) \) the diagonal matrix with the vector \( z \) along
its diagonal, and zeros elsewhere. It was further shown that solving (3) is equivalent with solving [20]
\begin{equation}
\min_{\hat{p} \geq 0} \| y^* R^{-1}(\hat{p}) y + \| W \hat{p} \|_1 \\
\end{equation}
where
\begin{align*}
W &= \text{diag} \left( \left[ w_1 \ldots w_{M+N} \right] \right) \\
w_k &= \| a_k \|_2^2 / \| y \|_2^2, \text{ for } k = 1, \ldots, N + M
\end{align*}
with \( a_k \) denoting the \( k \)th column of \( A \). By comparing
(2) and (10), it is clear that both problems minimize a
signal fitting criteria, where the former more explicitly
minimizes the distance between the model and the data,
whereas the latter measures the distance through the
inverse of the (model) covariance matrix. Furthermore,
both problems include the \( \ell_1 \) norm, with the first one
penalizing the parameters corresponding to the different
candidates in the dictionary \( B \), whereas the second,
the so-called SPICE formulation, penalizes both the
parameters corresponding to \( B \) and the parameters corre-
responding to the noise.

In this paper, we generalize the SPICE approach to
allow for different penalties on \( p \) and \( \sigma \), as given in
(5) and (7), respectively, for two different cases; the first
being when all \( \sigma_k \) are equal, and the second when all
\( \sigma_k \) are allowed to differ. In the first case, we show that
the choice of norm for the noise parameters corresponds
to different choices of the regularizing parameter, \( \mu \), and
the regularization norm, for a generalized form of the
(weighted) square-root LASSO. In the case when all \( \sigma_k \)
are allowed to be different, the choices of norms are
similarly shown to affect the sparsity level. This results in
the fact that even if the different SPICE formulations are
hyper-parameter free, one may interpret the choices of
norms as the equivalence of selecting hyper-parameters
dictating the sparseness of the solution, and that the
original SPICE version is equivalent to one particular
choice of norms. We also provide an efficient grid-based
implementation of the proposed method, which, indi-
rectly, allows for solving (weighted) square-root LASSO
problems for a wide choice of regularizing parameters.
Additionally, we state a semi-positive programming
(SDP) problem that allows for solving the proposed
SPICE extension, for the sinusoidal case, without the
use of a grid search.

II. THE \( \{r, q\} \)-SPICE FORMULATION

It is worth noting that the second term in (10) penalizes
the magnitude of each \( p_j \) and \( \sigma_k \), thus promoting a sparse
solution with only a few of the terms in \( p \) being non-
zero. However, since the penalty does not distinguish
between setting the different terms to zero, one may
expect that some of the \( \sigma_k \) may be forced to be zero as
a part of the minimization. If one is interested in finding
a sparse solution from the columns of the dictionary
\( B \) (in the same sense as in (2)), setting some of the
noise parameters \( \sigma_k \) to zero makes little sense. Another
intuition is given if one interprets (10) to require that \( R \)
should be invertible. Assuming this, setting \( \sigma_k \) to zero is
problematic as the resulting covariance matrix, \( R \), loses
rank, unless some of the \( p_j \) are non-zero. Similar conclu-
sions were stated in [26], where a gridless formulation
of SPICE where derived. It was shown that for the gridless
version of SPICE, \( R \) had full rank with probability
one, which in turn made the method overestimate the
model order. Consequently, setting many \( \sigma_k \) to zero will
force the resulting \( p \) to be less sparse, thus increasing
the estimated model order. Thus, in the original SPICE
formulation, \( \sigma_k \) and \( p_j \) are competing for the sparseness
allowed in the solution of (10).

Alternatively, one could proceed to treat the \( \sigma_k \) terms
different from the rest of the \( p_j \) terms. A naive way of
doing this could be to omit \( \sigma_k \) from the cost function
of (10), but this would result in all the \( p_j \) terms being
set to zeros as \( \sigma_k \) may then take on any value which
will make \( R \) full rank, and will thus make the \( p_j \)
terms redundant. Clearly, the \( \sigma_k \) terms must instead be
penalized to produce a meaningful solution to (11). This
may be done in different ways, for instance using
\begin{equation}
\min_{p \geq 0, \sigma \geq 0} y^* R^{-1} y + \| W p \|_r + \| W \sigma \|_q
\end{equation}
Thus, setting \( r, q \geq 1 \), such that

\[
\|Wp\|_r = \left( \sum_{k=1}^{M} w_k^r p_k^r \right)^{1/r}
\]

\[
\|W_\sigma \sigma\|_q = \left( \sum_{k=1}^{N} w_{M+k}^q \sigma_k^q \right)^{1/q}
\]

\[
W = \text{diag}\left( \begin{bmatrix} w_1 & \ldots & w_M \end{bmatrix} \right)
\]

\[
W_\sigma = \text{diag}\left( \begin{bmatrix} w_{M+1} & \ldots & w_{M+N} \end{bmatrix} \right)
\]

Thus, setting \( r = 1 \) and \( q = 1 \) yields the original SPICE formulation. Note that more general regularization functions could also be used, but in this paper, we confine our attention to the \( \{r, q\}\)-norm case, which we hereafter term the \( \{r, q\}\)-SPICE formulation. It should be noted that using an approach reminiscent of the one presented in [27], it is possible to also consider the case when all \( 0 < r, q < 1 \) resulting in a concave penalty term. Herein we restricted our attention to the case where \( r \geq 1 \) and \( q \geq 1 \).

### III. LINKING \( \{r,q\}\)-SPICE TO PENALIZED REGRESSION

To demonstrate the effects of introducing the \( r \)- and the \( q \)-norm to SPICE, we follow the derivation in [23,24], and proceed to examine the connection between \( \{r, q\}\)-SPICE and a penalized regression problem such as the LASSO expression in (2). In order to do so, we distinguish between two cases, namely the case when each \( \sigma_k \) is allowed to have a distinct value, and the case when all \( \sigma_k \) are equal. First, we recall a lemma that will be helpful for the following derivation (see also [24]).

**Lemma 1.** Let

\[
\tilde{\Sigma} = \text{diag}\left( \begin{bmatrix} \sigma_1 & \ldots & \sigma_N \end{bmatrix} \right)
\]

and

\[
\tilde{P} = \text{diag}\left( \begin{bmatrix} p_1 & \ldots & p_M \end{bmatrix} \right)
\]

\[
\tilde{\Sigma} = \tilde{P} \tilde{\Sigma} \tilde{P}^T
\]

Then, using Lemma 1, one may rewrite (13) as

\[
\text{minimize}_{x,p,\sigma} \sum_{k=1}^{M} |y_k - b_k^* x|^2 / \sigma_k + \sum_{k=1}^{M} |x_k|^2 / p_k + \sum_{k=1}^{N} w_{M+k}^q \sigma_k^q \left( \sum_{k=1}^{M} w_k^r p_k^r \right)^{1/r} \left( \sum_{k=1}^{N} w_{M+k}^q \sigma_k^q \right)^{1/q}
\]

Solving (22) for \( p_j \) yields

\[
p_j = w_k^{-r+q+1} |x_k|^{r-1} \left( w_k^{1/2} x \right)^{r-1} \left( w_k^{1/2} x \right)^{-1}
\]

Differentiating the function to be minimized in (22) with respect to \( \sigma_k \) and setting it to zero yields

\[
\frac{|y_k - b_k^* x|^2}{\sigma_k^2} + \frac{w_{M+k}^q \sigma_k^{-1} - 1}{\|W_\sigma \sigma\|_q^{-1}} = 0
\]

Summing over \( k \) on both sides and simplifying, one arrives at

\[
\|W_\sigma \sigma\|_q = \|W_\sigma^{1/2} r\|_{\frac{2q}{q+1}}
\]
Inserting (25) into (24) yields
\[
\sigma_k = w^{-\frac{q}{q+1}} \frac{1}{N-k+1} \sum_{k=1}^{N} \left( y_k - \bar{y} \right)^2 \approx \left\| W_{\sigma}^{1/2} \right\| \frac{q-1}{q+1} \frac{q_0}{q+1} \quad (26)
\]
Finally, inserting (23) and (26) into (22) yields
\[
\operatorname{minimize}_{x} \left\| W_{\sigma}^{1/2} (y - Bx) \right\|_2 + \left\| W_{\sigma}^{1/2} x \right\|_q \quad (27)
\]
From the resulting expression, it may be noted that using \( q = 1 \) yields the least absolute deviations (LAD) estimate, whereas using \( q = \infty \) yields the (unscaled) square-root LASSO. The implications of this is discussed further below.

Clearly, regardless of the choice of \( q \), the corresponding problem in (13) will still be scale invariant. To see this, we follow (24) and scale each \( p_k \) and \( \sigma_k \) with a constant \( c \) and do the same for the cost function in (13), defining
\[
g(p, \sigma) \triangleq c y^*(A c P A^*)^{-1} y + c \left[ \sum_{k=1}^{M} w_k c^T x_k \right]^{1/r} + c \left[ \sum_{k=M+1}^{M+N} w_k c^T x_k \right]^{1/q} \]
\[
= y^*(A c P A^*)^{-1} y + c^2 \left[ \sum_{k=1}^{M} w_k c^T x_k \right]^{1/r} + c^2 \left[ \sum_{k=M+1}^{M+N} w_k c^T x_k \right]^{1/q} \quad (28)
\]
Defining the cost function in (13) as \( f(p, \sigma) \), we may use Lemma 2 in (24) to conclude that if
\[
\{ \hat{p}, \hat{\sigma} \} = \operatorname{arg min}_{p, \sigma} g(p, \sigma) \quad (29)
\]
and
\[
\{ \hat{p}, \hat{\sigma} \} = \operatorname{arg min}_{p, \sigma} f(\hat{p}, \hat{\sigma}) \quad (30)
\]
then
\[
\hat{p} = c \hat{\sigma} \quad (31)
\]
where \( c > 0 \), which is true in the here examined case as well. Due to this scale invariance, one may conclude that the \( \{ r, q \} \)-SPICE method is hyper-parameter free in the same sense as SPICE. Furthermore, it may be noted that when converting the \( p_k \) to \( x_k \), using (21), any scaling will disappear.

### B. Uniform noise variance

If, similar to (23)[24], one instead assumes that all the noise terms have equal variance, thus treating \( \sigma_k = \sigma \), \( \forall k \), one arrives at an interesting conclusion: with this assumption, it has been shown that the SPICE problem is connected to the (weighted) square-root LASSO problem (23)[24], i.e.,
\[
\operatorname{minimize}_{x} \left\| y - Bx \right\|_2 + \mu \left\| W_{\sigma}^{1/2} x \right\|_1 \quad (32)
\]
where \( \mu = N^{-1/2} \) yields the SPICE estimator. Following the derivation in Section III-A together with the assumption that all the noise terms have equal variance, yields \( \mu = N^{-1/2q} \) for the \( \{ r, q \} \)-SPICE formulation, implying the equivalent formulation
\[
\operatorname{minimize}_{x} \left\| y - Bx \right\|_2 + \mu \left\| W_{\sigma}^{1/2} x \right\|_r \quad (33)
\]
Thus, the choice of \( q \) corresponds to the weight that governs the trade-off between the model fitting term and the regularization of the parameters, and the choice of \( r \) decides which norm will be used in the regularization of the parameters. Thus, using \( r = 1 \) means that increasing \( q \) corresponds to increasing the sparsity in the (weighted) square-root LASSO; this implies that if the signal at hand is assumed to be sparse, solving \( \{ r, q \} \)-SPICE
with \( q > 1 \) will yield preferable estimates. Furthermore, setting \( r \to \infty \) yields a ridge regression problem, with \( q \) governing the amount of regularization. We note that it might be preferable to solve (33) using the \( \{ r, q \} \)-SPICE formulation, rather than solving (33) directly.

IV. EFFICIENT IMPLEMENTATION

As will be argued later, for sparse problems, the most interesting setting for \( \{ r, q \} \)-SPICE is when \( r = 1 \), since, according to (33), this will yield an \( \ell_1 \) regularization. To this end, we will in this section derive an efficient implementation for this case. In [20], an efficient implementation of SPICE was introduced. To derive the steps of this algorithm, it was noted that the original SPICE minimization in (10) could also be expressed as

\[
\min_{\{p_k \geq 0\}_{k=1}^N, \{\sigma_k \geq 0\}_{k=1}^N} y^* R^{-1} y \quad \text{subject to} \quad Q^* A = I \tag{34}
\]

Furthermore, it was noted that one could further rewrite the objective in (34) by considering the optimization problem

\[
\min_{Q} y^* Q^* P^{-1} Q y \quad \text{subject to} \quad Q^* A = I \tag{35}
\]

which has the solution \( Q_0 = PA^* R^{-1} \). By defining

\[
\beta = Q y \tag{36}
\]

one may rewrite (34) as

\[
\min_{\{p_k \geq 0\}_{k=1}^M, \{\sigma_k \geq 0\}_{k=1}^N} \sum_{k=1}^M \frac{|\beta_k|^2}{p_k} \quad \text{subject to} \quad \sum_{k=1}^M w_k p_k + \sum_{k=1}^N w_k \sigma_k = 1 \tag{37}
\]

The estimates may then be found by iteratively updating \( R \) and solving for \( p_k \) in (37). For \( \{ r, q \} \)-SPICE, with \( r = 1 \), when assuming different values for the \( \sigma_k \), the same update for \( R \) may be used, but instead of (37), one needs to solve

\[
\minimize_{\{p_k \geq 0\}_{k=1}^M, \{\sigma_k \geq 0\}_{k=1}^N} \sum_{k=1}^M \frac{|\beta_k|^2}{p_k} + \sum_{k=1}^N \frac{|\beta_{M+k}|^2}{\sigma_k}
\]

subject to \( \sum_{k=1}^{M+N} w_k p_k + \left( \sum_{k=1}^N w_k^q \sigma_k^{q-1} \right)^{1/q} = 1 \) (38)

From the Karush-Kuhn-Tucker (KKT) conditions [28], it follows that

\[
- \frac{|\beta_k|^2}{p_k^2} + \lambda w_k = 0, \quad \text{for} \quad k = 1, \ldots, M \tag{39}
\]

\[
- \frac{|\beta_{M+k}|^2}{\sigma_k^2} + \lambda \sigma_k^q w_k^q \left( \sum_{k=1}^N w_k^q \sigma_k^{q-1} \right)^{1/q} = 0 \tag{40}
\]

where \( \lambda \) denotes the dual variable, for \( k = 1, \ldots, M \), together with the constraint in (37). Solving these equations for each \( p_k \) and \( \sigma_k \) yields

\[
p_k = \frac{|\beta_k|}{\sqrt{w_k \lambda^{1/2}}} \tag{41}
\]

\[
\sigma_{\ell} = \sqrt{\frac{w_{\ell}^{1/2} \lambda^{1/2}}{|W_{\sigma}^{1/2} \beta_{\sigma}| \frac{\lambda_{\ell}^{1/2}}{q+1} \frac{+1}{q+1}}} \tag{42}
\]

\[
|W_{\sigma}^{1/2} \beta_{\sigma}| \frac{\lambda_{\ell}^{1/2}}{q+1} \frac{+1}{q+1} \tag{43}
\]

\[
|W_{\sigma}^{1/2} \beta_{\sigma}| \frac{\lambda_{\ell}^{1/2}}{q+1} \frac{+1}{q+1} \tag{44}
\]

\[
|W_{\sigma}^{1/2} \beta_{\sigma}| \frac{\lambda_{\ell}^{1/2}}{q+1} \frac{+1}{q+1} \tag{45}
\]
This allows for the formulation of an efficient implementation by iteratively forming \( R \) from (4), \( \beta_k \) from \( \text{(36)} \), and \( p_k \) and \( \sigma_k \) from \( \text{(41)} \) and \( \text{(42)} \), respectively. Since \( \{1,q\}\text{-SPICE} \) allows for a more sparse solution than the original SPICE, one may speed up the computations further by removing the zero valued \( p_k \) when forming \( R \) and \( \beta_k \).

When instead assuming that \( \sigma_k = \sigma, \forall k \), one obtains the steps

\[
p_k = \frac{|\beta_k|}{\sqrt{w_k \lambda^{1/2}}} \tag{46}
\]

\[
\sigma = \frac{||\beta_M||_2}{N^{1/2q} \lambda^{1/2}} \tag{47}
\]

\[
\lambda = \left( ||W^{1/2} \beta||_1 + ||N^{1/(2q)} \beta_\sigma||_2 \right)^2 \tag{48}
\]

for \( k = 1, \ldots, M \). Algorithms 1 and 2 summarize the \( \{1,q\}\text{-SPICE} \) implementations for the two settings, with \( \hat{y} \) denoting the mean value of the vector \( y \). Similar to the previous case, since using \( q > 1 \) will enforce more sparsity than \( q = 1 \), one may utilize this added sparsity in the implementation of the algorithm. Since most of the elements in \( p \) will be zero, one may form \( R^{-1} \) by only considering the columns and rows of \( A \) and \( A^* \) corresponding to the non-zero entries in \( p \). Let \( K^{(i)} \) be the number of non-zero entries in \( p^{(i)} \) at iteration \( i \). Then, if \( K < N \), one may use the Woodbury matrix identity to efficiently calculate the inverse of \( R \) (see, e.g., [29]).

The termination criterias in Algorithms 1 and 2 can take on many forms. In this work, we have chosen to terminate the algorithms when the percentage of change in \( p \) and \( \sigma \) between two consecutive iterations falls below a certain level, say in the range \([10^{-9}, 10^{-3}]\).

Note that the algorithm described in Algorithm 2 solves a (weighted) square-root LASSO problem, where the different choices of \( q \) corresponds to different levels of sparsity, i.e., different values of \( \mu \) in (32). If one is interested in solving a (weighted) square-root LASSO with \( \mu = \mu_0 \), then one may instead solve the \( \{r,q\}\text{-SPICE} \) with \( q = \frac{1}{\log \mu \mu_0} \), as long as \( q > 1 \), and with \( r = 1 \). Thus, the algorithm in Algorithm 2 presents an attractive and efficient way of solving the (weighted) square-root LASSO problem, for a large range of different \( \mu \).

To give an idea of the running time of the proposed algorithm as compared with a standard SDP solver (see, e.g., [30,31]), the algorithms were tested on a problem with \( M = 10000, N = 10000 \), and with \( q = 5 \), and \( r = 1 \), where the data vector, \( y \), contained 3 sinusoids, using a standard PC (2.6 Ghz Intel Core i7, 16 GB RAM). The corresponding run times were roughly 4 seconds for the Matlab implementation in Algorithm 2 and 4132 seconds for the SDP Matlab solver.

V. Off-grid solution

Many forms of estimation problems are solved by evaluating over a grid of the parameters of interest. However, such a solution may cause concerns when the sought solution falls outside the grid or may be found in between grid points. A common solution to this problem is to increase the grid size to thereby minimize the distance from the closest grid point to the true parameter value (see, e.g., [32,33]). However, such a solution might cause the columns of the extended dictionary to be highly correlated, thereby decreasing the performance of the method (we instead refer the interested reader to other works treating this issue, e.g., [33–36] and the references therein). In [26] and [37], an off-grid solution to the original SPICE version was presented for the sinusoidal case. In this section, we similarly provide one possible version of off-grid estimation for the proposed \( \{r,q\}\text{-SPICE} \) method for a signal containing superimposed sinusoids. In order to do so, it may initially be noted that one may separate \( R \) into two different matrices, such that

\[
R = B^* \text{diag } (p) B + \text{diag } (\sigma) \triangleq T(u) + \text{diag } (\sigma) \tag{49}
\]

where \( T(u) \) is a Toeplitz matrix with \( u \) forming the first column of \( T(u) \). Thus, (13) may be expressed as (see 1}

1Our implementation of \( \{r,q\}\text{-SPICE} \) will be made available on the authors’ web-pages upon publication.
also \cite{26,37}

\[
\begin{align*}
\text{minimize} & \quad ||y||_2^2 + ||\text{diag}(T(u))||_r + ||W_\sigma \sigma||_q \\
\text{subject to} & \quad x + ||y^* T(u) + \text{diag}(\sigma)||_2 \geq 0 \\
& \quad T(u) \geq 0 \\
& \quad T(u) - T(u)^* = 0 \\
& \quad \sigma \geq 0
\end{align*}
\]

(50)

and under the additional constraint that $T(u)$ is a Toeplitz matrix. The optimization problem in (50) is convex, and may be solved using, e.g., a publicly available SDP solver, such as the one presented in \cite{30,31}. The final off-grid estimates may then be found using the celebrated Vandermonde decomposition in combination with, for instance, Prony’s method (see \cite{8,38} for further details on such an approach).

VI. NUMERICAL EXAMPLES

Using the interpretation provided by the reformulation in Section III, it is clear that the choice of $r$ will decide what kind of regularization that will be used. Thus, choosing $r = 1$ will yield an $\ell_1$ norm and letting $r \to \infty$ will result in the $\ell_2$ norm. In this paper, we consider sparse problems, and will therefore mainly confine our attention to the case where $r = 1$, since this will yield the most sparse convex regularizer, namely $\ell_1$.

From the discussion in Section II one may expect that SPICE will set some of the elements in $\sigma$ to zero, since the sparsity enforcing term in (10) also applies to these parameters. Figure 1 shows the estimated $p$ and $\sigma$ for the SPICE and the \{r,q\}-SPICE estimators, when applied to a linear signal formed using (1) with three non-zero components. As expected, using $r = 1$, \{r,q\}-SPICE offers a sparser $p$ vector as compared to SPICE, whereas the solution is more sparse in $\sigma$ for SPICE. As a result, the sparsity constraints on the $\sigma_k$ terms in \{r,q\}-SPICE are thus relaxed and are instead subjected to a bounding of their power in the $q$-norm, thus allowing for more sparsity in $p$.

We will proceed by showing the difference in performance for different values of $r$ and $q$, to provide an example on how the different choices of these norms affect the estimates. We investigate two properties of the estimators, namely the resulting root-mean-squared error
The signal-to-noise ratio (SNR) is defined as $\text{SNR} = 10 \log_{10} \left( \frac{P_y}{\sigma^2} \right)$ (52), where $\theta_k$ is the true frequency of the $k$th component, whereas $\hat{\theta}_k$ is the formed estimate, and the ability to correctly estimate the model order. The signal was $N = 50$ samples long and contained 4 sinusoids with unit magnitude and random phase. The simulation was done using 100 Monte-Carlo simulations for each SNR-level, where the signal-to-noise ratio (SNR) is defined as

\[ \text{SNR} = 10 \log_{10} \left( \frac{P_y}{\sigma^2} \right) \] (52)

with $P_y$ denoting the power of the true signal. The noise used was circular white Gaussian noise, and the noise terms were allowed to differ.

The solution was obtained by solving (50) for all settings except for the original SPICE, where the estimates were obtained from solving the problem formulated in [37]. In Figure 2, the resulting RMSEs are shown for different values of $r$ and $q$, as a function of the SNR. To make the figures readable, one respectively two outliers were removed for SPICE and for the $r = 3, q = 2$ case for $\{r, q\}$-SPICE at the 5 dB SNR-level. Furthermore, to remove the noise peaks that appear when using small values of $q$, all peaks smaller than 20% of the largest found peak were removed. Note, however, that this is not necessary for the case where $q$ is larger. As is clear from the figure, the RMSE is decreased as the sparsity level is increased, with the $\{r, q\}$-SPICE versions outperforming the original SPICE. This is also true for the resulting model order estimation, which is shown in Figure 3. As may be expected, when increasing $q$ the sparsity is increased and the spurious peaks are removed, but as $q$ is further increased, the true peaks start to disappear. In this setting, it seems to be beneficial to set the norms around $q = 1.5$ and $r = 1$. From these results, we conclude that the generalized version of SPICE allows for better estimation of parameter values, as well as model order. As was expected, using $r > 1$ was not beneficial when confronted with a sparse signal, and we will therefore, in the succeeding example, restrict our attention to the case where $r = 1$, referring to the method as $q$-SPICE. However, it should be stressed that for certain situations, it might be preferable to use $r > 1$, e.g., in situations when otherwise considering to use ridge regression; we will further examine this aspect in future works.

Arguably, the most important property of a sparse estimator is the ability to return the true support of the signal, as well as yielding reasonable amplitude estimates for this support. However, it seems inevitable that when including a sparsity enforcing penalty, one also introduced a (downwards) bias on the magnitude of the amplitudes. Fortunately, this problem is often easy to overcome by simply re-estimating the amplitudes using, e.g., least squares, once the true support is known. Accordingly, we will in this section focus on the methods ability of finding the true support of the signal. To this end, 200 Monte-Carlo simulation for each SNR level are formed. In each simulation, $N = 50$ samples of a signal containing three sinusoids, each with unit magnitude, and phase uniformly drawn from $(0, 2\pi)$, was created. The normalized frequencies were uniformly selected, but were at least $1/2N$ apart.

The dictionary contained $M = 1000$ candidate sinusoids, selected on a uniform frequency grid from $(0, 1]$. The estimated support was selected to be the elements of the vector $x$ that had a corresponding absolute value of at least 20% of the largest estimated value in $x$. This was done to allow for comparison with the less sparse $q$-SPICE versions, for cases with small $q$ value (most notably $q = 1$). It may be noted that for values of $q$ that are large, this is not necessary. The support was deemed correctly estimated if the estimated frequencies were at most two grid points away from the true frequencies.

Figure 4 shows the results of applying $q$-SPICE, for different values of $q$, assuming that all the $\sigma_k$ are the same, with $q = 1$ yielding the SPICE estimate. As is clear from the figure, the results improve with increasing $q$ values. From the discussion in Section III-B we note that this corresponds to increasing the value of $\mu$ in (32), thus increasing the sparsity in the estimates. Thus,
one could assume that when further increasing $q$, the estimate of the support should decline. In Figure 6, this behavior can be seen, where now $q$-SPICE is evaluated over a range of larger $q$ values. It is also apparent from the figure that the best value for $q$ is for this signal somewhere around $q = 2$, which corresponds to using $\mu \approx 0.38$ in (33). Next, we investigate the precision for different values of $q$, by using the RMSE of the frequency estimates. Figure 5 shows the resulting RMSE of the frequency estimates, for the three largest values of $x$. As can be seen in the figure, the RMSE is clearly improving as $q$ is increased, corresponding to sparser solutions. For smaller values of $q$, the results are not very sparse, and large spurious noise peaks can be found. To improve readability, seven, two, and three outliers were removed from the cases $q = 1$, $q = 1.25$, and $q = 1.5$, respectively. If $q$ is increased too much this will, of course, make the solution too sparse, thus risking setting non-noise peaks to zero. This can also be seen in Figure 6, where for about $q = 3$, the probability of retrieving the true support of the signal starts to decline, and at $q > 3.5$, the solution is too sparse.

We proceed by considering the case when the $\sigma_k$ parameters are allowed to take on different values, using the same set-up as above. Figures 7 and 8 show the probability of estimating the correct support of the signal and the RMSE of the three largest frequency estimates, respectively. Again, in the interest of readability, three outliers were removed from $q = 1$, six outliers from $q = 1.25$, and three outliers for $q = 1.5$. As previously noted, it is clear from the figures that $q$ governs the sparsity enforced on the solution. From the figures, one may also see that for this setup, it is advantageous to choose $q$ in the interval $q = [1.25, 2.25]$. To demonstrate the differences in the solutions obtained from using different values of $q$, we show a typical simulation result for four different values of $q$, namely $q = 1, 1.5, 2,$ and $2.5$, for the settings above, with SNR$= 5$ dB. Figure 9 shows the results, where it may again be noted that the sparsity level increases with $q$.

Finally, we provide a numerical example showing the results from solving the $\{r, q\}$-SPICE using (50), with $r = 1$ and $q = 1.75$, and for the case where each noise variance are allowed to differ across the samples. In this scenario, we evaluated the gridless version of $\{r, q\}$-SPICE, given in (50), and the gridless version of SPICE, given in (37), together with the grid-based $\{r, q\}$-SPICE, given a frequency grid of $M = 500$ grid points. In each of the 100 Monte-Carlo simulations, the $N = 50$ samples long signal contained four sinusoids, each with random phase, with two peaks having magnitude 4, one peak magnitude 2, and the last one unit magnitude. The frequencies were selected not to be closer than $1/2N$ from each other and were randomly selected in each simulation from the interval $(0, 1]$. Both gridless versions were computed using the SDP-solver in CVX [30][31]. Figure 10 and 11 show the resulting RMSE and probability of finding the correct model order as functions of the SNR level. As seen in the figures, the two versions of the $q$-SPICE outperforms the gridless version of SPICE. It is worth noting that in this scenario, only SPICE had the benefit of removing the smallest peaks. Furthermore, the model order was deemed correct if the method found the true number of peaks, thus there were no limitation on how close an estimated frequency had to be the true value. If the model order was too high, the four largest
peaks were selected to compute the RMSE, whereas if the model order was too low, these estimates were omitted from the RMSE evaluations.

Furthermore, one may see that the gridless version of $q$-SPICE is slightly better than the gridded version. However, this slight improvement from using the gridless $q$-SPICE version may not be worth the extra computation time; the gridless version took on average 9.4 seconds to execute, whereas the gridded version only took 0.5 seconds. However, it is worth recalling that other works on gridless solutions implicate that faster implementations are available (see, e.g., [39]), and these improvements in implementation can likely also be applied to the gridless $q$-SPICE.

VII. CONCLUSION

In this paper, we introduced a generalization of the SPICE method, in which we allow for a trade-off between the penalties for the model, using a $q$-norm, and the noise parameters, using an $r$-norm. We show that for larger values of $q$, one achieves a higher level of sparsity and better performance for recovering the support of the signal. Furthermore, we show that the proposed method is equivalent to a penalized regression formulation, with the $\frac{2q}{q+1}$ norm on the model fit, for the case when we let the noise variance vary across all samples. In the case where the noise variance is assumed to be equal for all samples, it is shown that the proposed method is equal to the (weighted) square-root LASSO, where the regularization parameter has a one-to-one correspondence to the choice of $q$ for a given problem. Furthermore, we provide a fast and efficient implementation for both the case when $r = 1$ and the noise variances are equal for all samples, and where they are allowed to differ. As a result of the shown equivalence, the presented implementation offers an attractive alternative for solving $\frac{2q}{q+1}$-norm problems, and, perhaps more interesting, (weighted) square-root LASSO problems for different regularization parameters. We also present a gridless version of $\{r, q\}$-SPICE for the sinusoidal signals, which is on the form of an SDP problem. Numerical result show the preferred performance of the $\{r, q\}$-SPICE as compared to the original SPICE method, both for gridded and for gridless versions for the estimator.
