**Abstract**

*Hepatozoon* spp. is the causative agent of a vector-borne parasitic disease in many animal species. In felids, *Hepatozoon felis*, *Hepatozoon canis* and *Hepatozoon silvestris* have been molecularly isolated. Hepatozoonosis usually causes asymptomatic infections in domestic cats, but clinical cases have recently been reported in Europe. We describe the first Italian case of hepatozoonosis in a cat with an unusual presentation. An 11-year-old neutered European shorthair cat was urgently hospitalized for intestinal intussusception. Hematology, biochemistry, FIV-FeLV tests, blood smears and molecular investigation targeting the 18S rRNA gene of *Hepatozoon* spp. were performed on blood samples; in addition, histological and molecular investigations were performed to analyze surgical samples to identify *Hepatozoon* infection. *Hepatozoon* gamonts were detected in granulocytes in the blood smear, and *Hepatozoon* spp. DNA was confirmed by PCR on blood. The intussusception was caused by a sessile endoluminal nodule that was surgically removed. Histologically, many elements referring to parasitic tissue forms were identified in the intestinal cells, and then the specimens were molecularly confirmed to harbor *H. silvestris*. This is the first description of symptomatic hepatozoonosis in a domestic cat in Italy. *Hepatozoon silvestris* has been described in wild felids, which are usually resilient to the infection, whereas the domestic cat seems to be more susceptible. Indeed, *H. silvestris* in cats usually presents tropism for skeletal muscle and myocardium with subsequent clinical manifestations. This is the first description of a domestic cat with *H. silvestris* localized in the intestinal epithelium and associated with intussusception.

**Keywords:** Domestic cat, Infection, Intestinal nodule, *Hepatozoon silvestris*, Italy

Hepatozoonosis is a vector-borne disease affecting many of animals, including reptiles, birds and mammals; it is caused by an apicomplexan parasite, of which almost 340 species are currently described [1–3]. Almost 50 species are recognized in mammals [1], but comprehensive information regarding their life cycle is known for only a few of them. Usually, the *Hepatozoon* life cycle involves an intermediate and a definitive host represented by a vertebrate animal and an arthropod vector, respectively [4]. In contrast to other vector-borne protozoa (e.g. *Babesia* spp., *Leishmania infantum*) transmitted to humans and animals bitten by infected arthropods, in hepatozoonosis, the vertebrate host becomes infected through the ingestion of infected arthropods [1, 2]. In the vertebrate host, the asexual replication of *Hepatozoon* takes place, generating intracellular gamonts that circulate in the bloodstream. The vectors, mostly represented by ticks, ingest *Hepatozoon* gamonts through blood-feeding from infected animals, and sexual replication takes place within the ticks, ending in the production of mature oocysts that are ready to infect a new vertebrate host.
and complete the life cycle when the arthropod will be ingested [2]. Interestingly, other transmission routes have been reported, e.g. in the *Hepatozoon canis* and *Hepatozoon felis* life cycles, vertical intrauterine transmission is described, and in the *Hepatozoon americanum* life cycle, predation (i.e. the ingestion of infected prey) has been proven to be an additional transmission route [2, 5, 6].

In felids, hepatozoonosis is still mostly unknown worldwide, but recent epidemiological studies and case reports are raising attention about this parasite and its pathogenicity [7, 8]. Currently, three species of *Hepatozoon* are recognized in wild and domestic felids in Europe, i.e. *Hepatozoon felis*, *Hepatozoon canis* and *Hepatozoon silvestris* [3, 9–11], but no information about the involved arthropod vectors are available, even if ticks seem to be the most likely arthropod vector [12–15]. Usually, hepatozoonosis in domestic and wild felids is considered subclinical, despite replicative forms (i.e. meronts) being found in skeletal muscles and in the myocardium of infected felids [2, 16, 17]. Recently, two cats with clinical signs were described in Central Europe; the first cat was presented with severe and fatal myocarditis and *H. silvestris* infection [7], and the second cat was in poor general condition and exhibited lethargy, anorexia, icterus, a painful abdomen, fever, ruffled hair and *H. felis* infection [8]. This study describes, for the first time in Italy to our knowledge, a clinical and survival case of hepatozoonosis with an unusual presentation in a domestic cat.

An 11-year-old neutered European shorthair cat living in a cat household with > 30 individuals in a pre-alpine area at 700 masl (45°15′59″N, 7°40′56″E) and having free outdoor access was examined for its yearly routine veterinary check-up (day -7). A tick was found attached to the cat’s neck and was removed; then, the cat was treated with fipronil. The blood count presented some alterations in red blood cell, reticulocyte and monocyte total counts, and serum albumin was low (IDEXX Laboratories, Italy); no other remarkable findings were observed (Table 1). Five days later, the cat presented mild depression and loss of appetite; in a few days, a worsening of the clinical signs was observed, with anorexia, severe depression and vomiting. The cat was admitted to the hospital (day 0), and no particular findings were revealed during the physical examination such as fever, abdominal mass or pain. A complete hemato-biochemical profile (IDEXX Laboratories, Italy) and an abdominal ultrasound were performed.

The blood count showed an inflammatory leukogram with left shift and monocytosis, and the biochemical profile presented several alterations (i.e. electrolytes, CPK, AST, fructosamine) reported in Table 1. Microscopy of May Grunwald Giemsa-stained blood smear revealed single ovoid inclusions in neutrophils attributable to *Hepatozoon* gamonts (11.2 × 5.1 µm, with an ovoid central nucleus, Fig. 1); subsequently, the protozoan parasite was confirmed at the genera level (i.e. *Hepatozoon* spp.) on a blood sample by PCR targeting the 18S-rRNA gene with a cycle threshold (Ct) of 36.3 (IDEXX Laboratories, Germany).

Additionally, the cat tested negative for feline immunodeficiency virus (FIV) antibodies and feline leukemia virus (FeLV) antigens (SNAP FIV-FeLV Combo test, IDEXX Laboratories, Inc.). The results were also confirmed by molecular investigations targeting the FeLV proviral DNA (IDEXX Laboratories, Germany). The abdominal ultrasound identified an intestinal intussusception; thus, the cat was urgently admitted to the operating room for a laparotomy.

At surgery, a jejunal endoluminal pedunculated nodule of approximately 1.5 cm, almost occluding the intestinal lumen and causing intussusception, was found. The biochemical parameters improved and normalized within 13 days after surgery (Table 1). The cat was administered a 30-day regimen of oral doxycycline at 5 mg/kg bid. Blood PCR was performed 10 days after the end of doxycycline administration (day +40), and the result was positive (Ct = 36.9) for the targeted *Hepatozoon* DNA (IDEXX Laboratories, Germany); 1 month later (day +70), it finally became negative. The time line of the events and their brief descriptions are reported in Fig. 2.

No other vector-borne pathogens were tested because the hemato-biochemical profile and the rapid worsening of clinical conditions were suggestive of acute and severe disease; it was decided to wait for the clinical recovery of the cat before testing for other pathogens; then, since the cat recovered quickly, no other investigations for VBDs were done.

The intestinal nodule was submitted to histopathological and molecular investigations (University of Padova). Tissue sections revealed a severe inflammatory reaction characterized by chronic ulcerative enteritis with polymoid proliferation and severe lymphangiectasia. Many protozoal inclusions were revealed within the enterocytes of the intestinal villi and near the lumen (Fig. 3). The protozoa were roundish, of variable size (with an average size of 15 to 25 µm) and characterized by dark basophilic-staining small nuclei. These forms were referred to as parasitic inclusions of *Hepatozoon* spp. Away from the nodule, along the surgical section in the healthy intestinal tissue, no protozoal inclusions in the enterocytes were observed. Subsequently, to identify the protozoa affect ing the intestinal tissue and causing the local host reaction and the nodule, conventional PCR was performed, targeting the 18S-rRNA of *Hepatozoon* spp. with primers described by Tabar et al. [18]. A positive (sequenced DNA of naturally infected cat) and negative (no DNA

added) control was added to each PCR. The PCR products were sequenced (Macrogen, Spain) in both directions with the same primers used in PCR. The sequences were compared with those already deposited in GenBank by BLAST software (https://blast.ncbi.nlm.nih.gov/Blast.cgi). Sequence analysis revealed the presence of *Hepatozoon silvestris* (100% homology, accession number: KY649445.1).

Epidemiological studies reported the detection of *H. silvestris* DNA in wildcats from Bosnia and Herzegovina [3, 21] and in domestic cats from northeastern [10], southern Italy [9] and central Europe [7, 11]. This study describes the case of a cat coming from a hilly area in northwestern Italy close to the Swiss borders, where a fatal case of myocarditis caused by *H. silvestris* in a cat was recently reported [7] and where the presence of wild felids such as the European lynx is frequently described [22, 23]. European lynx and wildcats are already reported as potential reservoirs of several parasites for domestic cat populations sharing the same context of living [10, 21, 24]. Even though in the northwestern Italian regions the presence of lynx and wildcats is rarely observed, the possibility that these animals cross the Alps from highly endemic territories such as neighboring France and Switzerland is probable, as already demonstrated in recent years [23].

The presence of the tick on the cat’s neck during the yearly routine examination (day -7) suggests that exposure to arthropod activity and the ingestion of infected ticks by the cat during fur grooming are possible. Unfortunately, the tick was removed and not conserved; thus, morphological identification and molecular investigations for detecting *Hepatozoon* DNA were not possible; in addition, no other ticks were found after the cat was treated with fipronil. The predation of infected prey, e.g. mostly rodents, was considered another possible route of *Hepatozoon* transmission [2, 5].
In domestic and wild cats, *Hepatozoon* causes a generally subclinical inflammation of skeletal muscles and myocardium [2, 19, 20] as well as elevated values of CPK enzyme in the majority of affected subjects [2, 16, 17]. This finding was observed in our case study, suggesting a potential involvement of skeletal muscles. In cats, the level of parasitemia is generally low and not correlated with the infection burden and the presence of meronts in muscle tissues, and the reason is not yet clear [16, 19]. Neutrophils containing gamonts are usually < 1% [2, 16], as observed in our blood smear evaluation. Specifically, rare gamonts were identified only in the blood smear performed during hospitalization; in all subsequent blood smears, not one gamont was observed.

The intestinal intussusception was generated by a sessile endoluminal nodule, which could have been due to (1) the inflammatory local response to the parasite's penetration through the intestinal mucosa and/or (2) an inflammatory process that was already present where the *Hepatozoon* found a good substrate for replicating. Considering the *H. canis* life cycle already described by Baneth et al. [4], the parasitic inclusions (15–25 µm) found in the histological sections of the sessile nodule, even if smaller than those reported in the literature, could be referred to as protozoan replicative forms such as meronts of *H. silvestris*, suggesting that the nodule was probably the first site of protozoan replication. In addition, the altered values of CPK and AST at day 0 suggested light skeletal muscle damage (i.e. subclinical myositis), as previously reported in cats with hepatozoonosis [16, 17], even if, in this particular case, inflammation of the intestinal muscle layer could be hypothesized. At day 0 circulating sodium and chloride concentrations were low probably because of vomiting. In addition, fructosamine concentration was increased and normalized a few days later; although unproven, it is possible that longstanding stress of the disease temporarily and mildly increased glucose levels. The

improvement of CPK immediately after surgery supports the hypothesis that the nodule was the source of the clinical signs. Finally, doxycycline therapy seemed to be helpful for the complete recovery of the cat. Other treatment protocols are reported in cats in the literature such as the combination of doxycycline with imidocarb, oxytetracycline with imidocarb and imidocarb dippionate with doxycycline [8, 17]. Actually, there were no controlled studies on the treatment of feline hepatozoonosis, and all information is anecdotal with debatable results. The choice to adopt only doxycycline was due to the difficulties of (i) the off-label use of imidocarb dippionate in Italy and (ii) finding imidocarb on the market easily and/or quickly.

Unfortunately, further histological investigations from other muscle sections and organs before and after treatment would have been useful to evaluate the skeletal muscle involvement, infection burden and efficacy of the treatment protocol but would have been unethical. In addition, the cat was treated to ensure its complete recovery without considering the novelty of Hepatozoon infection and the scientific publication.

Further investigations are needed to improve the scientific knowledge on Hepatozoon infections in felids, particularly in domestic cats, to prevent severe and potentially fatal clinical cases. Increased knowledge regarding the Hepatozoon life cycle in wild and domestic felids as long as arthropod vectors are involved would surely be useful for the adoption of adequate preventative measures in cats.

In conclusion, contrary to the other European case [7] in which H. silvestris caused fatal myocarditis in a domestic cat, in this report, the patient recovered completely after surgical removal of the “parasitic” nodule and monthly doxycycline therapy. The intestinal intussusception caused the sudden worsening of the clinical conditions, and surgical resolution was necessary to save the cat. However, the intestinal nodule was probably the result of a local inflammatory reaction to limit the Hepatozoon penetration, and it became the first site of protozoan replication; its surgical removal helped the cat to rapidly recover. Despite the unusual clinical presentation of this case, surgery should not to be the treatment of choice in every hepatozoonotic infections with intestinal signs and/or ultrasonographic abnormalities. Feline hepatozoonosis is an emerging vector-borne disease, and considering the recent reports of symptomatic cases, monitoring in cat populations is strongly advised.

Acknowledgements
We are grateful to Dr. Valter Fiore for his enthusiasm and help in chronologically reconstructing the facts of this particular clinical case.

Author contributions
VF and GSi followed the clinical case and provided all data regarding the cat from anamnesis to recovery; SMD performed hemato-biochemical analyses, LC and MEG performed histopathological evaluations; SMo, MG and GD performed DNA extraction and molecular analyses on nodule sections; GSi and EZ conceived and revised the manuscript; GSi wrote the manuscript draft. All authors read and approved the final manuscript.

Funding
This study was funded by the Department of Animal Medicine, Production and Health, University of Padova, Italy (BIRD193835, 2019).

Availability of data and materials
All data analyzed during this study are included in this published article.
