How Zwickly already ruled out modified gravity theories without dark matter

Various theories, such as MOND, MOG, Emergent Gravity and \(f(R)\) theories avoid dark matter by assuming a change in General Relativity and/or in Newton’s law. Galactic rotation curves are typically described well. Here the application to galaxy clusters is considered, focussed on the good lensing and X-ray data for A1689. As a start, the no-dark-matter case is confirmed to work badly: the need for dark matter starts near the cluster centre, where Newton’s law is still supposed to be valid. This leads to the conundrum discovered by Zwickly, which is likely only solvable in his way, namely by assuming additional dark matter. Neutrinos with eV masses serve well without altering the successes in (dwarf) galaxies.

1 Introduction

Niets is gewichtiger dan donkere materie

Dark matter enters the light in 1922 when Jacobus Kapteyn employs this term in his First Attempt at a Theory of the Arrangement and Motion of the Sidereal System [1]. It took a decade for his student Jan Oort to work out the stellar motion perpendicular to the Galactic plane, and to conclude that invisible mass should exist to keep the stars bound to the plane [2]. Next year, in 1933, Fritz Zwicky applied the idea to the Coma galaxy cluster and concluded that it is held together by dark matter. Interestingly, he starts with the expression \textit{dunkele (kalte) Materie} [(cold) dark matter, (C)DM] [3], which is now popular but just referred to cool and cold stars, macroscopic and microscopic bodies and gases [4]. The subject nevertheless remained dormant until Vera Rubin and collaborators demonstrated that galactic rotation curves flatten [5], while for many the definite proof for the existence of DM came from the Bullet Cluster [6]. In principle, the galactic and cluster DM can be different, so we may speak of Oort DM, baryonic or not, and nonbaryonic Zwicky DM.

Presently, it is assumed that both types of DM coincide. The standard model of cosmology ΛCDM is very successful in explaining the WMAP and Planck data [7, 8], so ΛCDM is rightfully a good effective theory. But is it a fundamental theory? Many puzzling observations make this nonevident. The CDM particle, the WIMP, if it exists, keeps on hiding itself 6 more years since its “moment of truth” [9]. One observes 19 quasars with spins aligned with their hosts large-scale structures on a scale of almost 1 Gpc [10] and dozens of radiojets from AGNs aligned on a scale of 30 Mpc [11]. A ring (actually, a spiral) of 9 gamma ray bursts extends over nearly 2 Gpc [12]; the “cosmic train wreck” galaxy cluster A520 has a central \(3 - 4 \times 10^{13} M_\odot\) mass clump with mass-to-light ratio \(800 M_\odot/L_\odot\) [13–16]; in the cluster A3827 the offset between baryonic and dark mass [17] is an order of magnitude “too large” [18].

Puzzles in galaxies include: the brightness fluctuations in the Twin Quasar allow a DM interpretation in terms of a large halo of free floating planets in the lensing galaxy [19]; the observed satellites

of the Galaxy lie in a plane, not in random ΛCDM directions [20]; the predicted transition for the most massive galaxies to transform from their initial halo assembly at redshifts \( z = 8 - 4 \) to the later baryonic evolution known from star-forming galaxies and quasars is not observed [21]; the galaxy power spectrum deduced from SDSS-III observations fits well to the stretched exponential \( \exp[-(k/k_0)^{1/2}] \) from turbulence [22]. Various further arguments can be found in our investigations [23, 24].

Consequently, various studies consider other explanations for the DM effect. One option is that, beyond a certain scale, the force gets enhanced with respect to the Newton law. The best known case is MOdified Newtonian Dynamics (MOND), where \( g_{\text{inv}} \), the Newtonian gravitational acceleration due to the baryonic matter, gets replaced by \( a = \sqrt{g_{\text{inv}}/a_0} \) in the domain \( g_{\text{inv}} < a_0 \), where the crossover acceleration is \( a_0 = cH_0/2\pi \) [25]. In essence, this replaces the Newton fall of \( g_{\text{inv}} = GM/r^2 \) by an effective fall off \( a = \sqrt{GM}/r \), which implies a flattening of the rotation curve, \( v \rightarrow \text{const for large } r \), as observed in galaxies. The approach acts as a faithful prediction for the rotation velocity based on the knowledge of the baryonic matter, that is, stars, brown dwarfs, Jupiters, clouds, etc. It achieves a scaling for a collection of rotation curves and explains the baryonic Tully-Fisher relation \( M \sim v_{\text{rot}}^4 \) [26].

Related deviations from Newton’s law are MOG [27] and \( f(R) \) gravity [28, 29], while Emergent Gravity [30] also leads to a variant of MOND. These non-Newtonian gravities have mainly been used to explain Oort DM, while MOND is known to need neutrinos in clusters [31–33].

In recent years we have made a series of studies for the case of neutrinos as Zwicky DM, specialising to the cluster Abell 1689, for which good lensing and gas data are available [34–36]. This leads to a perfect fit without missing baryons for a neutrino mass of 1.9 eV [37], a case consistent with the 2 eV upperbound from tritium decay [36, 37] and, if cosmic structure formation is nonlinear, not excluded beforehand by neutrino free streaming.

We now use the A1689 data to investigate the alternative gravity theories in their application to Zwicky DM. In section 2 we describe the data sets to be employed and in section 3 the quantities related to them. In section 4 we analyse the Newton acceleration of the normal (baryonic) matter in comparison with estimates from the lensing data. In the next sections we study in detail the application to MOND, MOG, Emergent Gravity and \( f(R) \) theories, respectively. We close with a discussion.

2 Data description

Lensing properties of A1689 are expressed by strong lensing (SL), that is, background galaxies for which the ideal Einstein ring is partly achieved as a set of arclets, up to 5 of them appear to be connected to a common source galaxy. Further information comes from weak lensing (WL): randomly oriented background galaxies get a systematic deformation (shear) which is distilled by averaging over the galaxies in a small field. Finally, X-ray observations yield the electron density and thus the gas mass density.

All our results are scaled to the flat ΛCDM cosmology with \( \Omega_M = 0.3 \), \( \Omega_{\Lambda} = 0.7 \), and a Hubble constant \( H_0 = 70h_70 \) km s\(^{-1}\) Mpc\(^{-1}\) with \( h_70 = 1 \). At the redshift \( z = 0.183 \) of the A1689 cluster, 1″ corresponds to 3.035 kpc.

2.1 Strong and weak lensing

We collect data from the literature. The SL analysis by Limousin et al. (2007) yields data for the line-of-sight mass density \( \Sigma(r) \) at radii between 3 and 271 kpc from the cluster centre [38]. The resulting 12 data points \( (r_i, \Sigma_i) \) and their correlation matrix were kindly supplied by M. Limousin; see [36] for the regularisation of the small eigenvalues. Essentially the same regime is covered by the SL analysis of Coe et al. (2010) [39], which has 20 data points; these two data sets overlap in the window between 40 and 150 kpc with both having small errors, giving faith in the approaches. However, discrepancies occur at small \( r \): Coe et al. have 3 data points below 40 kpc while Limousin et al. have there 6 data points with smaller errors. Beyond 150 kpc the Coe data become increasingly noisy. These differences stem from the different analysis and/or the neglect of correlations. Umetsu et al. (2015) present 14 data points for \( \Sigma \) between 125 kpc and 3 Mpc, derived mainly from WL [40], and kindly supplied by K. Umetsu, with their correlation matrix. These data have mostly substantially bigger errors than both previous sets, but are complementary and coincide within the error bars in the region where they overlap, again giving credit in the results.

Data for the WL shear \( g_s \) for radii between 200 kpc and 3 Mpc have also been presented in Umetsu et al. (2015). K. Umetsu has kindly generated for us a logarithmic binning in 13 data points in the way outlined in [41]. The resulting data agree well with the data of [41], but have less scatter.
2.2 X-ray gas

The gas data, kindly supplied to us by A. Morandi, stem from 2 CHANDRA X-ray observations with a total exposure time of 150 ks, presented in [42]. In the energy range 0.5–5.0 keV the vignetting-corrected brightness image is extracted from the 2 files. In a non-parametric way the gas density profile is recovered by rebinning the surface brightness into circular annuli and by spherical deprojection [38]. Fig. 1 exhibits the resulting 56 data points with 10 kpc < r < 1 Mpc. The Sérsic mass profile \( \rho = \rho_0 \exp[-(r/R_0)^{1/n_e}] \) gave inspiration for a cored Sérsic electron density (and, hence, gas mass) profile [37],

\[
 n_e(r) = n_e^0 \exp \left[ k_g - k_g \left( 1 + \frac{r^2}{R_g^2} \right)^{1/n_e} \right]. \tag{1}
\]

It appears to work well and has the best fit parameters \( n_e^0 = 0.0670 \pm 0.0027 \text{ cm}^{-3} \), \( k_g = 1.98 \pm 0.25 \), \( R_g = 21.6 \pm 2.7 \text{ kpc} \) and \( n_g = 2.97 \pm 0.14 \). The \( n_e \) error bars are asymmetric. The average errors of the \( n_e \) lead to \( \chi^2/\nu = 2.08 \); for the conservative maximum of upper and lower errors, \( \chi^2/\nu = 1.72 \). With \( \nu = 52 \) this yields the marginally acceptable \( q \)-value 9.10^{-4} of our spherical approximation.

Let us mention that \( n_e(r) = n_e^0(1 + r^2/R_g^2)^{-3/2} \), the popular “\( \beta \)-model”, yields a lousy best fit, \( \chi^2/\nu = 6.3 \).

Furthermore, data for \( n_{1e} \) have been obtained from the smaller ROSAT satellite with its less sensitive PSPC camera [43]. Given that \( n_{1e} = n_{1l}/12 \) when \(^4\)He occurs with 25% in mass, the connection is \( n_e = 7n_{1l}/6 \). As \( r \)-values we take the mid of the bins and as \( \Delta r \) their (mostly quite large) half widths. As seen in Fig. 1, the 14 ROSAT data have a big spread in \( r \), but lie at large \( r \) near the cored Sérsic profile. The \( \chi^2 \) fit is not ruined when including \( \min(\{n_{e1} - n_{e}(r)\})^2/\Delta n_{e1}^2, \{r - r(n_e(r))\})^2/\Delta r^2 \) for its last 6 points, where \( r(n_e) \) is the inverse of \( n_e(r) \) in (1). Now \( \nu = 58, \chi^2/\nu = 1.69, q = 8 \times 10^{-4} \). The resulting best fit is sharper,

\[
 n_e^0 = 0.0673 \pm 0.0027 \text{ cm}^{-3}, \quad k_g = 1.90 \pm 0.20.
 R_g = 21.2 \pm 2.4 \text{ kpc}, \quad n_g = 2.91 \pm 0.11. \tag{2}
\]

For a typical \( Z = 0.3 \) solar metallicity the gas mass density is \( \rho_g(r) = 1.167 m_N n_e(r) \) [34].

3 The observables

Because the background galaxies are far removed from the cluster, the lensing effects can be thought of as occurring due to mass projected onto the plane through the cluster centre. Hence the SL analysis yields data for the mass density accumulated along the line-of-sight,

\[
 \Sigma(r) = \int_{\infty}^{\infty} \text{d}r \left( \sqrt{r^2 + z^2} \right). \tag{3}
\]

In terms of the gravitational potential \( \phi \) it reads [34]

\[
 \Sigma(r) = \frac{1}{2\pi G} \int_{0}^{\infty} \text{d}s \cosh 2s \left[ \phi(r\cosh s) - \phi(r) \cosh^2 s \right]. \tag{4}
\]

Next, one defines the 2d mass, that is, the mass contained in a cylinder of radius \( r \) around the sight line, \( M_{2d}(r) = 2\pi \int_0^r s \Sigma(s) \) and its average over the disk, \( \bar{\Sigma}(r) = M_{2d}(r)/\pi r^2 \). This quantity can be expressed in \( \rho \) as

\[
 \bar{\Sigma}(r) = \frac{4}{r^2} \int_{0}^{r} \text{d}s s^2 \rho(s) + \int_{r}^{\infty} \text{d}s \frac{4\phi(s)}{s + \sqrt{s^2 - r^2}}, \tag{5}
\]

and in terms of \( \phi \) as [34]

\[
 \bar{\Sigma}(r) = \frac{1}{\pi G} \int_{0}^{\infty} \text{d}r \phi(r\cosh s). \tag{6}
\]

As imposed by their connections to \( M_{2d} \), the relation \( \Sigma(r) = \bar{\Sigma}(r) + \frac{1}{2} \Sigma' \bar{r}(r) \) can be verified from (4) and (6).

In a WL analysis one determines the shear \( g_\tau \), which relates to these quantities as

\[
 g_\tau(r) = \frac{\bar{\Sigma}(r) - \Sigma(r)}{\Sigma_c - \Sigma(r)}, \tag{7}
\]

where \( \Sigma_c \) is called critical density. It is fixed in the data analysis, because the observed galaxies must be connected to a fiducial common redshift \( \bar{z} \). Its values are
\[ \Sigma_c = (0.973, 0.579, 0.679) \text{ gr/cm}^{-2} \text{ for the data of [38], [39] and [40], respectively.} \]

### 3.1 Galaxies

By definition, a galaxy cluster contains many galaxies, which have large mutual separations. In the centre, the galaxy mass density is dominated by the often huge brightest cluster galaxy (BCG, “central galaxy” \(cg\)). Outwards, the thermal dark matter will be dominant up to a few hundred kpc, from where on the gas density becomes relevant too.

Limousin et al. propose a BCG distribution with mass \(M_{cg}\), core \((co)\) size \(R_{co}\) and extent \(R_{cg}\) of the form [44]

\[
\rho_G(r) = \frac{M_{cg}(R_{co} + R_{cg})}{2\pi^2(r^2 + R_{co}^2)(r^2 + R_{cg}^2)}. \tag{8}
\]

If \(R_{co} \ll R_{cg}\) it resembles a cored isothermal distribution between these scales. Its gravitational potential reads

\[
\varphi_G(r) = \frac{2GM_{cg}}{\pi(R_{cg} - R_{co})} \left( \frac{R_{co}}{r} \arctan \frac{r}{R_{co}} - \frac{R_{cg}}{r} \arctan \frac{r}{R_{cg}} \right) + \frac{1}{2} \log \left( \frac{1 + r^2/R_{co}^2}{1 + r^2/R_{cg}^2} \right), \tag{9}
\]

where here and below we take all \(\varphi = 0\) at \(r = 0\). There holds an explicit result for the line-of-sight mass density,

\[
\Sigma_G(r) = \frac{M_{cg}}{2\pi(R_{cg} - R_{co})} \left( \frac{1}{\sqrt{R_{co}^2 + r^2}} - \frac{1}{\sqrt{R_{cg}^2 + r^2}} \right), \tag{10}
\]

as well as for the 2d mass density,

\[
\Sigma_G(r) = \frac{M_{cg}}{\pi r^2} \left( 1 - \frac{R_{co} + R_{cg}}{\sqrt{R_{co}^2 + r^2} + \sqrt{R_{cg}^2 + r^2}} \right). \tag{11}
\]

### 4 Newton acceleration of normal matter

The 2d-mass, the mass inside a cylinder along the sightline of radius \(r\), relates to \(\Sigma\) as \(M_{2d}(r) = \pi r^2 \Sigma(r)\). With \(M(r) \leq M_{2d}(r)\) the Newton acceleration can be bounded,

\[
a(r) \equiv \frac{GM(r)}{r^2} \leq \frac{GM_{2d}(r)}{r^2} = \pi G \Sigma(r). \tag{12}
\]

While at \(r = 0\) one has \(\Sigma(0) = \Sigma(0)\), an isothermal decay \(\rho \sim 1/r^2\) yields \(\Sigma(r) = \frac{1}{2} \Sigma\) at large \(r\). Our interest being in the latter region, we can use data for \(\Sigma\) as a bound on \(a\),

\[
a(r) \leq 2\pi G \Sigma(r). \tag{13}
\]

Likewise, data for the transversal shear given by

\[
g_t(r) = \frac{\Sigma(r) - \Sigma(r)}{\Sigma - \Sigma(r)} \tag{14}
\]

can be used at large \(r\), where \(\Sigma(r) \ll \Sigma_c\), to estimate

\[
a(r) \leq 2\pi G \Sigma_c g_t(r). \tag{15}
\]

Figure 2 shows that the predictions (13) and (15) indeed lie above the \(a\) values from the fit of the NFW profile to the \(\Sigma\) data sets of Refs. [39, 40] and the \(g_t\) data [40]; the same would happen for the [38, 40] and [40] data sets. Figure 2 also shows the fit of our neutrino model [37] to the latter data sets. It is seen that beyond (before) \(r = 200\) kpc the fits lie near (well below) the estimates (13) and (15).
5 Newton gravity without dark matter

The full line in Figure 2 (the lower line) depicts the Newton acceleration due to the baryons alone, that is: the galaxies and the X-ray gas. For $r > 100$ kpc it lies an order of magnitude below the estimates (13) and (15) and below the NFW and neutrino fits. This forecasts a bad fit for Newton gravity without dark matter.

So let us quantify this and study the minimisation of $\chi^2$. While the X-ray data are confined by observations, the parameters of the BCG profile are obtained from a best fit. If we fix the BCG mass at a typical value of $M_{\text{BCG}} = (3 - 4)10^{13} M_\odot$ and optimise over $R_o$ and $R_\phi$, we get $\chi^2/v$ values of order 80-100, a failing fit. When we let $M_{\text{BCG}}$ free, this has the danger of run off to a “best” fit with unphysical parameters. If we look for the optimal fit we can achieve even the very good $\chi^2/v \sim 1.2$ when fitting the SL data of Coe with the SL and WL data of Umetsu, but this is suspicious, since the sharper SL data of Limousin combined with the SL and WL data of Umetsu would lead to a bad value $\sim 4$. Anyhow the fit brings $M_{\text{BCG}} \sim 1 - 2 \times 10^{15} M_\odot$, basically the mass of the whole cluster. Clearly, the BCG profile tries to model the missing dark matter. This, however, is unphysical and unwanted, since for that case much better modelling is achieved by NFW or our neutrino model [37]. Not surprisingly, when the inner and outer scale of the BCG are kept fixed at realistic values (e.g. 5 and 130 kpc, respectively), $M_{\text{BCG}} \sim 10^{13-14} M_\odot$ stays acceptable, but the fit $\chi^2/v \sim 7$ is lousy.

6 MOdified Newtonian Dynamics (MOND)

To solve the conundrum of flat rotation curves, it has been proposed that instead of dark matter to exist, Newton’s law should be modified in the regime of small acceleration. M. Milgrom proposes to take $g = \sqrt{a_0 \rho_m}$ for $g_m < a_0$, where $a_0$ is some scale of order $cH_0/2\pi$. When $g_m$ is written as $GM_F(r)/r^2$ with $M_F(r)$ the enclosed baryonic mass inside a sphere of radius $r$, $g$ will decay as $1/r$, which corresponds to a limiting rotation speed $v_{\text{rot}}(\infty) = [a_0 GM_F(\infty)]^{1/4}$. Reversely, the relation $M_F(\infty) \sim v_{\text{rot}}^4(\infty)$ is called the baryonic Tully-Fisher relation, and is satisfied reasonably well [26].

It has been long realised that MOND does not function well in clusters, and that it must be augmented with neutrinos to do so [31–33]. We shall test this in detail on the rather precise data for A1689.

In MOND the Poisson equation is modified to

$$\nabla \cdot \left\{ \mu \left( \frac{g}{a_0} \right) g \right\} = 4\pi G \rho_m$$

where $g = \nabla \phi$ and $g = |\mathbf{g}|$ and $\rho_m$ is the mass density of the normal matter, baryons and possibly neutrinos.

$$a_0 = \frac{4cG\rho_c}{3H_0} = \frac{cH_0}{2\pi} = 1.14 \times 10^{-10} \text{ms}^{-2}$$

The MOND function $\mu(y)$ goes to unity at large $y$ (large acceleration leading to Newton gravity), while $\mu \rightarrow 1$ at small $y$. We adopt the most common shape

$$\mu(y) = \frac{y}{1 + y^2}.$$  \hspace{1cm} (18)

In case of spherical symmetry Eq. (16) reads

$$\mu' \left[ \frac{\psi'}{a_0} \right] \frac{\psi''}{a_0} + \mu \left[ \frac{\psi'}{a_0} \right] \left( \psi'' + \frac{2}{r} \psi' \right) = 4\pi G \rho_m$$

Relating $\rho_m$ to the Newton potential $\varphi_m$ by the Poisson equation $\varphi'' + \frac{2}{r} \varphi' = 4\pi G \rho_m$, eq. (19) can be integrated, to become $\psi' = \sqrt{\varphi'' + 2\varphi' a_0} = \varphi_m'$. Inversion yields

$$\varphi' = \frac{1}{2} \varphi'_m + \frac{1}{2} \sqrt{(\varphi'_m)^2 + 4a_0 \varphi'_m}.$$  \hspace{1cm} (20)

Writing $\varphi'_m = g_m$, there result two first order equations,

$$\varphi' = \frac{1}{2} g_m + \frac{1}{2} \sqrt{g_m^2 + 4a_0 g_m}, \quad g'_m = \frac{2}{r} g_m = 4\pi G \rho_m.$$  \hspace{1cm} (21)

Since MOND primarily deals with the forces on massive bodies, one still has to theorise how light will propagate, see [45, 46]. We do not need to go that far. Since most of the A1689 cluster will turn out to be in the Newtonian regime, and one assumes that MOND satisfies the same post-Newtonian corrections as General Relativity, light propagation is basically, or even fully, set by the equivalence principle. With light rays moving in the gravitational potential $\varphi$, we can use the relation (4) for $\Sigma$ and (6) for $\Sigma$.

6.1 Baryons only

When matter consists only of baryons, Galaxies and X-ray gas, $\rho_m = \rho_G + \rho_g$ is explicit and the equations (21) can be solved straightforwardly. The role of the MOND parameter $a_0$ appears to be modest, and the fit to the data is very similar to the case of the pure Newton force, i.e., the limit $a_0 \rightarrow 0$. Again, the fit is very bad, except when we allow the central galaxy profile to mimic dark matter, in which case to fit is less bad but not optimal.
6.2 Adding neutrinos

It is well known that the MOND theory for clusters can be repaired by adding neutrinos [31–33]. We will now consider in how far this works for the precise data of A1689.

Neutrinos, like other particles, will move in the MOND force field. Let us assume, for simplicity, that they have equal masses and occupations, with their distribution having (basically or exactly) the standard equilibrium form,

$$\rho_\nu(r) = \int \frac{d^3p}{(2\pi \hbar)^3} \exp\left(\frac{i}{\hbar} \mathbf{p} \cdot \mathbf{v}(r) - \mathbf{p} \cdot \mathbf{\mu}/\sigma^2\right) + 1,$$  \hspace{1cm} (22)$$

where $g$ is the number of fermionic species ($g = 6$ for the active (anti)neutrinos), $m_\nu$ their common mass, $\mathbf{p} = m_\nu \mathbf{v}$ the momentum, $\mathbf{v}$ the velocity, $\mathbf{\mu}$ the chemical potential per unit mass and $\sigma$ the velocity dispersion. In (21) there now occurs $\rho_m = \rho_G + \rho_E + \rho_\nu$, with the latter having the form $\rho_\nu(r) = \rho_\nu [\varphi(r)]$. This couples the differential equations nontrivially, without changing their structure.

It appears that in the cluster the effect of $a_0$ remains very small in the presence of neutrinos. The fit of Eqs. (21) with $a_0 = cH_0/2\pi$ appears not to change within the error bars of the $a_0 = 0$ case of Ref. [37]. The physical reason is, again, that the $r > 1$ Mpc region, where non-Newtonian effects become relevant, has little statistical weight.

For $a_0 = 0$ we recall the most important results from the fit to the neutrino model in [37]. The BCG mass is

$$M_G = 3.2 \pm 1.0 \times 10^{13} M_\odot.$$  \hspace{1cm} (23)$$

The cluster yields a result for $g m_\nu^4$ since $d^3 p = m_\nu^4 d^3 \nu$ in Eq. (22). The resulting mass of the particle is

$$m_\nu = 1.92^{+0.13}_{-0.16} \left(\frac{12}{g}\right)^{1/4} \text{eV} \hspace{1cm} (24)$$

which must refer to active and/or sterile neutrinos.

For overdensities 500 and 200 the solution implies

$$r_{500} = (1.7 \pm 0.2) \text{ Mpc}, \hspace{1cm} M_{500} = (1.4 \pm 0.1) \times 10^{15} M_\odot,$$

$$r_{200} = (2.5 \pm 0.2) \text{ Mpc}, \hspace{1cm} M_{200} = (1.8 \pm 0.1) \times 10^{15} M_\odot.$$  \hspace{1cm} (25)$$

7 MOdified Gravity (MOG)

Also the MOdified Gravity (MOG) theory of J. Moffat attempts to do without DM [27]. The description of 106 clusters has been discussed in [32]; we single out the application to A1689. As noted above, the employed modelling of the gas density by a $\beta$-profile is bad. At $r = 0$ the value $\rho_\nu/1.17 m_\nu = 0.0168/cm^3$ is a factor 4 below our $n_\nu^0$ in (2) and the $\beta$-profile of [32] is globally rejected by the Chandra data at dozens of standard deviations.

In cluster centres the deviation of MOG from Newton theory is non-negligible, but adjustment of the BCG parameters allows a reasonable fit. Far out, MOG enhances the Newton force by a factor $1 + \omega = 9.89 \pm 0.34$ [47], which works reasonably. But in the intermediate range between 50 and 300 kpc the data for $\Sigma$ are poorly matched. To save the theory, an extra ingredient is needed. On the basis of previous section, we expect that the introduction of additional matter, such as neutrinos, can do the job.

8 Emergent Gravity (EG)

8.1 Generalities

E. Verlinde proposes that gravity emerges from an underlying “polymer” structure of space-time [30]. As discussed in a publicly available master thesis [48], one equates in this “emergent gravity” the gravitational field energy of dark matter inside a sphere of radius $R$

$$\frac{1}{8\pi G} \int \mathbf{d}^3 r \left(\nabla \varphi_d\right)^2$$

(26)

to the enclosed mass of normal matter, $M_m(R)$, times $c$ times the expansion speed at its border, $H_0 R/4\pi$. Inserting $\nabla \varphi_d = G M_d(r)/r^3$ one arrives at the central relation

$$\int_0^R dr \frac{G M_d^2(r)}{2r^2} = M_m(R) \frac{cH_0 R}{4\pi}.$$  \hspace{1cm} (27)$$

Taking the derivative with respect to $R$ leads to

$$M_d(r) = r \sqrt{\frac{a_0}{G} \left[M_m(r) + 4\pi r^3 \rho_m(r)\right]}.$$  \hspace{1cm} (28)$$

8.2 Lensing test

We first express the above in a more suitable form. With $g_m = \varphi_m = GM_m/r^2$ and $\varphi_d = GM_d/r^2$, Eq. (28) implies
that the total EG potential \( \varphi = \varphi_m + \varphi_d \) and \( g_m \) satisfy
\[
\varphi' = g_m + \sqrt{a_0(g_m + 4\pi G\rho_m)}, \quad g'_m = 2G \rho_m = 4\pi G \rho_m, 
\]
(29)
to be compared to the expressions (21) for MOND.

Due to the equivalence principle, light rays move in the gravitational potential \( \varphi \), so Eqs. (4) and (6) are valid. Neutrinos do the same, hence Eq. (22) is well motivated.

The fit to the data is as in the MOND case, because also in the EG case, the role of \( a_0 \) is almost negligible in the A1689 cluster. In the case where matter consists only of baryons, the fit does not seriously differ from the one with the pure Newton force, and suffers from the severe problems explained in section 4 and summarised in fig. 2.

If massive neutrinos are present, a very good fit can be achieved, not differing within the error bars from the neutrino fit in Newton theory or MOND theory. The results are essentially the same as in eqs. (23) and (24).

9 Gravitational potential in \( f(R) \) theories

In a modification of general relativity one replaces in the Hilbert-Einstein action the curvature scalar \( R \) by some function \( f(R) \), hence the name of these theories. On the basis of this, a modification of Newton’s law has been proposed, where the gravitational potential \( \varphi \) deviates from the Newton potential \( \varphi_m \) in the form [49]
\[
\varphi(r) = \frac{1 + \delta e^{-r/R}}{1 + \delta} \varphi_m(r), \quad \varphi'' + \frac{2}{r} \varphi' = 4\pi G \rho_m, 
\]
(30)
where \( \rho_m \) is the matter density. We consider the interval \(-1 < \delta < 0\) where this enhances \( \varphi_m \) at \( r \gg R \), allowing to mimic dark matter effects. Indeed, a value \( \delta \approx -0.98 \) is employed to fit cosmological data [49]. But the derivative
\[
\varphi'(r) = \frac{1 + \delta e^{-r/R}}{1 + \delta} \varphi'_m(r) - \frac{\delta e^{-r/R}}{(1 + \delta)R} \varphi_m(r), 
\]
(31)
involves both \( \varphi'_m > 0 \) and \( \varphi_m < 0 \), so for \(-1 < \delta < 0\) the second term counteracts the enhanced gravity one searches for, and even exhibits an “anti-gravity” effect: at small \( r \), where \( \varphi'_m(r) = 4\pi G \rho_m(r)/3 \) and \( \varphi_m(0) < 0 \), Eq. (31) involves a domain with \( \varphi' < 0 \). One may even wonder whether the second term in (31) is admissible on principle grounds. Indeed, rewriting (6) as
\[
\Sigma(r) = \frac{1}{\pi G} \int_r^{\infty} \frac{du}{\sqrt{u^2 - r^2}} \psi(u), 
\]
(32)
It is seen that \( \Sigma(r) \sim |\varphi_m(0)|\delta/\pi GR(1 + \delta) \) log \( r \) goes to minus infinity for \( r \to 0 \) when \(-1 < \delta < 0\). Because of the relation \( \Sigma = \Sigma + 1/2 R \delta \), which holds between (4) and (6) for any smooth \( \varphi(r) \), it follows that also \( \Sigma(r) \) becomes negative at small \( r \), which is excluded by the data at many standard deviations. Indeed, numerical fits are truly bad.

However, in view of the arguments of previous sections, it is unlikely that \( f(R) \) theories with \( \varphi'(0) = 0 \) can achieve an acceptable match with the data of the A1689 cluster. But it is possible that such \( f(R) \) theories, which next to baryons, also have heavy neutrinos, fare better.

10 Discussion

Modifications of Newton’s law, such as MOND, MOG, Emergent Gravity and \( f(R) \) theories have been (partly) motivated by the wish to avoid dark matter (DM). For galaxies, this works quite well, in particular for MOND. For the A1689 cluster it appears not to work, [31–33, 50]. There seems to be no way to sail between the Scylla of Newton theory in the centre and the Charybdis of the need for DM at some 50 kpc out of the centre. So while these alternative theories can do without Oort (galactic) DM, they need still normal Zwicky (cluster) DM. We have confirmed for MOND, shown for Emergent Gravity and coined for MOG and \( f(R) \), that eV neutrinos can do the job.

It is broadly assumed that active neutrinos are very light \( m_\nu \lesssim 0.1 \text{ eV} \). In this scenario our massive neutrinos are sterile. There is no reason to assume, as we did in [37] and here, that their masses are equal to each other, but our results will still be indicative.

It is also possible that the active neutrinos (the standard ones) have such an eV mass. Then our results are more indicative. Firstly, because of the small neutrino oscillation effects, all active neutrino masses are basically equal. Then the non-observation of neutrinoless double \( \beta \)-decay implies that the active \( \nu_e \) are (nearly) of Dirac type [37], so that each active neutrino has a sterile, right handed partner of (nearly) the same mass. Just using the Planck cosmic dark matter fraction, even though based on WIMPs while the true DM would be neutrinos, this implies a neutrino mass \( m_\nu = (1.861 \pm 0.016) \text{ eV} \) [37], which will be tested soon at KATRIN [51].

The Pauli principle for eV may explain the offset between dark and normal matter in A3827 and the central dark clump in A520 [37].

Our analysis shows that, if sterile and/or active neutrinos have eV-scale masses, the A1689 data will hardly discriminate between (non-)Newtonian gravity theories.
Acknowledgements. We thank M. Limousin, A. Morandi, K. Umetsu and D. Eckert for supplying data.

Key words. MOND, MOG, $f(R)$, Emergent Gravity, galaxy cluster, Abell 1689, dark matter, neutrinos.
