How to get from imaginary to real chemical potential

Using the exactly solvable Gross-Neveu model as theoretical laboratory, we analyse in detail the relationship between a relativistic quantum field theory at real and imaginary chemical potential. We find that one can retrieve the full information about the phase diagram of the theory from an imaginary chemical potential calculation. The prerequisite is to evaluate and analytically continue the effective potential for the chiral order parameter, rather than thermodynamic observables or phase boundaries. In the case of an inhomogeneous phase, one needs to compute the full effective action, a functional of the space-dependent order parameter, at imaginary chemical potential.

I. INTRODUCTION

Progress in understanding the phase diagram of quantum chromodynamics (QCD) at finite temperature and chemical potential is hampered by the sign problem: A real chemical potential yields in general a complex fermion determinant, thereby rendering the standard Monte-Carlo algorithms inapplicable. One interesting idea to overcome this problem is to compute at imaginary chemical potential where the sign problem is absent. An imaginary chemical potential is primarily a formal trick. Nevertheless, it has two physical interpretations we are aware of:

1) The grand canonical partition function

\[ Z_{gc}(T, \mu) = \text{Tr} e^{-\beta(\hat{H} - \mu \hat{N})} \quad (\beta = 1/T) \]  

at imaginary \( \mu \) can be viewed as Fourier transform of the canonical partition function

\[ Z_c(T, N) = \text{Tr} \left( e^{-\beta \hat{H}} \delta(\hat{N} - N) \right) \]

with respect to fermion number,

\[ Z_c(T, N) = \int_{-\pi}^{\pi} \frac{d\theta}{2\pi} e^{-iN\theta} Z_{gc}(T, \mu = i\theta/\beta). \]

Since the canonical partition function yields any thermodynamic observable, it seems at first sight that the sign problem has been overcome. Unfortunately, this point of view is rather academic. A numerical Fourier transform for large volumes and particle numbers is out of question, as it would require exponentially increasing accuracy. Although this method has been applied successfully to small systems, the thermodynamic limit cannot be reached. The only known way of evaluating integrals with extremely rapidly varying integrand is the saddle point method. The saddle point is the solution of

\[ \frac{\partial}{\partial \theta} \left\{ i\theta N + \beta \Psi(T, i\theta/\beta) \right\} = 0 \]

with \( \Psi \) the grand canonical potential,

\[ \Psi(T, \mu) = -\frac{1}{\beta} \ln Z_{gc}(T, \mu) \]

Since \( \Psi \) is an even function of \( \mu \) or \( \theta \) due to CP invariance, Eq. 4 cannot have a real solution for \( \theta \). Thus evaluation of the integrand at the saddle point takes us back to the original problem of chemical potential with a real part, and nothing has been gained.

2) A second physical interpretation arises if we invoke the so-called temperature inversion symmetry. Due to covariance, the partition function at inverse temperature \( \beta \) for a system with one compact space dimension is invariant under exchange of space and imaginary time, provided one uses periodic (anti-periodic) boundary conditions for bosons (fermions),

\[ Z(\beta, L) = Z(L, \beta). \]

If one takes the limit \( L \to \infty \), one can relate a hot, extended system to a cold, compressed system, e.g. the free energy is related to the Casimir (ground state) energy. An imaginary chemical potential can be "gauged away" by a space-dependent phase transformation of the fermion fields \( (L = \beta) \),

\[ \psi'(x) = e^{i\theta x/L} \psi(x). \]

Like a magnetic field in an extra dimension, this changes the boundary conditions in the compact direction from anti-periodic to quasi-periodic ones,

\[ \psi'(L) = -e^{i\theta} \psi'(0) \]

interpolating between fermionic \((\theta = 0)\) and bosonic \((\theta = \pi)\) boundary conditions. Phase transitions as a function of imaginary chemical potential in the original system go over into quantum phase transitions as a function of the boundary condition (or the fictitious magnetic field).
The 2nd point of view gives a physical picture, but no clue as to how to get from imaginary to real \( \mu \). The first one suggests such a pathway which however is illusionary. In practical lattice calculations, the following strategy has usually been adopted \[3, 4, 11, 12, 13\]: One tries to determine observables or phase boundaries by analytic continuation from imaginary to real \( \mu \). Typically, one evaluates some function of \( \mu \) at imaginary \( \mu \), fits it by a low order polynomial (or a ratio of polynomials \[13, 14\]) and then uses it at real chemical potential. The main drawback here are the limitations due to singularities in the complex plane. Moreover, there does not seem to be any way to follow a phase boundary beyond a tricritical point, so that the phase diagram cannot be fully reconstructed, no matter how much effort is invested at imaginary \( \mu \).

In the case of QCD, very little is known about the analytic structure of the thermodynamic potential in the complex \( \mu \) plane. Besides, even calculations at imaginary \( \mu \) suffer from limited accuracy and numerical noise. In order to gain more insight into the problem of how to use imaginary \( \mu \)-computations most efficiently to learn about the real world, we propose to look at a simple, solvable model field theory. We choose the Gross-Neveu (GN) model in 1+1 dimensions \[15\] where in the large \( N \) limit all thermodynamic observables can easily be computed at both real and imaginary chemical potential, to any desired accuracy. Nevertheless the phase diagram at real \( \mu \) is non-trivial, sharing qualitative properties with QCD (see \[15\] for a recent review). We then pretend that we are only able to compute all quantities at imaginary \( \mu \) and try to extrapolate them to real \( \mu \), controlling our procedure against the exact results at each step. In this way, we are able to come up with a scheme which allows to overcome some of the limitations mentioned above and suggests some future work in lattice QCD.

This paper is organized as follows. In Sect. II, we briefly consider free massless fermions in 1+1 dimensions where everything can be done analytically. This serves to illustrate the general principles in a fortunate case where there is no phase transition and all analytic continuations can be done in closed form. In Sect. III, we consider massive free fermions. After these preparations, we turn to the GN model in Sect. IV. We apply the common procedure of analytically continuing the phase boundary and show how to go beyond that. We restrict ourselves to the translationally invariant solution with homogeneous condensates. In Sect. V we briefly contemplate the recently found inhomogeneous phase (soliton crystal) of the GN model and investigate whether one could find it at all with imaginary \( \mu \). In Sect. VI we summarize our findings and draw some conclusions concerning lattice QCD calculations.

### II. FREE MASSLESS FERMIONS IN 1+1 DIMENSIONS

Our starting point is the grand canonical (gc) potential density at real chemical potential, regularized via an UV momentum cutoff,

\[
\psi = -\frac{1}{\beta \pi} \int_0^{\Lambda/2} \mathrm{d}k \ln \left[ (1 + e^{-\beta(k-\mu)}) (1 + e^{\beta(k+\mu)}) \right]
\]

\[
= -\frac{\Lambda^2}{8\pi} - \frac{\Lambda \mu}{2\pi} + \frac{1}{\beta \pi} \int_0^\infty \mathrm{d}k \ln \left[ (1 + e^{-\beta(k-\mu)}) (1 + e^{-\beta(k+\mu)}) \right]
\]

As usual we drop the divergent vacuum terms, i.e., use the bottom line of Eq. (9) as definition of the regularized gc potential density. The integral over momenta yields the familiar result

\[
\psi = -\frac{\pi}{6\beta^2} - \frac{\mu^2}{2\pi}.
\]

(10)

For later use we also compute the free energy density by a Legendre transformation,

\[
f = \psi - \mu \frac{\partial \psi}{\partial \mu} = -\frac{\pi}{6\beta^2} + \frac{\pi}{2\beta^2} \rho^2
\]

(11)

with the fermion density

\[
\rho = \frac{\partial \psi}{\partial \mu} = \frac{\mu}{\pi}.
\]

(12)

We now turn to the less familiar gc potential density at imaginary chemical potential \( \mu = i\theta/\beta \). It can be expressed in closed form with the help of the dilogarithm,

\[
\psi = -\frac{1}{\beta \pi} \int_0^\infty \mathrm{d}k \ln \left[ (1 + e^{-\beta(k+i\theta)}) (1 + e^{-\beta(k-i\theta)}) \right]
\]

\[
= -\frac{1}{\pi \beta^2} \left[ \text{dilog} (1 + e^{i\theta}) + \text{dilog} (1 + e^{-i\theta}) \right]
\]

(13)

[we use the Maple notation \( \text{dilog}(z) = \ln \Gamma_2 (1 - z) \)]. \( \psi \) is a periodic function in \( \theta \) which can be simplified to

\[
\psi = -\frac{\pi}{6\beta^2} + \frac{\theta^2}{2\pi \beta^2}
\]

(14)

in the interval \([ -\pi, \pi ]\). Fig. 1 shows the comparison between \( \psi \) at real and imaginary chemical potential. The discontinuities in the first derivative at \( \theta = (2n + 1)\pi \) \((n \in \mathbb{Z})\) is due to the branch point of \( \ln_2 (z) \) at \( z = 1 \).

A power series expansion in \( \theta \) around \( \theta = 0 \) reduces to a second order polynomial for \(|\theta| < \pi\). It is noteworthy that the singularity at \( \pi \) can be given a physical interpretation: At this value, the Fermi-Dirac distribution is converted into a Bose-Einstein distribution at zero chemical potential. The singularity is the same one which gives rise to Bose-Einstein condensation in higher dimensions.
The fact that everything can be done explicitly in this simple example enables us to illustrate the general ideas mentioned in the Introduction. We first verify the claim that the gc partition function at imaginary chemical potential can be used in principle to derive the canonical potential, this renders the method useless for lattice calculations. However, note that the saddle point is not reached at high temperatures or chemical potential. We shall come back to this point in Sect. IV.

III. FREE MASSIVE FERMIIONS IN 1+1 DIMENSIONS

We next turn to free massive fermions in two dimensions. Dropping again T-independent divergent terms, the gc potential density is given by an expression similar to Eq. (9),

$$\psi = -\frac{1}{\beta\pi} \int_0^\infty \frac{dk}{k} \ln \left[ \left(1 + e^{-\beta(\epsilon - \mu)}\right) \left(1 + e^{-\beta(\epsilon + \mu)}\right) \right],$$

except that the dispersion relation is now $\epsilon = \sqrt{m^2 + k^2}$. At imaginary chemical potential, the argument of the log can be expanded and the momentum integration carried out with the help of the integral representation of a Bessel function,

$$\psi = -\frac{1}{\beta\pi} \int_0^\infty \frac{dk}{k} \ln \left[ \left(1 + e^{-\beta(\epsilon + i\theta)}\right) \left(1 + e^{-\beta(\epsilon - i\theta)}\right) \right]$$

$$= \frac{2m}{\beta\pi} \sum_{n=1}^\infty \frac{(-1)^n}{n} K_1(n\beta m) \cos(n\theta).$$

The curves corresponding to Eqs. (20,21) look qualitatively like Fig. 1 and will not be shown here. The only notable difference is the fact that the peaks in the upper curve are washed out since the singularities move away from the imaginary $\mu$-axis. The Fourier series (21) converges at real but not at imaginary $\theta$, so that it cannot be used directly for the analytic continuation (see however (19)). $\psi$ is an even, periodic function in $\theta$. In the complex $\nu(= \beta\mu = i\theta)$ plane, the singularities are produced by the branch point of the log (vanishing of the argument), see Fig. 2 (due to the periodicity along the Im $\nu$ axis, a stripe of width $2\pi$ contains all the information). A power series

$$e^{-\beta L f} \approx \int_{-\infty}^{\infty} d\theta \frac{1}{2\pi} e^{-iN\theta - \beta\Psi(T, i\theta/\beta)}$$

$$= \sqrt{\frac{\beta}{2L}} \exp \left( \frac{\pi L}{6\beta} - \frac{1}{2} \pi L \beta \rho^2 \right).$$

The vacuum energy density, using heat kernel regularization,

$$E = -\frac{1}{L} \sum_n \left| k_n e^{-\lambda |k_n|} \right|$$

(18) can now easily be worked out. Assuming $\theta \in [-\pi, \pi]$ and taking the limit $\lambda \to 0^+$, one finds

$$E = -\frac{1}{\pi\lambda^2} - \frac{\pi}{6L^2} + \frac{\theta^2}{2\pi L^2}.$$  

(19)

Upon dropping the irrelevant quadratic divergence and replacing $L$ by $\beta$, we indeed recover the gc potential density $\psi$ at imaginary chemical potential, Eq. (14).
around \( \nu = 0 \) has a radius of convergence given by the distance to the closest singularity,

\[
\nu_{\text{max}} = \sqrt{\beta^2 m^2 + \pi^2}. \tag{22}
\]

For \( m = 0 \) or high temperatures, we recover the value of \( \pi \) from the previous section. For large masses or low temperatures on the other hand, \( \nu_{\text{max}} \) is determined by \( \beta m \gg \pi \) and therefore much larger. This will turn out to be important for the GN model later on. To illustrate the role of \( \nu_{\text{max}} \), we show a numerical example in Fig. 3. We compare the full gc potential at real \( \nu \) with its power series expansion around \( \nu = 0 \), as it would be relevant for an analytic continuation from imaginary to real chemical potential. The value of \( \nu_{\text{max}} \) clearly limits the convergence of the power series. In principle, one can continue analytically to any value of \( \nu \) by a succession of expansions around different points with overlapping circles of convergence. By way of example, we first continue analytically to \( \nu = \nu_0 < \nu_{\text{max}} \), expanding around 0. The

\[
\nu_{\text{max}} = \begin{cases} 
\nu_0 + \frac{\sqrt{(\beta m - \nu_0)^2 + \pi^2}}{\beta m - \nu_0}, & \text{if } 0 \leq \nu_0 \leq \beta m \\
\nu_0 + \pi, & \text{if } \beta m \leq \nu_0 \leq \pi
\end{cases} \tag{23}
\]

In practice, this requires a high order calculation in the primary expansion to get sufficient accuracy to lower order in the secondary one (one has to find a kind of intermediate asymptotics). An example is also included in Fig 3. Due to the high order in the expansion around \( \nu = 0 \) needed, this would not be a very realistic option in lattice QCD.

IV. GROSS-NEVEU MODEL IN 1+1 DIMENSIONS, ASSUMING UNBROKEN TRANSLATIONAL INVARIANCE

The GN model is a four-fermion theory defined by the Lagrangian

\[
\mathcal{L} = \sum_{i=1}^{N} \bar{\psi}^{(i)} \gamma^\mu \partial_\mu \psi^{(i)} + \frac{1}{2} g^2 \left( \sum_{i=1}^{N} \bar{\psi}^{(i)} \psi^{(i)} \right)^2. \tag{24}
\]

In the ’t Hooft limit (\( N \to \infty, N g^2 = \text{const.} \)) its phase diagram is well understood. Originally, translational invariance had been assumed at all temperatures and chemical potentials \[20\]. Then the only issue is the fate of the discrete chiral symmetry \( \psi \to \gamma_3 \psi \). It is broken in the vacuum (leading to a dynamical fermion mass) but gets restored at high \( T \) or \( \mu \), see Fig. 4. The tricritical point B where the 2nd order line AB goes over into a first order line BD is reminiscent of QCD. More recently, a third, inhomogeneous phase (a kink-antikink crystal) has been identified \[21, 22\]. It is more stable at high \( \mu \), low \( T \) and requires a revision of the phase diagram shown in Fig. 4,
The renormalized gc potential density reads

\[ \psi = \frac{m^2}{4\pi} \ln m^2 + \frac{1}{4\pi} \frac{1 - m^2}{4\pi} + \psi_{\text{free}}(m) \]  

Here, \( \psi_{\text{free}} \) is given in Eqs. (20,21) at real and imaginary chemical potential, respectively. Minimization of \( \psi \) with respect to \( m \) at real \( \mu \) results in the phase diagram of Fig. 4.

Let us first mimic the procedure which has been applied in QCD lattice calculations at imaginary potential. We minimize the gc potential at imaginary chemical potential with respect to \( m \) and find the phase diagram in Fig. 5. Since \( \psi \) is periodic in \( \theta \), it is sufficient to display one period, say \(-\pi < \theta \leq \pi \). Inspection of the effective potential shows that the curve is a 2nd order phase boundary where the dynamical fermion mass vanishes continuously. Figs. 4 and 5 do not have much resemblance. They only coincide at \( \mu = \theta = 0 \), see the common point A on the phase boundaries.

Before turning to the relationship between the two phase diagrams via analytic continuation, let us try to understand the physics behind the unfamiliar result at imaginary chemical, Fig. 5. For this purpose, it is useful to return to the interpretation of imaginary \( \mu \) in terms of the temperature inversion symmetry discussed in the Introduction. If we adopt the picture of the Casimir effect, the phase diagram in Fig. 5 tells us that for a given boundary condition phase \( \theta \) (or, equivalently, a magnetic field in an extra dimension), there is always a 2nd order quantum phase transition with restoration of chiral symmetry if we decrease the size of the compact space direction. The critical length \( L \) is the inverse of the critical temperature \( T \) plotted in Fig. 5: It decreases with increasing \( \theta \) and vanishes at the bosonic point \( \theta = \pi \), i.e., for periodic boundary conditions (this corresponds to the asymptotes in Fig. 5). This claim can easily be made more precise. In Sect. 4.2 of [23], the gap equation for the GN model on a finite interval with anti-periodic boundary conditions was derived. Setting \( m = 0 \), the critical length or, by temperature inversion symmetry, the critical temperature at \( \mu = 0 \) was found. It is a simple exercise to repeat this derivation with quasi-periodic boundary conditions, resulting in the condition

\[
\ln \Lambda = \sum_{n=0}^{N_\Lambda} \left( \frac{1}{2n + 1 + \theta/\pi} + \frac{1}{2n + 1 - \theta/\pi} \right)
\]

with \( N_\Lambda = L\Lambda/(4\pi) \). The sums can be performed in terms of the digamma function \( \Psi(z) = (\ln \Gamma(z))' \) and yield in the limit \( \Lambda \to \infty \)

\[
2 \ln \left( \frac{4\pi}{\beta} \right) + \Psi \left( \frac{1}{2} - \frac{i\nu}{2\pi} \right) + \Psi \left( \frac{1}{2} + \frac{\theta}{2\pi} \right) = 0 \tag{27}
\]

Replacing \( L \) by \( \beta = 1/T \), this is indeed the implicit equation describing the true phase boundary in Fig. 5, now interpreted as a quantum phase transition when compressing fermions at \( T = 0 \) for different boundary conditions parametrized by \( \theta \).

We now go back to the phase diagram at real \( \mu \) in Fig. 4 and the relation between these two phase diagrams. At real chemical potential, the 2nd order line ABC in Fig. 4 has been computed analytically using perturbation theory some time ago with the result

\[ 2 \ln \left( \frac{4\pi}{\beta} \right) + \Psi \left( \frac{1}{2} - \frac{i\nu}{2\pi} \right) + \Psi \left( \frac{1}{2} - i\nu/2\pi \right) = 0 \tag{28} \]

This agrees perfectly with Eq. (27) once we replace \( \nu \) by \( i\theta \) and identify \( \beta \) with \( L \). These curves can therefore be related by analytic continuation.

Following the method which has been applied to QCD, we try to infer the phase boundary at real \( \mu \) from the one at imaginary \( \mu \) by a power series around \( \mu = 0 \). The digamma function \( \Psi(z) \) is an analytic function and has

\[ \Psi(z) = \ln 

\]

FIG. 5: Phase diagram of Gross-Neveu model at imaginary chemical potential \( \mu = i\theta/\beta \), assuming unbroken translational invariance. This figure should be periodically continued to the left and to the right. The phase boundary is a 2nd order line, the analytic continuation of curve ABC in Fig. 4 (the point A is common). The lines \( \theta = \pm \pi \) are asymptotes to the phase boundary.
the nearest singularity at $z = 0$. The radius of convergence of the power series of Eq. (27) is therefore $\nu = \pi$. Since the fermion mass vanishes at the boundary, it is not surprising that we recover the same value which we encountered in the expansion of the gc potential for free massless fermions in Sec. II. In Fig. 6, we show several approximations corresponding to different orders in $\nu$. With a sufficiently large number of terms one gets an accurate picture of the true phase boundary AB, but one can also continue past the tricritical point B where the curve ceases to be the phase boundary. By the method of overlapping circles of convergence, one would be able even to go beyond $\nu = \pi$, as is clear from the analytic structure of Eq. (27). Going back to the full phase diagram in Fig. 4, we observe that the calculation at imaginary $\mu$ followed by an arbitrarily precise analytic continuation reproduces the 2nd order line but gives no clue whatsoever about the location of the tricritical point B, let alone the first order line BD.

Where has the information about the first order phase transition gone in the process of making $\mu$ imaginary? The reason for this apparent loss of information is clear: The phase structure is contained in the shape of the effective potential $\Psi$ as a function of $m$, for given $T, \mu$. Thus for example, along the first order line, $\Psi$ has two local minima of equal depth. In the present case, the potential at imaginary $\mu$ has less structure and displays only one minimum. This may be caused by a change of sign of some coefficient in the series expansion in $m$ under the transition $\nu \to i\theta$. If we only consider the minima of the respective potentials, there is simply no way to recover the full information. This is exactly what happens if one performs the thermodynamic calculation at imaginary $\mu$ as above. What one evidently has to do is go back one step from the observables (computed in the minimum) to the full $m$-dependent effective potential. In other words, we should keep the order parameter fixed and do the analytic continuation not just once, but for a whole range of $m$-values. In this way one might hope to reconstruct the effective potential at real $\mu$ from that computed at imaginary $\mu$ and then infer the phase diagram as usual.

Since the $\mu$-dependent part of the gc potential is the same as for free, massive fermions, we have all the necessary ingredients already. The crucial question about the convergence of the power series of $\Psi$ in $\nu$ can be answered with the help of Sect. III. By way of example, consider the point $T = 0.15, \mu = 0.66$ close to first order line. Eq. (28) yields a lower bound for the mass variable for which the series around $\theta = 0$ converges, namely

\[ m > \sqrt{\mu^2 - \pi^2 T^2} \]  

(29)

or $m > 0.46 (\beta m > 3.08)$ in the case at hand. This can be verified, see Fig. 7 for an illustration. By successive analytic continuations around different points, the region can be expanded as pointed out above, at the cost of high order calculations. An example is included in Fig. 7.

In this particular example, although we would not be able to determine the full $m$-dependence of the effective potential, the non-trivial minimum can be reconstructed with a reasonable effort. It is well within the region of convergence of the series around $\theta = 0$. On the other hand, the value in the trivial minimum ($m = 0$) could be obtained independently following Sect. II, so that one could decide which minimum is deeper. This is more generally true at low temperatures: The bound in Eq. (29) is dominated by the mass term, since the mass at the minimum is close to 1. The most difficult region is actually a small window in the vicinity of $\nu = \pi$, where the non-trivial minimum violates the bound at least in the truncation of the power series we are using. Thus, provided one has a rough idea of the shape of the effective potential, one can actually reconstruct the GN phase diagram, Fig. 4, in full glory, starting from a calculation of the $m$-dependent effective potential at imaginary chemical potential. This includes the information about the
order of the phase transition. In Fig. 8, we show the result of such a calculation, leaving out the above mentioned window where our method fails at the present level of accuracy. The tricritical point has been located and the unphysical branch BC of the 2nd order critical line (see Fig. 6) has disappeared.

V. KINK-ANTIKINK CRYSTAL FROM IMAGINARY CHEMICAL POTENTIAL?

The phase diagrams in Fig. 4 and Fig. 5 have been derived under the assumption that the order parameter $\langle \psi \psi \rangle$ is constant in space, i.e., the mean field acts like a mass term. Actually, at real chemical potential, an inhomogeneous phase with a periodically modulated scalar condensate, a kink-antikink crystal, is more stable in some part of the $(\mu, T)$-plane. The phase diagram of the GN model including the crystal phase is shown in Fig. 9. This immediately raises the question: How would the phase diagram at imaginary chemical potential change if we would allow for inhomogeneous mean fields? Is it at all possible to infer the existence and potential change if we would allow for inhomogeneous mean fields?

Since the calculation is analytical up to one-dimensional numerical integrations, we were able to switch from real to imaginary chemical potential but found no non-trivial minimum in the imaginary case. This does not rule out periodic potentials of different shape. The following argument shows that there is at least no perturbative instability towards breaking translational invariance: Using almost degenerate perturbation theory, one can derive the phase boundary ABF in Fig. 9 without reference to the exact potential, Eq. (30). The result at real chemical potential is encoded in the equation

$$S(x) = A \kappa^3 \frac{\sin(Ax, \kappa) \csc(Ax, \kappa)}{dn(Ax, \kappa)}.$$  

(30)

repeated the calculation of the gc potential for the GN model, using a two-parameter family of periodic scalar potentials which contain the self-consistent one at real chemical potential, namely the elliptic function

$$4 \ln \left( \frac{\beta}{4\pi} \right) = \min_{a \geq 0} \left[ \Psi \left( \frac{1}{2} + \frac{i(\nu + a)}{2\pi} \right) + \Psi \left( \frac{1}{2} - \frac{i(\nu - a)}{2\pi} \right) + (a \to -a) \right].$$  

(31)

At real $\nu$, the minimum is either at $a = 0$ (corresponding to the boundary AB of the homogeneous phase) or at $a > 0$ (the boundary BF of the crystal phase). If we switch to imaginary $\nu$, the non-trivial minimum disappears. For $a = 0$, $\nu = i\theta$, $\beta = L$ Eq. (31) leads us back to Eq. (21) above so that there is no indication of any inhomogeneous phase at imaginary $\mu$.

Following the reasoning of the last section, it is then clear that one should not think of analytically continuing observables or phase boundaries, but should go back one step. Whereas we dealt with the $m$-dependent effective potential there, now we have to consider the full effective action, a functional of the $x$-dependent scalar
mean field $S(x)$. The idea would be to compute the effective action (i.e., the gc potential density) at imaginary $\mu$ and do the analytic continuation to real $\mu$ before minimization. In practice, one could restrict oneself to a few parameter family of functions $S(x)$, so that the effective action would become a function of these parameters, thereby generalizing the function of one parameter $m$ in the translationally invariant case. We have not done this calculation for the GN model. However we can illustrate the idea using Eq. (31) for the phase boundary where the analytic structure is fully laid out. Let us pretend that we could derive Eq. (31) at imaginary chemical potential only. Then we would not find any non-trivial minimum, i.e., the instability with respect to crystallization. The result of such a calculation is shown in Fig. 10. Although the required order in the series expansion is quite high, it is interesting that there is a method which in principle allows us to infer the existence of a crystal phase, using only imaginary $\mu$ input. Incidentally, the radius of convergence as given by nearest by singularity of the digamma functions is $\nu = \sqrt{\pi^2 + \alpha^2}$, whereas the minimum for large $\nu$ is located close to $\alpha = \nu$. Hence there is no limitation to $\nu = \pi$ in this particular calculation and no fundamental obstacle to derive the phase boundary for large $\mu$ and low temperatures, far beyond the tricritical point.

VI. SUMMARY AND CONCLUSIONS

In this work, we have studied the relationship between a relativistic quantum field theory at real and imaginary chemical potential. Since lattice QCD can only be simulated at imaginary $\mu$ using the standard Monte Carlo method, we were interested in how to retrieve thermodynamic information from imaginary $\mu$. Using an exactly solvable toy model, the (large $N$) GN model in 1+1 dimensions, we first recovered the well-known limitations met if one tries to analytically continue phase boundaries or other thermodynamic observables. In order to overcome these barriers, one has to go one step back in the formalism and compute the full effective potential of the order parameter (here, the chiral condensate $\bar{\psi}\psi$) at imaginary $\mu$, before minimization. In the GN model studied here, this enabled us to reconstruct the full phase diagram with homogeneous phases, including the location of the tricritical point and the first order phase boundary. A similar computation of an effective action instead of an effective potential is likely to yield information about inhomogeneous phases.

It is possible that these results carry over to lattice QCD as well. One would have to compute the effective potential (for homogeneous phases) or the effective action (for inhomogeneous phases) at imaginary chemical potential. Although we do not have the expertise to judge whether such calculations are feasible with Monte Carlo methods, it may be worthwhile to think along these lines to learn more about the QCD phase diagram from first principles.
