Permeation and Gating in Ca\textsubscript{V}3.1 (α1G) T-type Calcium Channels Effects of Ca\textsuperscript{2+}, Ba\textsuperscript{2+}, Mg\textsuperscript{2+}, and Na\textsuperscript{+}

Nilofar Khan, I. Patrick Gray, Carlos A. Obejero-Paz, and Stephen W. Jones

Department of Physiology and Biophysics, Case Western Reserve University, Cleveland, OH 44106

We examined the concentration dependence of currents through Ca\textsubscript{V}3.1 T-type calcium channels, varying Ca\textsuperscript{2+} and Ba\textsuperscript{2+} over a wide concentration range (100 nM to 110 mM) while recording whole-cell currents over a wide voltage range from channels stably expressed in HEK 293 cells. To isolate effects on permeation, instantaneous current–voltage relationships (IIV) were obtained following strong, brief depolarizations to activate channels with minimal inactivation. Reversal potentials were described by $P_{ca}/P_{na} = 87$ and $P_{ca}/P_{ba} = 2$, based on Goldman-Hodgkin-Katz theory. However, analysis of chord conductances found that apparent $K_d$ values were similar for Ca\textsuperscript{2+} and Ba\textsuperscript{2+}, both for block of currents carried by Na\textsuperscript{+} (3 μM for Ca\textsuperscript{2+} vs. 4 μM for Ba\textsuperscript{2+}, at −50 mV; weaker at more positive or negative voltages) and for permeation (3.3 mM for Ca\textsuperscript{2+} vs. 2.5 mM for Ba\textsuperscript{2+}; nearly voltage independent). Block by 3–10 μM Ca\textsuperscript{2+} was time dependent, described by bimolecular kinetics with binding at $\sim$5 × 10\textsuperscript{8} M\textsuperscript{−1}s\textsuperscript{−1} and voltage-dependent exit. Ca\textsuperscript{2+}, Ba\textsuperscript{2+}, and Mg\textsuperscript{2+} also affected channel gating, primarily by shifting channel activation, consistent with screening a surface charge of 1 e\textsuperscript{−} per 98 Å from Gouy-Chapman theory. Additionally, inward currents inactivated $\sim$35% faster in Ba\textsuperscript{2+} (vs. Ca\textsuperscript{2+} or Na\textsuperscript{+}). The accelerated inactivation in Ba\textsuperscript{2+} correlated with the transition from Na\textsuperscript{+} to Ba\textsuperscript{2+} permeation, suggesting that Ba\textsuperscript{2+} speeds activation by occupying the pore. We conclude that the selectivity of the “surface charge” among divalent cations differs between calcium channel families, implying that the surface charge is channel specific. Voltage strongly affects the concentration dependence of block, but not of permeation, for Ca\textsuperscript{2+} or Ba\textsuperscript{2+}.

INTRODUCTION

It seems like a simple experiment: determine the concentration dependence of current through a voltage-dependent Ca\textsuperscript{2+} channel by varying the concentration of Ca\textsuperscript{2+}. But it has long been recognized that interpretation of such results is complicated. In particular, the whole-cell current is affected by gating as well as permeation. Ions can modify gating by a variety of mechanisms, including screening of surface charge (Frankenhaeuser and Hodgkin, 1957), effects of pore occupancy on gating (Swenson and Armstrong, 1981), and binding to sites outside the pore (Gilly and Armstrong, 1982).

The classical method for separating gating from permeation is the instantaneous current–voltage relationship (IIV) (Hodgkin and Huxley, 1952). Channels are first activated by a fixed depolarizing pulse, followed by repolarization to a wide range of voltages. The current measured “instantaneously” at each new voltage reflects the current through the population of channels opened by the prior depolarizing pulse (Fig. 1). Thus, the number of channels open is constant, so any variation in current must reflect the effect of voltage on permeation through those open channels. The IIV method makes several assumptions, most critically that currents can be accurately measured before gating processes affect the number of channels open (see Materials and methods).

Gating of Ca\textsubscript{V}3.1 is sufficiently slow for the IIV to be measured over a wide voltage range (Serrano et al., 1999, 2000). In this study, we examine the concentration dependence of current from 100 nM to 110 mM Ca\textsuperscript{2+} (or Ba\textsuperscript{2+}), from +100 to −150 mV. This dataset provides a detailed yet large-scale view of how voltage and ion concentration affect permeation. One major goal was to examine the basis of selectivity between Ca\textsuperscript{2+} and Ba\textsuperscript{2+}, for a channel that exhibits similar ionic currents with the two ions, but is selective for Ca\textsuperscript{2+} by other criteria (Serrano et al., 2000).

We also found that divalent cations modify gating, by two distinct mechanisms. First, Ca\textsuperscript{2+}, Ba\textsuperscript{2+}, and Mg\textsuperscript{2+} shift channel activation, in a manner largely consistent with screening of surface charge. This contrasts with high voltage–activated (HVA) Ca\textsuperscript{2+} channels (Byerly et al., 1985) and Na\textsuperscript{+} channels (Hille et al., 1975), where Ca\textsuperscript{2+} has larger effects than Ba\textsuperscript{2+} or Mg\textsuperscript{2+}, suggesting that Ca\textsuperscript{2+} can both bind to and screen surface charges. This implies that some or all of the “surface charge” is specific to a particular channel type.
ion channel. Second, Ba\textsuperscript{2+} speeds inactivation of inward currents (compared with Ca\textsuperscript{2+} or Na\textsuperscript{+}), and the effect correlates with pore occupancy.

**MATERIALS AND METHODS**

**Whole-Cell Recording**

Whole-cell recordings were performed from HEK293 cells stably transfected with rat Ca\textsubscript{v}3.1 (Lee et al., 1999) as previously described (Serrano et al., 1999). Data were recorded at room temperature using an Axopatch 200 amplifier driven by pClamp software (pClamp 8.2, Axon Instruments). Electrode resistances were 1.5–2 MΩ, giving series resistances in the whole-cell configuration of 3.8 ± 1.2 MΩ (mean ± SD, 57 cells) before compensation, usually with “correction” at 80–90% and “prediction” at 40–60%. Data were sampled at 50 kHz following 10 kHz analogue filtering using the amplifier. Both “raw” and leak-subtracted currents were recorded, and all current records and analyses shown are from leak-subtracted data. The holding potential was −100 mV, except −120 mV in 0.1 or 10 μM Ca\textsuperscript{2+}, or Ba\textsuperscript{2+} (to avoid possible resting inactivation).

**Recording Solutions**

The standard intracellular solution contained (in mM) 120 NaCl, 11 EGTA, 2 CaCl\textsubscript{2}, 1 MgCl\textsubscript{2}, 4 MgATP, 10 HEPES, pH 7.2, with 2 M NaOH. Ca\textsuperscript{2+} = 40 nM, Mg\textsuperscript{2+} = 1.0 mM, and total Na\textsubscript{i,o} = 145 mM including NaOH used for titration. Experiments with low Mg\textsuperscript{2+} (Fig. S15) used either a nominally 0 Mg\textsuperscript{2+}-0 ATP intracellular solution (120 NaCl, 2 CaCl\textsubscript{2}, 8 glucose, 11 EGTA, 10 HEPES, pH 7.2), or an intracellular solution calculated to have 0.2 nM free Mg\textsuperscript{2+} (120 NaCl, 2 CaCl\textsubscript{2}, 2.91 MgCl\textsubscript{2}, 4 Na\textsubscript{2}ATP, 11 EGTA, 10 HEPES, pH 7.2), as specified in the figure legend. Calculated free Ca\textsuperscript{2+} and free Mg\textsuperscript{2+} in buffered intracellular and extracellular solutions are from MaxChelator v. 2.5 (Patton et al., 2004) at the URL address http://www.stanford.edu/~cpatton/maxch.html. Comparable values were obtained using the program CHELATOR (Schoenmakers et al., 1992).

The standard extracellular solution contained (in mM) 140 NaCl, 2 CaCl\textsubscript{2} or BaCl\textsubscript{2}, 10 HEPES, 10 glucose, pH 7.2 with 2 M NaOH. In experiments where Ca\textsuperscript{2+} or Ba\textsuperscript{2+} concentrations were changed, NaCl was maintained constant at 140 mM, except in isotonic 110 mM solutions where no NaCl was included and the pH was adjusted using NMDG base. When Mg\textsuperscript{2+} was added, the extracellular NaCl concentration was maintained constant at 140 mM, except NaCl was reduced to 119 mM in 30 mM Mg\textsuperscript{2+}. Where noted (Fig. S20), NaCl was fully or partially replaced by equimolar NMDG-Cl\textsubscript{−}, (prepared by titration of NMDG base with HCl). Low Ca\textsuperscript{2+} concentrations were achieved with 1 mM EGTA (0.1 μM free Ca\textsuperscript{2+} with 0.379 mM total Ca\textsuperscript{2+}) or 1 mM HEDTA (3 or 10 μM free Ca\textsuperscript{2+} with 0.334 mM or 0.633 mM total Ca\textsuperscript{2+}, respectively). However, we found that block of inward currents carried by Na\textsuperscript{+} was significantly faster and more potent when 10 μM Ca\textsuperscript{2+} was added directly to a nominally Ca\textsuperscript{2+}-free extracellular solution than with our HEDTA-buffered 10 μM Ca\textsuperscript{2+} solution, as if the actual free Ca\textsuperscript{2+} was ~1.6× higher in the unbuffered solution (see Fig. S1, available at http://www.jgp.org/cgi/content/full/jgp.200809986/DC1). Extracellular solutions with nominally zero Ca\textsuperscript{2+} had <3 μM total Ca\textsuperscript{2+}, as measured by atomic absorption flame spectroscopy (Perkin Elmer Atomic Absorption Spectrometer 3100), consistent with the block of current carried by Na\textsuperscript{+} by nominally Ca\textsuperscript{2+}-free extracellular solution with no added calcium buffer (Fig. S1 B). We attempted to calibrate the Ca\textsuperscript{2+}-HEDTA system, using arsenazo III or Fura 6F as calcium indicators, but we have not obtained results with sufficient reproducibility and precision to measure the K\textsubscript{i} for HEDTA (not depicted). Since EGTA-like buffers may bind contaminating cations possibly contained in unbuffered solutions, the data we present here with 3 or 10 μM Ca\textsuperscript{2+} are with HEDTA-buffered solutions.

**Junction Potentials and Activities**

For most experiments, extracellular solutions were exchanged using a multibarrel perfusion system, with flow driven by gravity,
and an Ag/AgCl ground electrode in the bath. This configuration results in a liquid junction potential between the perfusing solution and the bath. The effect of the junction potential in the measurement of the membrane potential (V_M) was calculated (Neher, 1992):

\[ V_M = V - V_{IJ} - V_{JL}, \]

where \( V \) is the command potential, \( V_{IJ} \) is the liquid junction potential between the 2 mM Ca^{2+} sealing (also control) solution and the intracellular solution, and \( V_{JL} \) is the liquid junction potential established between the 2 mM Ca^{2+} control solution and the test solution. Liquid junction potentials were calculated using a generalized Henderson equation implemented in the JPCalc software (Barry, 1994) that is incorporated into Clampex (Axon Instruments). \( V_{IJ} \) in our experimental conditions is 0 mV, but \( V_{JL} \) ranged from −0.3 in low Ca^{2+} concentrations to 6.9 mV in isotonic CaCl_2 solutions. Junction potentials in isotonic CaCl_2 solutions were confirmed experimentally using a 100-μl perfusion chamber grounded with a 3 M KCl 3% agar bridge, in the current clamp configuration of the Axopatch 200 amplifier. Measurements were corrected only for junction potentials calculated to be >1 mV. For analyses where values had to be compared directly at each voltage, values with significant junction potentials were linearly interpolated to the desired voltage (Fig. 5, Fig. S12, E and F, and Fig. S20 E). Original current records in Fig. 1 C, Fig. S5 C, Fig. S11, and Fig. S20 A are not corrected for junction potentials.

For the experiments in Fig. S20, B and F–H, solutions were changed by bath superfusion (including exposure of the 3 M KCl 3% agar bridge electrode to the test solution). This procedure does not result in a change in junction potential for the whole-cell recording configuration, so no correction was necessary. Where noted, thermodynamic activities were calculated for Na^{+}, Ca^{2+}, and Mg^{2+} in mixed solutions where Cl^{-} was the major anion, multiplying each ion concentration by the activity coefficient calculated using Pitzer’s formalism (Pitzer and Mayorga, 1973; Harvie and Weare, 1980; Anderson and Crerar, 1993).

**Whole-Cell Protocols and Analysis of Permeation**

In eachionic condition, currents were recorded with two protocols, which we call the IIV protocol (Fig. 1) and the IV protocol (Fig. S5). Because of channel rundown and other time-dependent changes, we recorded first in a reference solution (usually (Fig. S5). Because of channel rundown and other time-dependent changes, we recorded first in a reference solution (usually

The leak current tended to be nonlinear in “leaky” cells, producing artifactual time-independent outward currents at strongly depolarized voltages (Obejero-Paz et al., 2004). Most cells with >0.2 nA of inward holding current at the holding potential were excluded from analysis. This criterion was relaxed for ~15% of the cells recorded in 0.1–100 μM Ca^{2+} or Ba^{2+}, since the leak tended to be high in that condition, but currents were also large (giving a high signal-to-leak ratio). In such cells, currents inactivated essentially to zero except at the most positive voltages (well above the reversal potential), where the contribution of leak to the measured current was estimated to be <10%.

For a few cells, to reduce 60 Hz noise, a section of baseline (lasting an integral number of 60 Hz cycles, usually 1 or 2) was fitted to a 60 Hz sine wave plus several harmonics (usually 9), adjusting the amplitude and phase for the best fit. The sum of the sine waves was then subtracted from the entire record. This was done with a program written by S.W. Jones in Microsoft Visual Basic v6.

**Effects of ions on permeation were assessed using IV relations, measured by fitting single exponentials to the decay of current following a brief (2 ms) step to +60 mV (Serrano et al., 2000).** The exponential fit began when the tail currents reached a peak, as an estimate of the current at the time when accurate voltage clamp was actually achieved, and extended 20 ms into the voltage steps. The amplitude of the fitted exponential at the starting point of the fit was used for the IV measurements shown. In most of our experimental conditions, the time course of block is fast, i.e., pore occupancy has reached steady state by the time the IV is measured. The time course of block can be resolved by careful analysis in certain conditions (1 mM Mg^{2+} in 2 mM Ba^{2+}, Serrano et al., 2000; 10 μM Ca^{2+}, Figs. 7–9), but the single exponential fit did not include those very fast (τ > 0.1–0.2 ms) components, so we interpret the IV measurements as representing steady-state block in all experimental conditions in this study.

Chord conductances (G) were calculated from

\[ G = I/(V - V_b) \]

where \( V_b \) was estimated by linear interpolation between the two data points on either side of reversal. More sophisticated means of estimating \( V_b \) were attempted, including polynomial fits to the IV relationship (Talavera et al., 2003a,b). However, there were small but systematic differences between the experimental IV relationship in 2 mM Ca^{2+} (−150 to +100 mV) and the best fit to even a seventh order polynomial function (not depicted). Small errors in estimation of \( V_b \) significantly affected \( G \) measurements near \( V_b \).

To minimize error resulting from differences in channel expression levels among cells, measurements were normalized by

\[ X_{N,i} = X_i Y_{avg} / Y_i, \]

where \( X_i \) is a raw measurement from cell \( i \), and \( X_{N,i} \) is the normalized value for that cell. \( Y_i \) is a measure of channel expression level, calculated for each cell (\( Y_i \)), and averaged over all cells recorded in the same reference condition (\( Y_{avg} \)). For IV currents, \( Y \) was the sum of the absolute values of currents from −120 to +100 mV; for conductances, \( Y \) was the sum of the corresponding conductance values. One advantage of this procedure is that the “normalized” values have the same units as the raw measurements. Data recorded in the test solution were also normalized using \( Y \) values recorded in reference solutions.

The concentration dependence of \( \text{Ca}^{2+} \) permeation and block was described in terms of chord conductances (G), analyzed as the sum of two components:

\[ G = G_{CaK_b}/([\text{Ca}^{2+}]_o + K_b) + G_{Ca}[\text{Ca}^{2+}]_o/([\text{Ca}^{2+}]_o + K_P). \]

\( G_{Ca} \) is the component of conductance that is blocked by \( \text{Ca}^{2+} \), with \( K_b = K_{Pb} \) and \( G_{Ca} = \text{the component that saturates with increasing } \text{Ca}^{2+} \), with \( K_b = K_P \). Both components were described by the law of mass action (Eq. 4), except that at the most positive potentials (where no clear increase in \( G \) vs. \( \text{Ca}^{2+} \) was observed at high concentrations) \( G_{Ca} \) was assumed to be constant. Taken literally, this analysis assumes that currents carried by \( \text{Ca}^{2+} \) and \( \text{Na}^+ \) are independent, which is not true for a calcium channel. Therefore, we present this only as a simple way to empirically describe the voltage and concentration dependence of \( \text{Ca}^{2+} \) permeation and block. Effects of \( \text{Ba}^{2+} \) were described in the same manner, except that \( G_{Ca} \) was assumed to be constant from +20 to +100 mV.
subject to large error nearby. In principle, this singularity can be
driving force) can increase error as well, so we present $P_{O,r}$ values
$+100 \text{ mV}$ (except in $110 \text{ mM Ca}^{2+}$ or Ba$^{2+}$, where those voltages
often exceeded 1.0 (in $2 \text{ mM Ca}^{2+}$, $1.10 \pm 0.08$, mean $\pm$ SD,
were near the reversal potential and $P_{O,r}$ was not accurately mea-
surable, so unnormalized values were used).

Effects of ions on gating were determined using the peak currents
from the I-V protocol, $T_{\text{Peak}}$ and $\tau_{\text{inact}}$, from the I-V protocol, $\tau_{\text{act}}$
from the IV protocol, and channel activation (from the I-V/IV
current ratio, $P_{O,r}$) (Serrano et al., 1999).

Peak currents from the I-V protocol were measured following
1 kHz Gaussian filtering, as the average between two cursors placed
by eye in Clampfit (Axon Instruments) to delineate the maximal
current. Near the reversal potential, cursor placement was based
in part on the location of peak inward and outward currents at
nearby voltages, with care taken to avoid a fast transient outward
gating current (Burgess et al., 2002). Currents and chord con-
ductances were normalized by Eq. 3 to reduce effects of cell–cell
variability in expression levels, based on the sum of the absolute
value of currents (or conductances, as appropriate) from $-90$ to
$+100 \text{ mV}$.

Currents from the I-V protocol were fitted by the sum of two
exponentials, from the time where activation was approximately
half-maximal, to the end of the 100-ms step, following 2 kHz
Gaussian filtering. The slower time constant was defined as $\tau_{\text{inact}}$
and $T_{\text{Peak}}$ was calculated as the time where the calculated
difference in currents (or conductances, as appropriate) from
activation). Errors where
$<2.5 \text{ nA}$ in all conditions (except $100 \text{ nM Ca}^{2+}$, or Ba$^{2+}$), so errors
should be $<2 \text{ mV}$ (with 0.75 $\Omega$ of uncompensated series resis-
tance). Errors in $T_{\text{Peak}}$ should also be small, since that value was
also measured from inward currents with the IV protocol. Activation
curves were calculated from the I-V/IV ratio, and the error
can be significant for the IV. In the worst case ($100 \text{ nM Ca}^{2+}$, or Ba$^{2+}$),
at the measured 50% activation voltage ($\pm 50 \text{ mV}$), there
would be $\approx 7 \text{ mV}$ of error for the IV. The error would be less than
half that value at $10 \text{ mM Ca}^{2+}$ or Ba$^{2+}$, and even smaller in all other
conditions (e.g., for $110 \text{ mM Ca}^{2+}$, 2 $\text{ mV}$ error near half ac-
tivation). Errors in $T_{\text{Peak}}$ will be significant ($\approx 15 \text{ mV}$) for the
large inward tail currents at $0.1-10 \text{ mM Ca}^{2+}$ or Ba$^{2+}$, $\approx 7 \text{ mV}$
in $110 \text{ mM Ca}^{2+}$ but $<5 \text{ mV}$ in other conditions. Overall, activation
measurements should be reliable (except perhaps at $100 \text{ nM}$),
predicted (e.g.) by a surface charge mechanism. $P_{O,r}$ was fitted a
Boltzmann relationship raised to the fourth power for each cell, with
the slope factor the same in reference and test solutions, using
the Solver function in Excel to minimize the sum of squared
errors. Log($\tau_{\text{inact}}$) was linearly interpolated to the value at 2 ms
from data at $-70$ to $-120 \text{ mV}$ (see Fig. S7, A and B, and Fig. S15,
A and B). Log($T_{\text{Peak}}$) was interpolated to the value at 7 ms
from data over a 30-mV range ($-30$ to $-60 \text{ mV}$, or more positive
voltages in 8 or $110 \text{ mM Ca}^{2+}$, or Ba$^{2+}$; see Fig. S7, E and F, and
Fig. S15, E and F). This strategy for measuring voltage shifts is
similar in principle to Talavera et al. (2003a,b), although the specific
measurements differ in detail.

Series Resistance Error
Whole-cell experiments required accurate voltage clamp to con-
trol the large currents observed over a wide voltage range. Cells
were selected primarily based on the time course and shape of the
tail current near $-100 \text{ mV}$ with the IV protocol. In some cells, se-
ries resistance error was also evaluated from the effect of partial
inactivation on the time course of tail currents at $-100 \text{ mV}$
(Serrano et al., 1999). The average series resistance was 0.75 $\Omega$
(assuming 80% compensation), which would give 16 $\text{ mV}$ of error
for a 21-nA current. This is significant for the largest currents
observed in this study, but we note that use of the IV protocol elimi-
nates the negative slope conductance region normally observed
for calcium currents. Series resistance error would selectively un-
derestimate the conductance change in low Ca$^{2+}$ or Ba$^{2+}$ by $\approx 15%$
(calculated for a 16-mV error with 120-mV driving force). The
error will be proportionally less for the smaller currents observed
with millimolar concentrations of Ca$^{2+}$ or Ba$^{2+}$ (e.g., $\approx 5%$ error
for the conductance at the most negative voltage in 110 $\text{ mM Ca}^{2+}$).
Put another way, the estimated error was 1% for each 13 nS of
countactance. No correction was made for this effect.

Figure 2. IIV relations at different concentrations of Ca$^{2+}$ (A and B) and Ba$^{2+}$ (C and D). Values are from 5, 8, 5, 7, 4, and 3 cells in Ca$^{2+}$, and 3, 5, 7, 6, 4, and 3 cells in Ba$^{2+}$ (respectively, 100 nM, 10 $\mu$M, 0.1
mM, 0.5 mM, 8 mM, and 110 mM). Control values at 2 mM Ca$^{2+}$, or Ba$^{2+}$, are averaged from all these cells (32 in Ca$^{2+}$, 28 in Ba$^{2+}$). In each cell, the con-
trol value was the average of measurements before
and after the test solution, to correct for rundown. Values were normalized for each cell as described in Materials and methods. Figs. 3–5 are based on this
same dataset.
although small shifts (<5 mV) should be interpreted with caution. For the relatively small currents with 2 mM Ca\textsuperscript{2+} or Ba\textsuperscript{2+}, the estimated errors in our voltage shift measurements are <1 mV, so the small effects in Fig. 12 (C–F) should not be affected by series resistance error (which would be similar in Ca\textsuperscript{2+} vs. Ba\textsuperscript{2+}, in any case). Voltage shifts shown in the figures are not corrected for series resistance errors.

**Surface Potential Calculations**

Effects of ions on $P_{o,r}$ were analyzed by Gouy-Chapman theory, i.e., assuming that ions screen but do not bind to a uniform planar surface charge. The measured shift in $P_{o,r}$ was interpreted as a change in surface potential ($\Delta \Psi$). Surface potentials ($\Psi$) were calculated from the Grahame equation (Grahame, 1947)

$$\sigma^2 \Psi^2 = \sum_i \left[ C_i \left( e^{-zF \Psi / RT} - 1 \right) \right],$$

where $\sigma$ is the surface charge, $G$ is a constant that equals 270 Å\textsuperscript{2}e\textsuperscript{-1}M\textsuperscript{M}, at room temperature, $z_i$ is the valence of the $i$th ion species, $F$ is the Faraday constant, and $R$ is the gas law constant. For a given $\sigma$ value, Eq. 5 was solved for $\Psi$ by a Newton algorithm for each extracellular solution used experimentally, and voltage shifts were calculated as $\Psi$ (test solution) − $\Psi$ (2 mM Ca\textsuperscript{2+} or Ba\textsuperscript{2+}). The one free parameter in Gouy-Chapman theory, $\sigma$, was found by minimizing the sum of squared differences between experimental and calculated voltage shifts, using the Minimize function of Mathcad.

**Frequency Domain Experiments**

Stationary noise analysis of whole-cell currents was studied at membrane potentials showing prominent window currents, with overlapings early in the voltage steps (see Fig. S3), followed by rare isolated bursts as channels transiently recover from inactivation.

Within visually identified bursts, single-channel events were detected by half-amplitude threshold crossing analysis in current records interpolated with eight points between every two sample points (Colquhoun and Sigworth, 1983; Obejero-Paz et al., 1998). Current records were filtered before analysis with a Gaussian filter so the effective cutoff frequency of the combined analogue and digital filters was 2 kHz, with a dead time of 180 μs. The maximum likelihood method was used to fit open and closed time histograms to the sum of exponential functions. We used twice the natural logarithm of the likelihood ratio to assess the number of exponential functions required to fit the distributions (Horn, 1987). Generally, open time distributions were described by a single exponential, and closed times by two exponentials (see Fig. S4). We interpret the fast component of intraburst closed times as closings of a single channel, and do not interpret the slow component.

The single-channel slope conductance was calculated fitting a straight line to the current-voltage relationship of the main conductance level between ~90 and ~40 mV. Single-channel current amplitudes were calculated by averaging the longest open events (usually ~20 events) at each membrane potential.

**Gating Model**

We assessed the effect of Ba\textsuperscript{2+} on gating of Ca\textsubscript{3.1} channels using the model of Serrano et al. (1999). Equilibrium state occupancies and transient behavior were calculated analytically by solving the general $Q$ matrix of transition rates between states (Colquhoun and Hawkes, 1995), using the “eigenvec” and “eigenvem” functions implemented in Mathcad.

A global fit to the voltage dependence of $P_{o,r}$, $T_{peak}$, and $\tau_{IV}$ in 2 mM Ca\textsuperscript{2+} was first performed by finding the model parameters that minimize the sum of squares of scaled differences using the Minimize function implemented in Mathcad. The effective $\tau_{IV}$ was calculated as the weighted average of the $\tau$s of the three largest components (weighted by the respective amplitudes). In a second step, the voltage dependence of $P_{o,r}$, $T_{peak}$, and $\tau_{IV}$ in Ca\textsuperscript{2+} and Ba\textsuperscript{2+} were fitted simultaneously, allowing only the rate constant for inactivation to change.

**General Data Analysis**

Data were analyzed using Clampfit v8.2, Mathcad 2001 Professional (Mathsoft), Microsoft Excel, and Microcal Origin. For the analysis of $K_d$ and $G$ values for permeation and block (Fig. 5), and for Woodhull models for Mg\textsuperscript{2+} block (Fig. S12, E and F), parameters were estimated by the Solver function of Excel, minimizing the sum of squared errors. Values are given as mean ± SEM unless noted otherwise. Statistical significance levels given in the text are from two-tailed $t$ tests (Excel), with $P < 0.05$ considered to be significant. For averaged data in the figures, error bars are shown if larger than the symbols. Current records in the figures were digitally Gaussian filtered in Clampfit, with cutoff frequencies specified in figure legends. Figures were prepared in Microsoft PowerPoint, from graphs imported as Windows Metafiles from Origin v. 5.

**Online Supplemental Material**

The online supplemental material is available at http://www.jgp.org/cgi/content/full/jgp.200809986/DC1. Fig. S1 compares currents recorded with 3–10 μM Ca\textsuperscript{2+} buffered by HEDTA, vs. 0–10 μM Ca\textsuperscript{2+} added to nominally Ca\textsuperscript{2+}-free solution. Fig. S2 and Table S1 contain results from stationary noise analysis of Ca\textsuperscript{2+} block. Fig. S3 illustrates the protocol used for single-channel recording, and Fig. S4 shows open and closed time distributions. Fig. S5 illustrates sample current records with the I-V protocol, for
228  Permeation and Gating in Ca V 3.1 T-type Calcium Channels

Figure 3. Effect of Ca$^{2+}$ o and Ba$^{2+}$ o on $V_R$. Values in 110 mM Ca$^{2+}$ o or Ba$^{2+}$ o are corrected for junction potentials. The smooth curves are the best fits to GHK theory for Ca$^{2+}$ o (solid lines) and Ba$^{2+}$ o (short dashed lines).

Figure 4. Chord conductances from IIV relations. (A and B), Ca$^{2+}$ o (D and E) Ba$^{2+}$ o. (C and F) Block by 0.01–0.5 mM Ca$^{2+}$ o (G) or Ba$^{2+}$ o (F), calculated from the conductance in the indicated concentration divided by the conductance in 100 nM Ca$^{2+}$ o or Ba$^{2+}$ o. Error bars (SEM) include errors in both numerator and divisor, from standard error propagation analysis. Note that these comparisons across datasets yield limiting ratios (at $+100$ mV) not exactly equal to 1. Same symbols and color coding as Fig. 2.

Figure S6 compares estimates of channel activation from our $P_{O,R}$ method vs. chord conductances. Figs. S7 and S8 analyze effects of Ca$^{2+}$ o and Ba$^{2+}$ o on the voltage dependence of gating. Figs. S9 and S10 compare effects of Ca$^{2+}$ o and Ba$^{2+}$ o at equal concentrations. Figs. S11–S18 analyze effects of Mg$^{2+}$ o and Fig. S19 effects of Mg$^{2+}$ i. Fig. S20 examines replacement of Na$^{+}$ o by NMDG. Fig. S21 compares chord conductances to slope conductances, calculated from IIV relationships. Fig. S22 compares currents evoked by the I-V and IIV protocols at $-20$ mV, to demonstrate that channel activation is not maximal at that voltage. Figs. S7–S20 are described in the Supplemental Results section.

Table S2 (a Microsoft Excel worksheet) includes the data for the Ca$^{2+}$ o, Ba$^{2+}$ o, and Mg$^{2+}$ i,o dependence of currents through the CaV3.1 channel, obtained with the IIV protocol.

RESULTS

Effect of Ca$^{2+}$ o and Ba$^{2+}$ o on Permeation

Our approach was to examine the effect of ion concentration on the IIV, using near normal ionic conditions as the reference. Fig. 1 illustrates this for changes to the extremes, 100 nM Ca$^{2+}$ o and 110 mM Ca$^{2+}$ o. It is immediately apparent that inward currents are substantially increased in both test solutions. With 100 nM Ca$^{2+}$ o, outward currents are also increased. This illustrates several well-known features of calcium channel permeation. First, in the near absence of Ca$^{2+}$ o, channels are highly permeable to monovalents (in our conditions, Na$^+$). Second, the inward current through calcium channels is not saturated at the physiological concentration (2 mM Ca$^{2+}$ o). Third, Na$^+$ can carry large outward currents, but these outward currents are reduced by 2 or 110 mM Ca$^{2+}$ o. This is consistent with the view that T-type calcium channels, like other calcium channels, are essentially nonselective cation channels in the absence of Ca$^{2+}$ o (Fukushima and Hagiwara, 1985; Carbone and Lux, 1987). Furthermore, Ca$^{2+}$ can either block current carried by monovalent cations, or permeate, depending on voltage and concentration.

Fig. 2 (A and B) illustrates the effect of Ca$^{2+}$ o on the IIV over a wide (10$^4$-fold) range, using normalized IIV relations to correct for rundown and cell–cell variation in expression levels (see Materials and methods). Effects of Ba$^{2+}$ o are qualitatively similar (Fig. 2, C and D). The IIV relations are nonlinear, but monotonic, with voltage. One clear effect is a positive shift in $V_R$ with increasing Ca$^{2+}$ o or Ba$^{2+}$ o (Fig. 3). $V_R$ was near 0 mV at 0.1 mM or lower Ca$^{2+}$ o or Ba$^{2+}$ o, and was more positive with Ca$^{2+}$ o vs. Ba$^{2+}$ o at higher concentrations. The difference in $V_R$ was statistically significant for 0.5, 2, and 110 mM Ba$^{2+}$ o vs. Ca$^{2+}$ o; in a separate set of 3 cells where 8 mM Ba$^{2+}$ o was compared directly to 8 mM Ca$^{2+}$ o, the shift in $V_R$ was 8.3 ± 1.9 mV (P < 0.05). $V_R$ was described reasonably well by Goldman-Hodgkin-Katz theory with $P_{Ca}/P_{Na}$ = 87 and $P_{Ba}/P_{Na}$ = 44, although $V_R$ in 0.1 mM Ca$^{2+}$ o ($-2.8 ± 1.5$ mV) and 0.5 mM Ba$^{2+}$ o ($+2.5 ± 1.2$ mV) was less positive than expected ($+2.7$ and $+6.0$ mV, respectively). Above 2 mM, the shift with Ca$^{2+}$ o or Ba$^{2+}$ o approached the Nernstian slope for a divalent cation, both for the calculated Goldman-Hodgkin-Katz (GHK) $V_R$ and for the experimental $V_R$, although the $V_R$ in Ca$^{2+}$ o was $-100$ mV negative to the Nernst potential (Fukushima and Hagiwara, 1985). When activities were used (instead of concentrations), $P_{Ca}/P_{Na}$ = 234 and $P_{Ba}/P_{Na}$ = 122.
The effects of Ca\textsuperscript{2+}\textsubscript{o} and Ba\textsuperscript{2+}\textsubscript{o} on permeation are illustrated more clearly by chord conductance–voltage relationships (Fig. 4), which eliminate the discontinuity in the IIV at \(V_R\) (Fig. 2). Consider the effect of increasing Ca\textsuperscript{2+}\textsubscript{o} from 100 nM to 10 \(\mu\)M (Fig. 4 A). At extreme negative and positive voltages, Ca\textsuperscript{2+}\textsubscript{o} had little or no effect. However, 10 \(\mu\)M Ca\textsuperscript{2+}\textsubscript{o} clearly blocked current through calcium channels at intermediate voltages (Fig. 4 C). Qualitatively, this can be explained by a Woodhull (1973) model for voltage-dependent block, where Ca\textsuperscript{2+} rapidly exits to the extracellular solution at positive voltages, or to the intracellular solution at negative voltages. A U-shaped voltage dependence for block by Ca\textsuperscript{2+} has been reported previously for T currents in lymphocytes and sensory neurons (Fukushima and Hagiwara, 1985; Lux et al., 1990). Block was stronger at 0.1 – 0.5 mM Ca\textsuperscript{2+}\textsubscript{o} (Fig. 4 C), but still little effect was apparent near +100 mV.

At millimolar concentrations (Fig. 4 B), Ca\textsuperscript{2+}\textsubscript{o} increased the conductance at negative voltages, reflecting permeation, but reduced the conductance at the most positive voltages, reflecting block of outward current carried by Na\textsuperscript{+}. Again, results in Ba\textsuperscript{2+}\textsubscript{o} were similar (Fig. 4, D–F).

It is instructive to view conductance both as a function of voltage (with concentration as a parameter; Fig. 4), and as a function of concentration (with voltage as a parameter; Fig. 5, A–D). The smooth curves in Fig. 5 (A–D) are fits to a simple empirical model, where the total conductance is the sum of a component blocked by Ca\textsuperscript{2+}, and a component carried by Ca\textsuperscript{2+} (see Materials and methods). (E and F) Analysis of chord conductances as the sum of Na\textsuperscript{+} and Ca\textsuperscript{2+}/Ba\textsuperscript{2+} conductances. (E) Maximal conductances; (F) apparent \(K_d\) values for permeation (activation of \(G_{Ca or Ba}\)) and block (inhibition of \(G_{Na}\)).

The effects of Ca\textsuperscript{2+}\textsubscript{o} and Ba\textsuperscript{2+}\textsubscript{o} on permeation are...
Permeation and Gating in Ca V 3.1 T-type Calcium Channels

resulting from time-dependent block by Ca 2+ o (Lux et al., 1990). Consistent with that interpretation, tail currents were also biphasic in 3 μM Ca 2+ o (Fig. 6 B), and the fast component was visibly slower in 3 vs. 10 μM Ca 2+ o (Fig. 6, B and C). Biexponential fits to the tail currents demonstrated a slow component with a time constant of 10 ms, which did not depend on Ca 2+ o, and a concentration-dependent fast component (Fig. 6 D). The simplest explanation is that much of the block by Ca 2+ o is relieved by strong depolarization (the 2-ms step to +60 mV, Fig. 6 A), and then Ca 2+ o reenters the pore upon repolarization to voltages where steady-state block is stronger (see Figs. 4 and 5). The fast component does not decay completely to zero, suggesting a rapidly equilibrating but incomplete block, followed by normal tail current kinetics for channels that remain unblocked (at 20 to 60 mV most channels inactivate rather than close; Serrano et al., 1999). If so, the relative amplitude of the fast tail current component reflects the fraction of channels blocked (Fig. 6 E).

Rapid block by Ca 2+ o on this time scale (0.1–1 ms; Fig. 6 D) would be expected to produce significant amounts of channel noise. This was examined by stationary noise analysis, exploiting the existence of a “window current” resulting from incomplete inactivation of Ca V 3.1 channels (Serrano et al., 1999). A continuous record of the current at −60 mV over several minutes is shown in Fig. 7 A. Switching from 2 mM Ca 2+ o to 3–10 μM Ca 2+ o increased not only the baseline holding current, but also the noise level. The holding current and noise were both reduced by 2 mM Cd 2+ o, suggesting that the noise results from activity of calcium channels.

Power spectral analysis confirms that the noise is substantially greater in 3 μM Ca 2+ o than in 2 mM Cd 2+ o below 1 kHz (Fig. 7 B). The difference spectrum (assuming

Figure 7. Noise analysis of block by Ca 2+ o. (A) “Window” currents at −60 mV in 2 mM, 3 μM, and 10 μM Ca 2+ o, and in 2 mM Cd 2+ o, 8-pole analogue Bessel filter at 2 kHz. (B) Averaged power spectra in 3 μM Ca 2+ o and 2 mM Cd 2+ o, from ~60 s records analyzed in 819.2 ms segments, using a Hamming window. (C) The difference between the spectra shown in B, fitted to the sum of two Lorentzian components (440 and 10.5 Hz, corresponding to time constants of 0.36 and 15 ms).
that the residual noise in \( \text{Cd}^{2+} \text{o} \) reflects sources other than calcium channel activity) could be described by the sum of two Lorentzian components (Fig. 7 C), with corner frequencies corresponding to time constants close to those obtained from biexponential fits to tail currents (Fig. 6 D). Compared with 0.1 \( \mu \text{M Ca}^{2+} \text{o} \) (where block by \( \text{Ca}^{2+} \text{o} \) should be negligible; Fig. 5), 3–10 \( \mu \text{M Ca}^{2+} \text{o} \) increased the fractional power in the fast component of the power spectrum (Fig. S2; Table S1, available at http://www.jgp.org/cgi/content/full/jgp.200809986/DC1).

Block by \( \text{Ca}^{2+} \text{o} \) should also affect single channel kinetics, as observed for L-type calcium channels (Lansman et al., 1986). In 0.1 \( \mu \text{M Ca}^{2+} \text{o} \), single channel activity could be resolved in cell-attached patches (Fig. 8 A; Fig. S3), with a slope conductance of 33 pS (\( n = 3 \); data from \(-90 \to -40 \text{ mV}) , consistent with results on T channels in sensory neurons (Carbone and Lux, 1987; Lux and Carbone, 1987). Channel gating was rapid with many brief flickers and occasional subconductance states. The mean open time was \( 1 \text{ ms} \), and was not clearly voltage dependent from \(-40 \) to \(-80 \text{ mV} \) (Fig. 8 B; Fig. S4). In addition to long interburst closed times, mean \( \geq 10 \text{ ms} \), brief closings (mean closed times 0.2–0.3 ms) were also observed (Fig. 8 C).

In patches containing 3–10 \( \mu \text{M Ca}^{2+} \text{o} \), bursts of channel activity were observed, including relatively long closed times (Fig. 8 A). The mean open time was reduced by \( \text{Ca}^{2+} \text{o} \), and was not strongly voltage dependent (Fig. 8 B). In contrast, the faster closed time was longer in 3–10 \( \mu \text{M Ca}^{2+} \text{o} \) especially at more depolarized voltages (Fig. 8 C).
μM Ca$^{2+}$ could include both normal closed state(s) (as in A and B. constants (Fig. 6D) and steady-state block (from Fig. 6E); n = 9 for 10 μM Ca$^{2+}$, and n = 3 for 3 μM Ca$^{2+}$. For macroscopic data (frequency domain and time domain), rate constants were calculated assuming 1/τ = k$_{on}$ + k$_{off}$, and p$_{B}$ = k$_{on}$/ (k$_{on}$ + k$_{off}$); thus k$_{on}$ = p$_{B}$/τ, k$_{off}$ = 1/τ - k$_{on}$. In A, bimolecular rate constants were calculated by dividing k$_{on}$ by the free Ca$^{2+}$. The same symbols were used in A and B.

The dependence of the mean open time on Ca$^{2+}$ was consistent with block by Ca$^{2+}$ following bimolecular kinetics (Fig. 8D).

The fast component of closed times observed in 3–10 μM Ca$^{2+}$ could include both normal closed state(s) (as observed in 0.1 μM Ca$^{2+}$) and Ca$^{2+}$ block events. Since the time constants are not very different (Fig. 8C), we could not reliably resolve multiple fast components. For a closing rate of 1 s$^{-1}$ (from the mean open time in 0.1 μM Ca$^{2+}$), the blocking rate in 3 μM Ca$^{2+}$ is 2 s$^{-1}$ (assuming the mean open time in 3 μM Ca$^{2+}$ is the sum of closing and blocking rates, Fig. 8D). That predicts that ~2/3 of the “closed” times in 3 μM Ca$^{2+}$ are Ca$^{2+}$ block events. Correspondingly, nearly all of the closed times in 10 μM Ca$^{2+}$ should result from Ca$^{2+}$ block, so those values (Fig. 8C) should best reflect the true residence time of Ca$^{2+}$ in the pore. Thus, the apparent increase in the faster closed time with Ca$^{2+}$ may reflect a transition from brief Ca$^{2+}$-independent gating events to somewhat slower Ca$^{2+}$ blocking events, rather than an effect of Ca$^{2+}$ on fast gating kinetics.

Fig. 9 compiles estimates of the rate constants for Ca$^{2+}$ entry and exit from three distinct experimental approaches: single channel kinetics, whole-cell noise analysis (“Frequency domain”), and whole-cell tail currents (“Time domain”). Estimates of the Ca$^{2+}$ entry rate (expressed as second-order rate constants) depend little on voltage, and cluster around $3 \times 10^6$ M$^{-1}$s$^{-1}$ (Fig. 9A). The rate constant for Ca$^{2+}$ exit is more voltage dependent, e-fold for 26 mV for the single-channel data with 10 μM Ca$^{2+}$ (Fig. 9B).

The rates estimated from whole-cell tail current kinetics agree qualitatively with the single-channel and noise analysis results, but are approximately twofold slower for entry and approximately twofold faster for exit (especially at 10 μM). These discrepancies are in the direction expected if the initial amplitude of the fast tail current component is underestimated, which is not unexpected for a relaxation with τ ~ 0.2 ms (Fig. 6D).

Effects of Ca$^{2+}$ and Ba$^{2+}$ on I-V Relations and Activation

The next goal of this study was to determine whether Ca$^{2+}$ and Ba$^{2+}$ modify channel gating, in addition to the effects on permeation considered above. We analyzed this by combining information from the I-V protocol (which reflects effects on both gating and on permeation) with the IIV protocol (which isolates effects on permeation). Fig. S5 illustrates sample records obtained with the I-V protocol upon changes in Ca$^{2+}$ and Ba$^{2+}$, and averaged and normalized I-V relations are shown in Fig. 10. In most cases, the peak inward current shifted to more positive voltages as the divalent concentration was increased. However, I-V relations in 10 μM Ca$^{2+}$ were actually shifted to more negative voltages (compared with 100 nM Ca$^{2+}$), opposite to the direction expected from surface charge effects.

Many studies of calcium channel activation are based on chord conductances, measured from I-V relationships as in Fig. 10. However, the G-V relations are quite complex (Fig. 11, A and B) and do not remotely resemble the Boltzmann relation expected from simple models of channel activation, except in very limited voltage ranges (Fig. S6) (Jones, 2003). The main problem is that G-V is directly related to the extent of channel activation (i.e., open probability) only if the IIV is linear (Hodgkin and Huxley, 1952). For CaV3.1, the IIV is distinctly nonlinear under nearly all conditions (Fig. 2), invalidating that assumption.

A more direct measure of channel activation is provided by the ratio of the peak current evoked by direct depolarization (as in Fig. 10), divided by the instantaneous current through fully activated channels (Fig. 2). Activation curves calculated by this method are shown in Fig. 11 (C and D). These relationships are also not perfectly described by a simple Boltzmann relationship, likely resulting from the complex macroscopic gating kinetics of CaV3.1 channels (Serrano et al., 1999). Fits to
Boltzmann relations raised to the fourth power are shown in Fig. 11 (C and D). Although these fits are also not perfect (e.g., they systematically overestimate channel activation at the most negative voltages; Fig. S6, C and D), they are used in this study as an empirical measure of shifts in the voltage dependence of channel activation in different ionic conditions. Qualitatively, activation curves are similar at the lowest Ca$$^{2+}$$ or Ba$$^{2+}$$ concentrations, and shift toward more positive voltages at 2–110 mM. Ca$$^{2+}$$ and Ba$$^{2+}$$ also shifted other measures of channel gating, including $$\tau_{IV}$$ and $$T_{Peak}$$ (Supplemental Results; Figs. S7 and S8).

Fit of Activation Shifts to Gouy-Chapman Theory

Fig. 11 E shows a fit of Gouy-Chapman theory to effects of Ca$$^{2+}$$ and Ba$$^{2+}$$ on the activation curve. Comparable voltage shifts were also observed with Mg$$^{2+}$$ (Fig. 11 F; see also Figs. S11–S18). A value of 1 e$$^{-}$$ per 98 Å$$^{2}$$ describes most of the data well, although at the highest concentrations the experimentally observed shifts were less than the theoretical curves. If activities were used (instead of concentrations), the best fit was 1 e$$^{-}$$ per 91 Å$$^{2}$$ (unpublished data).

Faster Inactivation in Ba$$^{2+}$$, and Effects on Gating Parameters

It has been previously noted that inactivation of CaV3.1 is faster in Ba$$^{2+}$$ than in Ca$$^{2+}$$ (Klugbauer et al., 1999), opposite to expectations for Ca$$^{2+}$$-dependent inactivation. We find that inward, but not outward, currents inactivate more rapidly in Ba$$^{2+}$$ than in Ca$$^{2+}$$ (Fig. 12 A; Fig. S7). $$\tau_{inact}$$ was 35 ± 2% faster in Ba$$^{2+}$$ at 2 mM (for inward currents averaged as in Fig. 12 A; P = 10$$^{-17}$$). This analysis allows two novel conclusions. First, outward currents (carried by Na$$^{+}$$) inactivate more slowly than inward currents in 2–110 mM Ba$$^{2+}$$, comparable to inactivation of outward currents in 2–110 mM Ca$$^{2+}$$, or of inward currents carried by Na$$^{+}$$ (100 nM and 10 μM Ca$$^{2+}$$ or Ba$$^{2+}$$). Second, the effect of Ba$$^{2+}$$ on inactivation of inward currents correlates with block of current carried by Na$$^{+}$$, since kinetics were intermediate at 10–100 μM Ba$$^{2+}$$; the $$K_d$$ for block by Ba$$^{2+}$$ was 4–5 μM at those voltages. This suggests that the rate of channel inactivation depends on the ion occupying the pore, with Ba$$^{2+}$$ > Ca$$^{2+}$$ > Na$$^{+}$$.

Differences in inactivation rate could appear to affect the voltage dependence of channel activation. Qualitatively, if channels inactivate more rapidly in Ba$$^{2+}$$, fewer channels would be open when peak current is reached, which would decrease the measured channel activation, especially at more negative voltages (where activation is relatively slow). Faster inactivation could also shorten the time to peak current. And to the extent that $$\tau_{IV}$$ depends on inactivation, it would be faster in Ba$$^{2+}$$ than in Ca$$^{2+}$$. That is, faster inactivation in Ba$$^{2+}$$ would produce a downward shift of the activation, $$\tau_{IV}$$, and $$T_{Peak}$$ curves, which would appear to be a rightward shift along the voltage axis for activation and $$\tau_{IV}$$, but a leftward shift for time-to-peak (see Fig. 12, D–F). We explored this interpretation by simulating the effect of faster inactivation on these measurements, using the Serrano et al. (1999) model for CaV3.1. The model parameters were varied to optimize the fit to the data of Fig. 12 (D–F), with only the microscopic inactivation rate constant allowed to differ between Ca$$^{2+}$$ and Ba$$^{2+}$$ (see Materials and methods). The fits to the data were not perfect, but they reproduced the key qualitative features (rightward shifts for activation and $$\tau_{IV}$$, leftward shift $$T_{Peak}$$), and the amplitudes

Khan et al. 233
of the shifts were reasonably close to the experimental values (Fig. 12 C). We conclude that the subtle differences in gating observed between Ca$_{2+}$ and Ba$_{2+}$ result primarily from the more rapid inactivation for inward currents with Ba$_{2+}$.

**DISCUSSION**

We report effects on CaV3.1 T-type calcium channels of varying Ca$_{2+}$ and Ba$_{2+}$, over a wide range of concentration (100 nM to 110 mM) and voltage (−150 to +100 mV). One key feature of our experimental design was the use of I/V relations, to isolate effects on permeation from effects on channel gating. This study allows better comparison of ion selectivity in T channels to the classical results on L channels and other HVA calcium channels. In addition, Ca$_{2+}$ and Ba$_{2+}$ affect channel gating, largely as expected for screening surface charge, but pore occupancy by Ba$_{2+}$ also speeds inactivation.

Ca$_{2+}$ vs. Ba$_{2+}$: Permeation

Classically, T-type calcium channels cannot distinguish Ca$_{2+}$ from Ba$_{2+}$, in that inward currents are quite similar for the two ions. We confirm that basic observation (Fig. 2), although careful comparison demonstrates that inward currents are slightly smaller in Ba$_{2+}$ vs. Ca$_{2+}$ (Fig. S9). These results dramatically contrast with most HVA calcium channels, where currents are approximately two-fold larger for Ba$_{2+}$ vs. Ca$_{2+}$. Furthermore, we find that the pore binds Ca$_{2+}$ and Ba$_{2+}$ with similar apparent affinity, either for block of currents carried by Na$^+$ or for permeation (Fig. 5 F).

However, some measures of selectivity report larger differences between Ca$_{2+}$ and Ba$_{2+}$. First, $V_K$ was more positive with Ca$_{2+}$, consistent with $P_{Ca}/P_{Ba} = 2$ based on GHK theory (Fig. 3). Second, outward currents are larger with 2 mM Ba$_{2+}$ vs. Ca$_{2+}$ near +60 mV, demonstrating weaker block of currents carried by Na$^+$ by Ba$_{2+}$, although this effect is reduced at more strongly depolarized voltages (Fig. S9). Third, block by Mg$_{2+}$ is weaker with Ca$_{2+}$, as reported previously (Serrano et al., 2000). This effect is also seen for other pore-blocking ions, including Y$^{3+}$ (Obejero-Paz et al., 2004) and Ni$^{2+}$ (Obejero-Paz et al., 2008). We conclude that a T-channel, like an L- or N-channel, can tell the difference between a Ca$_{2+}$ ion and a Ba$_{2+}$ ion. However, not all
the analysis shown in D–F. Voltage shifts were measured as in Fig. 5, for both experimental data and model output. (D) \(P_{O,\tau}\) in 2 mM \(Ca^{2+}\) or \(Ba^{2+}\) (from Fig. 2, C and D). (E) \(T_{\text{Peak}}\) (from Fig. 3, A and B). (F) \(T_{\text{Peak}}\) (from Fig. 3, E and F). Smooth curves in D–F are calculated from a fit to the Serrano et al. (1999) model (see text). Parameter values for \(Ca^{2+}\) (named as in Serrano et al., 1999) were \(k_V = 2521.1 \text{ s}^{-1}\), \(k_O = 3601.1 \text{ s}^{-1}\), \(k_I = 43.1 \text{ s}^{-1}\), \(k_L = 1.4 \text{ s}^{-1}\), \(f = 0.7555\), \(h = 0.0999\), \(k_{i,\text{Ca}}\) and \(k_{i,\text{Ba}}\) changed with depolarization e-fold for 24.8062, −17.0591, and −34.1144 mV (respectively). Parameters were identical in \(Ba^{2+}\), except \(k_I\) = 122.5 s\(^{-1}\), thus \(k_{i,\text{Ca}}/k_{i,\text{Ba}} = 0.57\).

**Chord Conductance vs. Slope Conductance**

Many features of our analysis exploit chord conductances. Historically, most studies on calcium channel permeation simply measured ionic currents, or used slope conductances, primarily because \(V_R\) can be difficult to measure for these highly \(Ca^{2+}\)-selective channels. For \(CaV_{3.1}\) channels stably expressed in HEK 293 cells, we have previously demonstrated good current isolation (e.g., by the “envelope test”) over a very wide voltage range (Serrano et al., 1999; Obejero-Paz et al., 2004).

Chord conductances are directly related to ion permeation, by \(I = G(V - V_R)\). Chord conductances are always positive, while slope conductances can be negative, e.g., for strongly voltage-dependent block (Adelman and French, 1978). For the nonlinear \(I\text–}V\) relationships observed for \(CaV_{3.1}\), slope conductances will be systematically larger, and more voltage-dependent, than chord conductances. This effect is small for the relatively linear \(I\text–}V\) relationship observed with \(Na^+\) as charge carrier, but slope conductances are approximately two-fold larger than chord conductance at 2 or 110 mM \(Ca^{2+}\) or \(Ba^{2+}\) (Fig. S21). Block by \(Mg^{2+}\) reduces the slope conductance to near zero at voltages and concentrations where block is far from complete (Fig. S21, E and F; compare to Fig. S12, C and D). We do not mean that it is incorrect to use slope conductances as a measure of ion permeation, but it is worth noting that chord and slope conductances can give substantially different numerical values.
Time-dependent Block by Ca$^{2+}$

For most conditions in this study ion entry and exit from the pore are rapid with respect to the time course of gating. The exception was 3–10 μM Ca$^{2+}$. From three different experimental approaches (single channel gating, noise analysis of macroscopic currents, and macroscopic tail currents), we estimate that Ca$^{2+}$ blocked Ca$_{v}$3.1 channels at a bimolecular rate of $3 \times 10^9$ M$^{-1}$s$^{-1}$, with little voltage dependence from −20 to −80 mV (Fig. 9). Ca$^{2+}$ blocked whole-cell currents carried by Na$^+$ through T channels in sensory neurons at $1.9 \times 10^9$ M$^{-1}$s$^{-1}$ (Lux et al., 1990), and HVA channels at $1.4 \times 10^8$ M$^{-1}$s$^{-1}$ (Carbone et al., 1997), although block deviated from bimolecular kinetics at high Ca$^{2+}$ concentrations. Lansman et al. (1986) reported essentially voltage-independent block by Ca$^{2+}$ at $4.5 \times 10^6$ M$^{-1}$s$^{-1}$ for currents carried by Li$^+$ through single L channels, which led to the idea that Ca$^{2+}$ enters open channels at a diffusion-limited rate.

Time-dependent block by Ca$^{2+}$ is visible only in a relatively narrow window of concentration and voltage. For example, the pseudo first-order Ca$^{2+}$ entry rate would be 30 s$^{-1}$ at 100 nM Ca$^{2+}$, (slow with respect to channel gating, including inactivation) or 3,000 s$^{-1}$ at 0.1 mM Ca$^{2+}$ (not fully resolved by our voltage clamp). Detection of blocking kinetics also depends on the extent of block, which is weak at extreme voltages. We did not see evidence for time-dependent block in tail currents at 10 μM Ba$^{2+}$; possible contributing factors include slightly weaker block by Ba$^{2+}$, and a possible difference in Ba$^{2+}$ entry rate.

Ca$^{2+}$ block has a biphasic voltage dependence, becoming weaker either with strong depolarization or strong hyperpolarization (Fig. 4, C and F; Fig. 5 F). Qualitatively, this agrees with previous results on T channels (Fukushima and Hagiwara, 1985; Lux et al., 1990; Shcheglovitov et al., 2007) and HVA channels (Carbone et al., 1997). From −90 to −20 mV, voltage dependence results primarily from changes in exit rate (Fig. 9). At more depolarized voltages, we do not have separate measurements of entry vs. exit rates for Ca$^{2+}$, but relief of Y$^{2+}$ block by strong depolarization primarily reflected accelerated exit (Obejero-Paz et al., 2004).

Permeation Models and Mechanisms

Our results are consistent with the traditional view that calcium channel selectivity results from ion–ion competition in a single-file pore (Almers and McCleskey, 1984; Hess and Tsien, 1984; Yang et al., 1993), but also with alternative approaches such as Poisson-Nernst-Planck theory (Nonner and Eisenberg, 1998; Boda et al., 2006). The simple models used here, e.g., fitting $V_{g}$ shifts to GHK theory (Fig. 3), and fitting the concentration dependence of chord conductances to the sum of block and permeation components (Fig. 5), are essentially empirical approaches to data analysis, as opposed to full theories for ion selectivity and permeation. Such analysis can also be applied to current–voltage relationships predicted by a particular quantitative model. We expect that the dataset reported here (Table S2) will be useful to constrain and test future quantitative descriptions of calcium channel permeation.

Measurement of Channel Activation

We also examined effects of Ca$^{2+}$ and Ba$^{2+}$ on channel gating, measuring channel activation as the relative open probability ($P_{O,r}$), the ratio of the peak current evoked by the IV protocol to the maximally activated current (from the IIIV protocol). Many studies on calcium channels use chord conductances as a measure of channel activation, but that is valid only if the instantaneous IV for an open channel is linear. That is clearly not true for Ca$_{v}$3.1 (Fig. 2; see also Serrano et al., 1999, 2000). The voltage dependence of chord conductances from the IV protocol differs dramatically from the expected Boltzmann-like relationship (Fig. 11, A and B). However, the GV relationship in 2 mM Ca$^{2+}$ is well described by a Boltzmann relationship, if data above −20 mV are not included. Compared with our $P_{O,r}$ analysis, the $V_{1/2}$ is too negative by ~13 mV, and the steepness of the activation curve is greatly exaggerated (Fig. S6). The “maximal” conductance in that analysis occurs at ~20 mV, where a comparison of IV and IIIV protocols clearly demonstrates that channels are not maximally activated (Fig. S22).

The voltage dependence of block can affect voltage shifts measured from the position of peak current with the IV protocol, or from chord conductances, so such measurements (Shcheglovitov et al., 2007) may not accurately measure shifts in channel gating. Conversely, measurement of fractional inhibition from the IV protocol (using either currents or conductances) would not accurately estimate the extent of pore block, since that measurement would be affected by both block and by surface charge shifts. For example, measurements from the IV protocol overestimate the extent of Mg$^{2+}$ block (and its voltage dependence) at voltages where the activation curve is shifted by Mg$^{2+}$ (analysis not shown), and the shift in peak inward current (Fig. S14, C and D) greatly exceeds the voltage shift measured using $P_{O,r}$ (Fig. S16 A).

Channel activation is also shifted by extracellular protons, and the effect of H$^{+}$ is reduced by divalent cations (Talavera et al., 2003a). That is, reducing the pH from 7.2 (as used in the present study) might shift activation to more negative voltages, especially in low Ca$^{2+}$. A differential effect of H$^{+}$ ions would tend to underestimate the effects of Ca$^{2+}$, as measured at pH 7.2. This possibility remains to be evaluated.

Ca$^{2+}$ vs. Ba$^{2+}$: Gating

Although Ca$^{2+}$ and Ba$^{2+}$ shifted activation similarly, direct comparison of our three measures of voltage dependence ($P_{O,r}$, $T_{Peak}$) in 2 mM Ca$^{2+}$ vs. Ba$^{2+}$ showed subtle differences (Fig. 12, C–F). Simulations indicate
that these changes can be explained by faster inactivation of inward currents in Ba\(^{2+}\). Kinetic coupling of activation to inactivation means that changes in either process can appear to affect the other, at the macroscopic level (Talavera and Nilius, 2006). It has long been appreciated that channel "activation curves" do not solely reflect the activation process for a rapidly inactivating channel (Stimers et al., 1985), and the time course of activation (including \(T_{\text{peak}}\)) is also affected by inactivation (Gonoi and Hille, 1987).

The inactivation rate increased with Ba\(^{2+}\), (Fig. 12 A), correlating with the concentration dependence of Ba\(^{2+}\) block of Na\(^+\) current (Fig. 5, C and D). Therefore, we propose that Ba\(^{2+}\) occupancy of the pore speeds inactivation, compared with pores occupied by Na\(^+\) or Ca\(^{2+}\). Although there is ample precedent for effects on gating of pore occupancy by specific ions, it is not clear why Ba\(^{2+}\) would have this particular effect.

**Surface Charge Effects on Gating of Ca\(^{2+}\) and Na\(^+\) Channels**

Activation occurs at more positive voltages in Ca\(^{2+}\) vs. Ba\(^{2+}\) for both Na\(^+\) channels (Hille et al., 1975; Ohmori and Yoshii, 1977; Hanck and Sheets, 1992) and HVA Ca\(^{2+}\) channels (Ohmori and Yoshii, 1977; Wilson et al., 1983; Kota and Stefani, 1984; Byerly et al., 1985; Kass and Kraffe, 1987; Gantitkevich et al., 1988; Zamponi and Snutch, 1996; Smith et al., 1993). Na\(^+\) channels also activate at more positive voltages with Ca\(^{2+}\) vs. Mg\(^{2+}\) (Frankenhaeuser and Hodgkin, 1957; Hille et al., 1975; Hanck and Sheets, 1992). It is striking that this is not true for the Ca\(^{2+}\) T-channel, where activation was shifted similarly by Ca\(^{2+}\), Ba\(^{2+}\), and Mg\(^{2+}\) (Fig. 11, E and F). Qualitatively, it has been noted previously that Ca\(^{2+}\) channel activation is comparable between Ca\(^{2+}\) and Ba\(^{2+}\) (Klugbauer et al., 1999; Kaku et al., 2003), but a quantitative comparison of the concentration dependence does not seem to have been reported, and implications for the molecular basis of the surface charge have not been noted.

Why might surface charge effects for Ca\(^{2+}\) channels differ from both Na\(^+\) and HVA Ca\(^{2+}\) channels? Evolutionarily, based on analysis of conservation of amino acid sequence, Ca\(^{2+}\) channels are almost equidistant between Na\(^+\) channels vs. HVA (Ca\(^{2+}\)1 and Ca\(^{2+}\)2) channels. One known difference is that IQ and EF hand-like domains in the proximal C terminus are conserved among Na\(^+\) and HVA channels, but absent in Ca\(^{2+}\). It seems highly unlikely that these intracellular domains are causally related to surface charge effects observed for extracellular cations, but this is a precedent for functional characteristics shared among Na\(^+\) and HVA channels, but not Ca\(^{2+}\).

Our data are generally consistent with a classical Gouy-Chapman model, where ions shift channel activation by screening a uniform surface charge. In contrast, the larger voltage shifts with Ca\(^{2+}\) have led to the suggestion that Ca\(^{2+}\) can also bind to the surface charge, i.e., Gouy-Chapman-Stern theory (Hille et al., 1975; Byerly et al., 1985). It now seems abundantly clear that the "surface charge" is specific to a particular channel. For potassium channels, the surface charge may result primarily from charged groups on extracellular domains of the channel protein (Elinder and Arhem, 1999). This remains to be explored for calcium channels.

We thank Dr. Ed Perez-Reyes (U. Virginia) for the gift of cells stably transfected with Ca3.1.
