Keywords
Fibrinogen; prognosis; small-cell lung carcinoma; survival.

Abstract

Background: Elevated plasma fibrinogen (Fbg) levels contribute to tumor progression and metastasis; however, limited research on Fbg in small cell lung cancer (SCLC) has been conducted. This study evaluated the prognostic value of Fbg levels in patients with SCLC.

Methods: Data on plasma Fbg level, clinical features, and overall survival were retrospectively collected. Kaplan–Meier estimates and log-rank tests were used to analyze the relationship between Fbg level and survival. Multivariate analyses were performed to determine independent prognostic factors. Subgroup analyses were performed based on extensive/limited disease and Eastern Cooperative Oncology Group status.

Results: A total of 120 patients with SCLC were included. The one, three, and five-year survival rates for the entire cohort were 48.3%, 9.2%, and 1.7%, respectively. Univariate analyses revealed that age, alcohol use, clinical stage, pleural effusion, Eastern Cooperative Oncology Group grade, and Fbg and lactate dehydrogenase levels were associated with survival (P < 0.05). The median survival time for patients with high Fbg levels (> 400 mg/dL) was shorter than for those with low Fbg levels (8 vs. 14 months; P = 0.013). Furthermore, multivariate analysis revealed that Fbg was negatively and independently associated with SCLC prognosis (hazard ratio 1.505, 95% confidence interval 1.018–2.226; P = 0.041). Higher Fbg levels were associated with shorter survival in the extensive disease subgroup (7 vs. 12 months; P = 0.004).

Conclusions: Elevated plasma Fbg was an independent factor associated with poor outcomes in SCLC patients and could serve as a prognostic biomarker.

Introduction

Lung cancer remains the leading cause of cancer-related death worldwide.1 Small cell lung cancer (SCLC), the most aggressive type of lung cancer, has a five-year survival rate of only 1–3%, and approximately two-thirds of patients with SCLC have advanced disease at diagnosis.2,3 Treatment for SCLC patients includes chemotherapy, radiotherapy, and, in rare cases, surgery. As prognosis varies widely, prognostic biomarkers for patients with SCLC are urgently needed.

Many studies have reported an association between blood coagulation abnormalities and several malignancies, and hypercoagulation is associated with a poor prognosis.4–8 Indeed, activation of the coagulation system and procoagulant changes have been associated with angiogenesis and tumor cell invasion, cancer progression, and metastasis.9

Fibrinogen (Fbg), a plasma coagulation factor synthesized by the hepatocytes, is an acute-phase reactant protein and a proinflammatory marker that plays an important role in platelet aggregation, increasing plasma viscosity, vasoconstriction, growth factor release, and fibrin deposition.10 Elevated Fbg levels are associated with distant tumor metastasis and poor outcomes in various malignancies.11–13 In addition, Fbg is reported to have prognostic significance in non-small-cell lung cancer.
Considering that SCLC does not share the same biological characteristics and natural history of NSCLC, the aims of this study were to evaluate the pretreatment plasma Fbg levels and clinical parameters associated with overall survival (OS), and to analyze the prognostic value of Fbg in patients with SCLC.

**Methods**

**Study design and patients**

This cohort study retrospectively reviewed the records of 120 SCLC patients who underwent transbronchial needle aspiration, endobronchial ultrasound-guided biopsy, supraclavicular lymph node biopsy, or surgical confirmation of disease at Beijing Chao-Yang Hospital, Capital Medical University, China, between January 2011 and December 2015. The inclusion criteria were: (i) pathological diagnosis of SCLC; (ii) no history of preoperative adjuvant therapy; (iii) preoperative plasma Fbg level measurement within one week of biopsy or surgery; (iv) Eastern Cooperative Oncology Group (ECOG) grade 0–2 and administration of first-line chemotherapy or a postoperative chemotherapy regimen of etoposide (VP-16) + cisplatin or VP-16 + carboplatin, or ECOG grade 3–4 and no administration of chemotherapy; and (v) availability of complete patient records. Patients who received regular anticoagulation therapy or had other malignancies were excluded.

The Beijing Chao-Yang Hospital ethics committee approved the study protocol and waived the requirement for informed consent, as the study was retrospective.

**Data collection**

Demographic (gender and age); habitus (smoking and alcohol); clinical (stage, pleural effusion, and ECOG); pathological (vascular invasion); and biochemical data were extracted from medical charts. Clinical tumor staging was reviewed according to the fourth version of the National Comprehensive Cancer Network guidelines (2016). The functional status of each patient was evaluated using the ECOG performance scale.

**Outcomes**

The patients were routinely followed up by outpatient visits or hospitalization, depending upon their condition. OS was defined as the duration from treatment initiation to death from any cause. Follow-up was censored at the time of death or on December 31, 2016.

**Fibrinogen levels**

Blood samples were taken at admission and before any treatment using 4 mL vacutainer tubes containing 3.2% sodium citrate. Tubes were centrifuged at 3000 rpm at 4°C for 10 min. Fbg levels were routinely determined by immunoturbidimetry (Sysmex CA-7000/CS-50100, Sysmex Corp., Kobe, Japan) using the clotting method. The normal range for the test is 170–400 mg/dL.

**Statistical analysis**

Continuous data were expressed as mean ± standard deviation (SD) if normally distributed. A Student’s t-test was used to screen for differences between the groups. Categorical data were expressed as percentages. A chi-square test was used to examine categorical variables. Survival curves were analyzed using the Kaplan–Meier method, and clinical parameters were compared using the log-rank test. Multivariate analysis of potential prognostic factors was performed using a Cox regression model. All statistical tests were conducted using SPSS version 19.0 (IBM, Armonk, NY, USA). P values < 0.05 were considered statistically significant.

**Results**

**Patient characteristics**

During the study period, a total of 214 patients were diagnosed with SCLC. Among these, 22 patients had no Fbg data within one week of biopsy or surgery, 19 received radiotherapy before Fbg measurement, 12 received anti-tumor traditional Chinese medicine, 19 patients were lost to follow-up (no survival data), and 22 patients received anticoagulation therapy before Fbg measurement. Therefore, 120 patients met the eligibility criteria and were included in the study. The clinical characteristics of the 120 patients with SCLC are summarized in Table 1. The complete study cohort consisted of 86 men (71.7%) and 34 women (28.3%), with a mean age of 63.2 ± 10.7 years. The median preoperative plasma Fbg level of the entire cohort was 384.3 ± 121.6 mg/dL.

**Survival**

The median survival time (MST) for all patients was 12.0 months. At the end of the study, 107 (89.2%) patients had died, and 13 (10.8%) were alive. The one, three, and five-year estimated survival rates for the entire cohort were 48.3%, 9.2%, and 1.7%, respectively.
Univariate analyses

Univariate Cox regression analyses showed that age ≥ 65 years (P = 0.004), alcohol use (P = 0.023), extensive disease (P < 0.001), pleural effusion (P = 0.004), ECOG grade 3–4 (P = 0.001), Fbg level > 400 mg/dL (P = 0.017), and lactate dehydrogenase (LDH) level > 250 U/L (P = 0.002) were significantly associated with prognosis in SCLC patients (Table 2). Kaplan–Meier analyses and log-rank testing showed that MST for patients with high Fbg levels was shorter (8 months, 95% confidence interval [CI] 5–13 months) than for those with low Fbg levels (14 months, 95% CI 11–18 months; P = 0.013) (Fig 1).

Multivariate analysis

The aforementioned variables of statistical significance were included in a multivariate Cox regression model. The results revealed that clinical stage (hazard ratio [HR] 2.035, 95% CI 1.193–3.470; P = 0.009), ECOG grade (HR 1.850, 95% CI 1.064–3.216; P = 0.029), and Fbg level (HR 1.505, 95% CI 1.018–2.226; P = 0.041) were independently associated with OS (Table 3).

Subgroup analyses

The patients were stratified according to extensive versus limited disease and ECOG 0–2 versus 3–4. Higher Fbg levels were associated with shorter survival times in the extensive disease subgroup (P = 0.004) (Fig 2a), but no significant difference was observed for patients in the limited disease, ECOG 3–4, or ECOG 0–2 subgroups (all P > 0.05) (Fig 2b–d).

Discussion

High Fbg levels are associated with poor outcomes in many types of cancer, including NSCLC, but data are lacking for SCLC. The results of the present study strongly suggest that elevated plasma Fbg levels are independently associated with poorer OS rates in patients with SCLC. SCLC is an aggressive tumor. More than 90% of SCLC patients relapse after treatment, and the five-year survival rate is only 1–3%. In the present study, the five-year survival rate in patients with SCLC was 1.7%, consistent with results reported in the literature. Various baseline clinical characteristics (such as clinical stage, ECOG grade, and weight loss) are associated with patient outcomes. The multivariate analysis performed in this study revealed that advanced clinical stage and high ECOG grade were associated with poor outcomes, which was in line with previous findings. Moreover, the results of the present study indicated that elevated plasma Fbg levels were significantly associated with poor outcomes. These results are consistent with those observed in patients with NSCLC and other types of cancer. Indeed, studies have indicated that high Fbg levels are associated with reduced survival in NSCLC, and renal cell and colon cancers. In patients with advanced NSCLC, serum Fbg alterations are useful to identify those who will benefit from preoperative chemotherapy. It is well known that SCLC does not share the biological characteristics of NSCLC, hence the importance of verifying the eventual prognostic impact of Fbg in SCLC. The present study showed that plasma Fbg level

and survival are associated, as in other cancers and NSCLC.

The results of the present study and numerous other studies have indicated that patients with lung cancer have an increased propensity toward clotting, as well as fibrinolytic system aberrations.22–25 Fbg is synthesized by the liver and converted into insoluble fibrin by activated thrombin. It plays a vital role in blood clotting, as well as fibrinogen; CI, confidence interval; ECOG, Eastern Cooperative Oncology Group; Fbg, fibrinogen; HR, hazard ratio; LDH, lactate dehydrogenase; OS, overall survival; SCLC, small-cell lung carcinoma.

mediated apoptosis of tumor cells.27 Palumbo et al. showed that tumor cell spread and the establishment of micrometastasis was suppressed in Fbg-deficient mice, confirming that Fbg is a determinant of spontaneous metastatic potential.26 Furthermore, Fbg also influences the levels of several growth factors, including VEGF and FGF2, promoting tumor cell adhesion, proliferation, and migration, as well as neoplastic angiogenesis.28,29 Moreover, in the present study, abnormal activation of coagulation and fibrinolysis was reflected in increased plasma Fbg levels, thereby implying that increased Fbg levels were associated with a poor prognosis in SCLC patients.

Because patients with limited/extended disease and patients with different ECOG status have different survival rates,20 subgroup analyses of Fbg levels were performed in patients with extensive versus limited disease and in patients with ECOG grade 0–2 versus 3–4. Surprisingly, high Fbg levels were only associated with poor survival in patients with extensive disease. Therefore, it could be hypothesized that the impact of ECOG on survival is possibly independent from Fbg level, and that Fbg level has no impact in patients in which cancer has not yet disseminated. Nevertheless, additional studies are necessary to determine the mechanisms of Fbg leading to poorer survival.

Previous studies have shown that LDH levels are associated with SCLC prognosis.30,31 In the present study, LDH levels were associated with prognosis in univariate analysis, but not in multivariate analysis. It must be stressed that LDH is increased in cancer patients, but also in other conditions such as heart failure, hypothyroidism, anemia, some infections, and acute pancreatitis.32 Therefore, the lack of association could be a result of other factors influencing the LDH levels in our patients. Additional studies are necessary to address this point.

The present study has some limitations. Indeed, it was a retrospective, single-center study with a small sample size. Data were limited to what was available in the medical charts and prevented in-depth analysis of the coagulation pathways on survival. Multicenter studies should be performed to confirm the prognostic value of plasma Fbg level in patients with SCLC.
The results of the present study strongly suggest that higher Fbg levels were significantly and independently associated with poor prognosis in patients with SCLC. Fbg could serve as a simple and effective biomarker for assessing prognosis in SCLC patients.
