Chronic rhinosinusitis (CRS) is a clinical syndrome characterized by mucosal inflammation of the nose and paranasal sinuses. It has been suggested that CRS occurs as the result of an inappropriate or exaggerated response to external environmental triggers. The original criteria for diagnosis were first established in 1997 by the Task Force on Rhinosinusitis, which required the presence of either two major or one major and two minor criteria for a period of ≥12 weeks. Major criteria include facial pressure, nasal obstruction or blockage, hyposmia or anosmia, and purulent nasal drainage. Minor criteria include headache, fever, halitosis, cough, dental pain, fatigue, and ear pain or pressure. The diagnostic criteria for CRS were further updated by the American Academy of Otolaryngology in 2007 and again with the update of the European Position Statement in 2012, which required radiological or endoscopic documentation of inflammation in addition to two major criteria.

Clinically, CRS is generally divided into two broad categories—CRS with nasal polyposis (CRSsNP) and CRS without nasal polyposis (CRSsNP)—with the understanding that there is often significant overlap within a broad spectrum of inflammatory disease. CRSsNP is typically associated with other respiratory diseases such as asthma, aspirin sensitivity, and idiopathic bronchiectasis. In this article, the epidemiology of CRSsNP and its major subtypes are discussed.

Epidemiology and differential diagnosis of nasal polyps

ABSTRACT

Background: Chronic rhinosinusitis (CRS) is one of the most common chronic medical conditions, with a significant impact on patient quality of life. CRS is broadly classified into two groups: CRS with nasal polyps (CRSsNP) and CRS without NP (CRSsNP). Clinically, the major subtypes of CRSsNP may be divided into eosinophilic chronic rhinosinusitis (e.g., allergic fungal rhinosinusitis and aspirin-exacerbated respiratory disease [AERD]) and nasal polyps associated with neutrophilic inflammation (e.g., cystic fibrosis [CF]). CF is characterized by mutation of the gene encoding the CF transmembrane conductance regulator. Functional endoscopic sinus surgery is usually required for most NP patients with increased frequency in patients with AERD. This study provides a review of the epidemiology and major classification of CRSsNP.

Methods: A review was performed of the literature regarding different subtypes of CRSsNP.

Results: Many definitions of CRSsNP exist and estimates of prevalence vary.

Conclusion: CRSsNP is a clinical syndrome with a heterogeneous inflammatory profile. Of the subtypes associated with eosinophilic inflammation, AERD remains the most recalcitrant to medical and surgical therapeutic interventions.

Epidemiology and differential diagnosis of nasal polyps

Chronic rhinosinusitis (CRS) is a clinical syndrome characterized by mucosal inflammation of the nose and paranasal sinuses. It has been suggested that CRS occurs as the result of an inappropriate or exaggerated response to external environmental triggers. The original criteria for diagnosis were first established in 1997 by the Task Force on Rhinosinusitis, which required the presence of either two major or one major and two minor criteria for a period of ≥12 weeks. Major criteria include facial pressure, nasal obstruction or blockage, hyposmia or anosmia, and purulent nasal drainage. Minor criteria include headache, fever, halitosis, cough, dental pain, fatigue, and ear pain or pressure. The diagnostic criteria for CRS were further updated by the American Academy of Otolaryngology in 2007 and again with the update of the European Position Statement in 2012, which required radiological or endoscopic documentation of inflammation in addition to two major criteria.

Clinically, CRS is generally divided into two broad categories—CRS with nasal polyposis (CRSsNP) and CRS without nasal polyposis (CRSsNP)—with the understanding that there is often significant overlap within a broad spectrum of inflammatory disease. CRSsNP is typically associated with other respiratory diseases such as asthma, aspirin sensitivity, and idiopathic bronchiectasis. In this article, the epidemiology of CRSsNP and its major subtypes are discussed.

EPIDEMIOLOGY

CRS is one of the most prevalent chronic diseases worldwide. Affecting one in seven American adults, it is the second most common chronic condition in the United States. In Europe, the Global Allergy and Asthma Network of Excellence study reported the prevalence of CRS, as defined by European Position Statement criteria, as 10.9%. CRS also has a significant impact on quality of life, with symptom severity comparable with classically debilitating diseases such as congestive heart failure, chronic back pain, and chronic obstructive pulmonary disease. Despite these data, the prevalence of CRS formally diagnosed by physicians is only 2%. Potential causes of this variability in estimated prevalence include the use of different diagnostic criteria, diagnosis and management by variously trained medical professionals, and inconsistent diagnostic definitions. NP, in particular, can be clinically silent, and epidemiological studies use a mix of subjective and objective metrics of polyposis. Objective evidence of NP includes evaluation by anterior rhinoscopy or nasal endoscopy, and subjective measures rely on self-report surveys—leading to concerns that these measures may overestimate the actual prevalence. Overall, the literature suggests that CRSsNP increases with age, with a mean onset across all ethnic groups of 42 years. In most studies, NP is uncommon under the age of 20 years and occurs more frequently in men than in women, aspirin-sensitive patients, however, are more likely to be women.

PATHOPHYSIOLOGY

Despite growing evidence that bacteria, fungi, allergens, and superantigens play a prominent role in the pathophysiology of CRSsNP, the exact cause of polyposis is still unknown. The etiology of CRS is considered multifactorial. CRS is a clinical diagnosis characterized by a heterogeneous pattern of inflammation that may be initiated by any number of factors, with the result being a dysregulated interaction between the sinus epithelium and the lymphoid system. Over the past 10 years, research has revealed unique cytokine and cellular inflammatory profiles that contribute to CRS. Approximately 80% of CRSsNP in western countries are characterized by a robust T-helper 2 (Th2) response, eosinophilic infiltration, decreased T-regulatory function, and an abundance of IL-5 cytokine. This pattern is in contrast to nasal polyps found in Chinese patients where the majority of nasal polyps present with Th1 and Th17 (Th1/Th17) inflammatory profiles. This pattern has also been found in other Asian countries such as Thailand and Korea. Eosinophilic polyps were identified in 33.3% of patients (n = 30) in Korea and only 11.7% of patients (n = 149) in Thailand. Allergic inflammation in the upper and lower airways is common in CRSsNP, with 60% of patients suffering from comorbid asthma. The pattern of inflammation shown in CRS is seen in asthma as well, and asthmatic patients have increased IL-5 and Th2 activity. Of note, a recent pan-European sinusitis cohort within the Global Allergy and Asthma Network of Excellence study found the relationship between asthma and sinusitis to be of even greater magnitude in polyposis patients. The relation-
ship between upper and lower airway pathology is further corroborated by the improvement in lower airway disease that is observed when CRSwNP is effectively treated.36

DIFFERENTIAL DIAGNOSIS

Eosinophilic Chronic Rhinosinusitis

In western countries, eosinophilic CRS (ECRS) is the most common general category of CRSwNP. ECRS encompasses allergic fungal rhinosinusitis (AFRS), eosinophilic mucin rhinosinusitis (EMRS), eosinophilic fungal rhinosinusitis (EFRS), and even aspirin-exacerbated respiratory disease (AERD). The main distinction between the first three subtypes is with regard to the presence of allergy to molds and/or the presence of fungus in the sinuses. In AFRS, there is allergic mucin and local eosinophilia, as well as mold allergy. There is no specific IgE to mold allergens in EMRS and EFRS, but there is absence of fungus in EMRS. In both subtypes, polyps appear similar to AFRS but are typically bilateral without characteristic hyperdense secretions and less bony erosion into the orbit or skull base.29,30

Several studies point to fungi as a possible inflammatory trigger for CRS independent of a type I IgE allergic mechanism as seen in AFRS.28 Observations that eosinophils cluster around fungi intimate that eosinophils might target the fungi and trigger the inflammation in CRS patients. Furthermore, peripheral lymphocytes from CRS patients will produce large quantities of the cytokines IL-5 and IL-13 in CRS patients. Furthermore, peripheral lymphocytes from CRS patients when exposed to certain fungal antigens.31 Thus, the fungi in the nasal and sinus mucus may activate and induce Th2-type cytokine production independent from allergy. This has added to the controversy regarding the diagnosis of EMRS because of the advent of more sensitive techniques such as the use of chitin staining.32 Polymerase chain reaction amplification33–35 used to detect fungi indicates EMRS may also be related to a fungal inflammatory response. Ponikau et al.36 in 1999 suggested that fungi are present in almost all patients with CRS (96%) with <25% of these exhibiting a type I hypersensitivity to fungal antigens.31 Thus, the fungi in the nasal and sinus mucus may activate and induce Th2-type cytokine production independent from allergy. This has added to the controversy regarding the diagnosis of EMRS because of the advent of more sensitive techniques such as the use of chitin staining.32

The presence of multiclonal IgE in nasal polyps associated with local IgE against Alternaria or Staphylococcus provides another potential role of fungi in NP.38–41 Importantly, local IgE hypersensitivity to Alternaria and Aspergillus were also noted to contribute to local tissue eosinophilia in the adenoids of both atopic as well as nonatopic children (more so in atopic) who did not show systemic sensitization.31 AFRS and AERD will be discussed in more detail later in this article.

Allergic Fungal Rhinosinusitis

The pathogenesis of AFRS is an area of active research and deserves further mention. Studies indicate that a type I and, to a lesser extent, type III hypersensitivity to fungal allergens is responsible for the pathological findings and clinical symptoms.42,43 AFRS has been described as the nasal analog of allergic bronchopulmonary aspergillosis, because both are associated with specific type II major histocompatibility complexes.44

Historically, the diagnosis of AFRS was established by Kuhn’s criteria,35 which include: (1) presence of nasal polyps, (2) type I hypersensitivity, (3) characteristic computed tomography (CT) findings, (4) presence of allergic mucin without tissue invasion (Fig. 1), and (5) microscopic evidence of fungi. Characteristic CT scan findings include unilateral (up to 50%) or bilateral opacification of the sinuses with areas of hyperattenuation representing allergic mucin (Fig. 2). Significant bony erosion of the skull base can be seen (Fig. 3). Because the diagnostic criteria require histopathology, AFRS is typically diagnosed only after endoscopic sinus surgery. Fungal cultures obtained in these patients often yield dematiaceous fungi such as Bipolaris spicifera, Curvularia lunata, and Aspergillus species including Aspergillus fumigatus, Aspergillus flavus, and Aspergillus niger.46,47 Elevated serum IgE suggests AFRS, and IgE levels tend to fluctuate with disease activity.48 Shubert in 199848 developed another set of criteria for AFRS that excluded the presence of type I allergy to the fungus. In these criteria, the surgically obtained mucin must be positive for fungus with no tissue invasion and exclusion of other causes of fungal rhinosinusitis. The diagnosis of AFRS has been further modified according to the guidelines for clinical research in CRS.49 Criteria according to this classification require the presence of more than one clinical symptom of CRS with endoscopic documentation of allergic mucin and inflammation that includes either edema or polyposis, radiological evidence of CRS, and histological documentation of allergic mucin as well as type I hypersensitivity to fungi. These criteria were put forth because of the problems in culturing fungus postoperatively and the difficulty in fulfilling all Bent and Kuhn criteria. The presence of fungus culture, which has a yield of 64–100%, does not establish or eliminate the diagnosis of AFRS.50

Figure 1. Endoscopic view of allergic fungal mucin.

Figure 2. Coronal computed tomography (CT) scan of the paranasal sinuses with soft tissue windows showing unilateral opacification of the maxillary and ethmoid sinuses with bony erosion into the skull base (black arrow) as well as expansion into the left orbit. Note the characteristic hyperattenuated areas in the maxillary sinus suggestive of allergic fungal rhinosinusitis (AFRS; white arrow).
A strong association between Staphylococcus aureus superantigens and AFRS was found among patients with CRSwNP. S. aureus colonization was significantly more prevalent in AFRS when compared with other subtypes of CRSwNP. It has been postulated that superantigens may have an activating role, promoting the immune dysregulation that contributes to AFRS. These concepts underscore the likelihood of related and overlapping mechanisms contributing to eosinophilia in ECRS.

Aspirin-Exacerbated Respiratory Disease

In 1922, Widal et al. were the first to describe the association between nasal polyps, asthma, and aspirin hypersensitivity. After further characterization by Samter, the association became known as “Samter’s triad.” AERD is a clinical syndrome consisting of chronic sinusitis, NP, bronchoconstriction, and angioedema or urticaria associated with the ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs). Estimates of prevalence vary; research suggests AERD affects between 0.3 and 2.5% of the general population. Some studies, however, report up to a 33% prevalence in patients undergoing endoscopic sinus surgery for CRS. The prevalence of AERD is likely underestimated in the literature, partly because of the difficulty in establishing the diagnosis when relying on patient history alone. One study reported a 23% prevalence of AERD when patients with NP with or without asthma were evaluated with the oral aspirin provocation test. Of these patients who tested positive, 25% had no history of aspirin hypersensitivity. In a large study from Poland that included 12,971 randomly selected adults, the prevalence of AERD was 0.6% in the general population, 4.3% in asthmatic patients, 0.7–2.6% in CRS, and as high as 14–22% in NP patients.

AERD is typically seen in the third decade of life with a female/male ratio of 3:2. There are no clear ethnic associations, but individuals expressing the HLA A1/B8 phenotype have a higher incidence of AERD. The pathogenesis of AERD is related to dysregulation of eicosanoid synthesis. Eicosanoids are molecules that are derived from arachidonic acid through a series of enzymic modifications via the cyclooxygenase and lipoxygenase pathways. Aspirin competes with arachidonic acid by irreversibly binding to the cyclooxygenase active site, shifting substrates to the lipoxygenase pathway with a resultant increase in leukotrienes and reduction in prostaglandins.

Why some patients are more sensitive to these biochemical shifts is poorly understood, and some have theorized that viral infection in genetically predisposed patients may be the inciting event. T cells cultured with respiratory viruses have increased release of cytokines that attract eosinophils. These cytokines, particularly IL-5, also contribute to the overproduction of eosinophils in patients with aspirin sensitivity. Other potential pathophysiological and molecular dysregulations have been reported to be linked with NP and particularly with AERD. In a study by Fruth et al., an antiapoptotic cell regulator called surviving was overexpressed in patients with AERD polyposis. Thus, decreased apoptosis as well as cellular hyperplasia may contribute to the pathophysiology of nasal polyp formation.

NP in AERD is clinically very aggressive when compared with other forms of ECRS. Overall, between 36 and 96% of AERD patients are afflicted with NP. The early symptoms of AERD are rhinorrhea and nasal congestion. Patients typically present with nasal congestion, rhinitis, hyposmia, and chronic rhinorrhea, ultimately progressing to pansinusitis and, eventually, polyposis. They frequently undergo multiple sinus surgeries before diagnosis. The disease may evolve over time into full-blown AERD with NSAID intolerance and symptoms of asthma and bronchoconstriction. Individuals...
may also develop facial deformation due to the increased pressure of polyps on the sinonasal bones. The gold standard for diagnosing AERD is an aspirin challenge test, however, clinical diagnosis is important in identifying individuals with the constellation of symptoms and signs that are typical for AERD. Some patients will present before their first reaction to NSAIDs, but aspirin challenge will be diagnostic.

**Cystic Fibrosis**

Neutrophilic CRSwNP in western countries is unusual, but the genetic disease cystic fibrosis (CF) merits discussion. CF is an autosomal recessive disorder affecting around 30,000 children in the United States. CF patients have thick, tenacious mucus secondary to a mutation in the CF transmembrane conductance regulator (CFTR) chloride channel that affects mucociliary transport. Absence or lack of functional channels has deleterious effects on other organ systems, notably the lungs and gastrointestinal tract. The diagnosis of CF consists of identifying one of two manifestations as well as the presence of either two CF mutations, an abnormal transepithelial nasal potential difference, or two abnormal sweat chloride tests. Although the majority of CF patients do not report sinonasal symptoms, CRS is ubiquitous. Nasal polyps are seen in up to 86% of patients with CF. In CF CRS, inflammation is neutrophil driven where IL-8 is the primary cytokine. Sinus cultures typically grow *S. aureus*.

Examination of CF patients with NP usually reveals bilateral polyps, thick anterior and posterior nasal discharge, and facial deformities such as hypertelorism due to widening of the nasal bridge with relative prognathism. In addition to NP, CT scan findings include hypoplasia of the frontal or sphenoid sinuses as well as demineralization and medial displacement of the uncinate process. Mucocele formation is not uncommon in CF, and the presence of mucocoeles in a child should raise suspicion for CF. Pediatric patients with CRS that meet criteria for CF are more likely to be heterozygous for a CFTR mutation when compared with the general population (12% versus 4%). Furthermore, acquired defects in CFTR may be present in individuals without CF secondary to environmental local perturbations indicating defects in mucus clearance are present in individuals with sinus inflammation and NP. 

**CONCLUSIONS**

The majority of polyps in patients with CRSwNP in western countries are secondary to eosinophil-driven inflammation; CF is a prominent exception. The exact etiology of NP is still unknown. Multiple factors, including allergy, superantigens, and fungal infection, contribute to the pathophysiology of CRSwNP. Among the various eosinophilic subtypes of CRSwNP, AERD is the most treatment resistant.
