**Abstract**

We show that an \( n - n^- - n \) junction in 2D crystals can flexibly realize two basic valleytronic functions, i.e. valley filter and valley source, with gate controlled switchability between the two. Upon carrier flux passing through the junction, the valley filter and valley source functions are enabled respectively by intra- and inter-valley scatterings, and the two functions dominate respectively at small and large band-offset between the \( n \) and \( n^- \) regions. It can be generally shown that, the valley filter effect has an angular dependent polarity and vanishes under angular integration, by the same constraint from time-reversal symmetry that leads to its absence in one-dimension. These findings are demonstrated for monolayer transition metal dichalcogenides and graphene using tight-binding calculations. We further show that junction along chiral directions can concentrate the valley pump in an angular interval largely separated from the bias direction, allowing efficient harvest of valley polarization in a cross-bar device.

**1. Introduction**

Exploring diversified internal quantum degrees of freedom of carriers as the fundamental ingredients for device applications has led to the emergence of spintronics and pseudospintrons, attempting to go beyond present-day charge-based electronics. Utilizing the valley degree of freedom, an inherited property of a plethora of crystalline materials, for building device components has conceived the field of valleytronics [1–5]. Two-dimensional (2D) hexagonal materials such as graphene and transition metal dichalcogenides (TMD) are especially attractive for valleytronics [6, 7], with a time-reversal pair of valleys well separated in momentum space.

A widely adopted approach for producing valley currents in these 2D crystals is to introduce lateral junctions as scatterers. Novel uses of lateral junctions have been discussed in graphene exploiting the nature of massless Dirac fermions, for example, the effects of Klein tunneling [8, 9], electronic analogs of Veselago’s lens [10, 11], and guiding [12] at bipolar or unipolar junctions. Valleytronic functionalities arise from the valley contrasted scattering by the lateral junctions, for which various forms of realization have been proposed such as gated regions [13–15], strained areas [16–19], or line defects [20–25]. Most of these approaches use line scatters with momentum conserved in the parallel direction, such that the scattering is effectively one dimensional (1D) [13–20, 22]. The key mechanism exploited is the valley-dependent intra-valley scattering at oblique incidences upon the line scatters [13–20]. In such case, the lateral junction induces valley currents by permeating carriers of one valley more than the other, without producing net outward valley-polarized flows. This defines what valley filters are, as depicted by the left panel of figure 1(a).

It is worth noting that such valley filtering effect does not occur in intrinsic 1D systems (e.g. nanoribbons), where time-reversal symmetry dictates equal amounts of intra-valley reflections for incidences from either valleys [26]. For the effective 1D scattering event projected from 2D systems with line scatters, the symmetry between incidences at the two valleys can be effectively broken by the oblique incident angle. The magnitude and polarity of the valley filtering therefore depend on the incident angle. Concerning the absence of valley filtering in intrinsic 1D systems, the following question naturally arises. In the 2D geometries, can the valley filtering effect still give rise to nonzero valley flux under the integration over incident angles? In experiments for studying angle-dependent charge transport, the angle dependence is approached by prefixing the orientations of local contacts [11, 12, 27, 28]. With such inflexibility of angular probing and possible diffusive motions that blur the angular dependence, angle-integrated valley fluxes are practically preferable.
On the other hand, lateral junctions also induce inter-valley scattering, which can be non-negligible in addressing the valley functionalities [15, 21, 25, 26]. Interestingly, it is recently noted that inter-valley scattering can provide a useful resource for valleytronics, besides its well anticipated role in depolarizing valley [26]. In 1D systems, it is shown that inter-valley scattering by disorders can realize a distinct valleytronic functionality, the valley source, where upon passing charge current, valley currents are pumped in both the forward and backward directions, with a net outward valley flux (see the right panel of figure 1(a)) [26]. The exploration of such effect in the more relevant 2D scattering geometry is of importance for practical implementation based on 2D crystals.

Here we show that in 2D scattering by line scatters, the valley filtering effect from intra-valley scattering averages out after integration over the incident angles, a consequence of the time-reversal symmetry that has also dictated the absence of valley filtering in 1D systems. Nevertheless, inter-valley scattering functionalizes the line scatters as valley sources, which can efficiently pump valley current even under the integration over incident angles. We demonstrate these general points with explicit results from $n-n-n$ junctions in TMDs and graphene, which can have tunable functionality from a filter dominating regime to a source dominating regime, through the adjustment of the band-offset between the $n$ and $n^{-}$ regions. For junctions oriented along a chiral direction, we further show that the valley fluxes are pumped into tunable range of angles well separated from the direction of driving charge current, easing the harvest of the valley polarization in a cross-bar device.

Figure 1. (a): Net valley flows of a valley filter and a valley source. (b): directional valley filtering for two oblique incidences in 2D producing opposite valley fluxes (see the inset and the texts below). (c): 2D $n-n-n$ junction formed by deposited gates. (d): the fermi contours around the two valleys in momentum space zoomed in around two corners of the Brillouin zone, displaying how momentum conservation along the interface enables or disenable inter-valley scattering. In (a), the valley filter is more penetrable for incoming carriers with one valley polarity than the opposite polarity. Without inter-valley scattering, the net valley fluxes flow in the same direction on both sides of the filter (see the green arrows). The valley source however can flip the valley polarity of the incoming carriers and produces a net out-going valley flux (see oppositely directed green arrows). In (b), we have $k', q', k, q \in K'$ and $k, q, k', q' \in K$, where $'$ is the time-reversal of $'$, as indicated in the inset. There the blue and the red closed curves are the fermi contours of the $K$ and $K'$ valleys. The incident and the out-going momenta are marked as circles and crosses. Two momenta forming a time-reversal pair are connected by a dashed line. In (c), the junction is described by a potential well. The shape of the potential well is characterized by two length parameters $S$ (smoothing) and $W$ (well width), and a depth parameter $U_g$. The dashed horizontal line above indicates the incident energy $E_{in}$. They are specified in the following calculations. In (d), the solid- (dashed-)line portions on the fermi contours have right-moving (left-moving) states. An incidence on a right-moving state of the $K$ valley (the spot on the fermi contour of that valley) can be scattered to left-moving state on the same valley (see extended dashed lines from the spot) for all interface orientation. It can be scattered to the $K'$ valley only when the interface is not along the zigzag direction, due to momentum conservation along the interface (see the extended solid lines from the spot and their intersecting with the fermi contour of the $K'$ valley).
2. Switchable valley functionalities

2.1. Proof of vanishing angle-integrated valley flux in the absence of inter-valley scattering by line scatterers

We first explicate the general microscopic picture that underlies the vanishing of angle-integrated valley flux in the valley filtering effect of line scatterers. We denote the probabilities of scattering the in-coming carrier, injected from the left side of the interface at angle \( \theta \) and valley \( \tau \), to valley \( \tau' \), by \( R_{\tau\rightarrow \tau'}(\theta) \) (as reflection) and \( T_{\tau\rightarrow \tau'}(\theta) \) (as transmission). The angle-integrated fluxes are given by \( R_{\tau\rightarrow \tau'}(\theta) \equiv (2\pi)^{-1} \int d\theta R_{\tau\rightarrow \tau'}(\theta) \) and \( T_{\tau\rightarrow \tau'}(\theta) \equiv (2\pi)^{-1} \int d\theta T_{\tau\rightarrow \tau'}(\theta) \) where \( (2\pi)^{-1} \) comes as the normalization constant such that \( 1 = \sum_{\tau'\in\{K,K'\}} |R_{\tau\rightarrow \tau'}(\theta)|^2 + |T_{\tau\rightarrow \tau'}(\theta)|^2 \). Generally, given a scattering event, one can always find a counterpart event by designating the time-reversal of the in-coming (out-going) momentum of one event to be the out-going (in-coming) momentum of the other. The two events correspond to identical scattering probabilities by respecting time-reversal symmetry \([29]\). Explicitly, this implies that given an incident angle \( \theta \) and valley \( \tau \), one can accordingly find a corresponding angle \( \theta' \) such that

\[
R_{\tau\rightarrow \tau'}(\theta) = R_{\tau\rightarrow \tau'}(\theta'), \tag{1}
\]

where \( \tau' \) denotes the opposite valley of \( \tau \). For 2D crystals with a time-reversal pair of valleys, we visualize these paired momenta on the fermi contours by the inset of figure 1(b) (see the captions for more details). The consequence of equation (1) is illustrated in figure 1(b). The upper part of figure 1(b) describes how a valley unpolarized oblique incidence produces a valley current, i.e the valley filtering effect by intra-valley scattering. Its counterpart event is described in the lower part of figure 1(b). The two events produce opposite valley fluxes, as illustrated in figure 1(b). Thus, while each intra-valley scattering event has a valley-filtering function, the valley fluxes produced by the pair cancel each other.

On the other hand, directly summing all incident angles leads equation (1) to

\[
R_{K\rightarrow K'} = \mathcal{R}_{K\rightarrow K}. \tag{2}
\]

The angle-integrated valley fluxes in the reflection/transmission are defined by

\[
\begin{align*}
J^R_{\nu} &= J^R_{\nu TT} + J^R_{\nu TT'}, \tag{3a} \\
J^T_{\nu} &= [T_{K\rightarrow K'} - T_{K\rightarrow K}], \\
J^R_{\nu} &= -[\mathcal{R}_{K\rightarrow K'} - \mathcal{R}_{K\rightarrow K}]. \tag{3b}
\end{align*}
\]

where

\[
J^T_{\nu} = [T_{K\rightarrow K'} - T_{K\rightarrow K}], \\
J^R_{\nu} = -[\mathcal{R}_{K\rightarrow K'} - \mathcal{R}_{K\rightarrow K}].
\]

For valley filters, the contributions \( J^R_{\nu TT}, \) in equation (3c) are zero by definition. Immediately from equation (2) and the conservation law, leading to \( T_{K\rightarrow K'} = T_{K\rightarrow K} \), applied to equation (3), the vanishing angle-integrated flux \( J^R_{\nu TT} = 0 \) is proved. Note that equations (1) and (2) hold regardless the scatterer acts as a valley filter or valley source. As a result, we ensure that the net valley current under equilibrium condition is zero for both valley filters and sources (see appendix A).

2.2. Angle-resolved valley flux

Below we illustrate these general relations discussed above by \( n = n^- - n^+ \) junctions on TMD (schematically shown as figure 1(c)) with the armchair-oriented interface since inter-valley scattering is possible for all incident angles (see figure 1(d) and its captions). We present in figures 2(a) and (b) the intra-valley scattering probabilities respectively for small and large band-offsets between the \( n \) and \( n^- \) region (see appendix B for the method). Such a junction can be described as a potential well structure. The results at shallow (figure 2(a)) and deep (figure 2(b)) well depths both show that for a given incident angle \( \theta = \theta_0 \), one can always find another angle \( \theta = \theta'_1 \) (related to \( \theta_0 \) through time-reversal analysis) such that \( R_{K\rightarrow K}(\theta_0) = R_{K\rightarrow K}(\theta'_1) \) (comparing the red solid and the black long-dashed lines in figures 2(a) and (b)). This witnesses equation (1). For small band-offsets, the inter-valley scattering becomes negligible, namely, \( R_{\tau\rightarrow \tau'}(\theta) \approx 0 \) and \( T_{\tau\rightarrow \tau'}(\theta) \approx 0 \). Then by charge conservation \([1] = \sum_{\tau\in\{K,K'\}} |R_{\tau\rightarrow \tau'}(\theta) + T_{\tau\rightarrow \tau'}(\theta)| \) for all \( \tau \in \{K,K'\} \), \( T_{K\rightarrow K}(\theta_0) = T_{K\rightarrow K}(\theta'_1) \) also applies (see the blue dash-dot and orange short-dashed lines in figure 2(a)). These equalities exemplify the situation illustrated in figure 1(b). The valley fluxes on the two sides of the junction are given by

\[
\begin{align*}
J^T_{\nu}(\theta) &= \sum_{\tau\in\{K,K'\}} [T_{\tau\rightarrow K}(\theta) - T_{\tau\rightarrow K}(\theta)], \\
J^R_{\nu}(\theta) &= -\sum_{\tau\in\{K,K'\}} [R_{\tau\rightarrow K}(\theta) - R_{\tau\rightarrow K}(\theta)]. \tag{4}
\end{align*}
\]

where the minus sign in \( J^R_{\nu}(\theta) \) accounts for reflected flux flowing oppositely to the transmitted ones. Consequently with a shallow well, they satisfy \( J^R_{\nu}(\theta) = J^T_{\nu}(\theta) \). The valley flux on the left side thus flows into the junction interface while that on the right side flows outward from the interface, as shown by figure 2(c). This result shows that the \( n^- - n^+ \) junction with small band-offset behaves as a valley filter (the left panel of figure 1(a)). Note that the impossibility of producing valley current by 1D valley filter is reproduced by zero valley currents at normal incidence, \( J^R_{\nu}(0) = J^T_{\nu}(0) = 0 \) (see figure 2(c)).
At deeper well depth, the inter-valley scattering events then become not ignorable. Although we still have $\theta_1 = \theta'_1$, charge conservation law together with $\theta_0 \neq \theta'_0$, then leads to $\theta_{TK} \neq \theta'_{TK}$ (see the separated range of values between the blue dash-dot and orange short-dashed lines in figure 2(b)). Under such circumstance, figure 2(d) shows that the valley fluxes on both sides of the junction flow outward from the interface. This signifies that such $n - n - n$ junction with sufficient large band-offset works as a valley source (the left panel of figure 1(a)). The out-going angle distributions of the reflected (the left semi-circle) and the transmitted (the right semi-circle) fluxes carrying valley $K$ (the blue line) and $K'$ (the red line), (a), (c) and (e) are in filter-dominating regime with $U_g = -77.4$ meV while (b), (d) and (f) are in the source-dominating regime, using $U_g = -530$ meV. In (a), the intersects between the green vertical and horizontal lines exemplifies the equality shown on the plot’s vicinity. These equalities underlie the cancellation of opposite valley fluxes by time-reversal paired scattering events. In (b), only $R_{K' \to K}(\theta) = R_{K' \to K}(\theta')$ is identified. The lack of such equality in transmission coefficients signifies the importance of inter-valley scattering. The incident energy $E_m$ is measured from conduction band bottom, $E_F$, by $E_m - E_F = 44.24$ meV. Other well shape parameters are $S = 10a$ and $W = 110a$, where $a$ is the lattice constant. These parameters are fixed otherwise specified. The slight asymmetry between $\theta_1$ and $\theta_{TK}$ with respect to $0^\circ$ is due to the trigonal warping of the fermi contours.

2.3. Angle-integrated valley flux
2.3.1. Interface along armchair direction

The different contributions to the angle-integrated valley fluxes are further presented as different symbols in figures 3(a) and (b) respectively for higher (sufficient for visible trigonal warping) and lower incident energies, as a function of the well depth. The cancellation of the reflected valley fluxes discussed previously, equation (2), is a general phenomena and is expected to be independent of the details of the scatterers. This is witnessed by $f_{K' \to K}$ being a vanishing constant (see equation (3b)) in both figures 3(a) and (b) (the black circles), independent of the well depths. A small valley flux contributed by $f_{K' \to K}$ readily appears at zero well depth (see the values of the blue triangles for $U_g = 0$ in figures 3(a) and (b)). It is due to more injection in $K'$ than in $K$ (see figure 3(c) and its captions) without scattering and such difference is reduced by shifting the incident energy closer to the band edge (comparing the values of the blue triangles for $U_g = 0$ in figures 3(a) and (b)). Apart from this, in the filter-dominating regime
(shallower well depth with negligible $J_{Rw}^+$), the angle-integrated valley fluxes excluding $J_{Rw}^-$ is very small. This verifies the above general analysis for valley filters. Tuning of the well depth from filter-dominating to the source-dominating regime is accompanied by the rise of the importance of inter-valley scattering, $-J_{Rw}^-$ (the red squares) and $-J_{Tw}^-$ (the orange diamonds) around $\approx-550\,\text{meV}$. The consequent rise of $+J_{Tw}^+$ (the blue triangles) is due to the charge conservation with sizable contribution from inter-valley reflection $-J_{Rw}^-$.

These results demonstrate that the rise of angle-integrated valley flux are from the actions of a valley source, other than a valley filter. The same kinds of investigations into the valleytronics of 2D $n^- - n^-$ junctions on TMD are also carried out for graphene (see figure 4). The results there show that the angle-integrated valley flux is zero in the filter regime and the band-offset can be tuned to switch the valley functionalities between valley filters and valley sources, reaching the same conclusion for 2D $n^- - n^-$ junctions on TMD.

2.3.2. Interface along chiral direction

The above discussion has shown that the effectiveness of the valley source relies on the inter-valley scattering. To better harness these valley fluxes, one then wishes to separate the valley flow from the charge flow. In figure 2(f) (as a valley source), the valley fluxes are distributed over a range of angles of 180°, predetermined by the interface orientation being the armchair one. By orientating the 2D junction along a chiral direction, the angular range of inter-valley scattering becomes concentrated and deviated from the bias direction (see figure 5(a)). This provides the possibility to separate the valley flux from the charge flux induced by the bias. The results are exemplified in figure 5(b), showing that the valley fluxes are focused within a certain range of angles, oriented away from the bias direction (see the yellow/green shaded areas in figure 5(b)). The subsequent valley fluxes in oblique directions can be collected by additional electrodes that extend perpendicularly to the biased direction, as the cross-bar sketched in figure 5(c).
Below we assess the performance of the above scenario of generating and collecting valley fluxes. The longitudinal direction of the collecting electrodes makes an angle $\alpha$ with the interface orientation of the junction. The collected fluxes carrying valley $\tau'$ obtained from incidence at valley $\tau$ are thus given by

$$\int_0^{\alpha} \theta \theta' = \tau' \pi \alpha - \int R_d \hat{\tau}$$

and

$$\int_0^{\alpha} \theta \theta' = \tau \pi \alpha - \int T_d \hat{\tau}$$

for the reflected and the transmitted beams respectively. The collected valley (charge) fluxes are then defined by

$$\hat{\tau} \tau \{ \hat{\tau} \} \tau' \tau$$

and

$$\hat{\tau} \tau \{ \hat{\tau} \} \tau' \tau$$

where the subscript '$v/c$' stands for valley/charge and the lower sign is for the charge flux. The efficiency of generating collectable valley fluxes relative to passing charge current is defined by,

$$\eta_{\tau'} = \frac{\sum_{\tau' \tau} \{ \hat{\tau} \} \tau' \tau}{\sum_{\tau' \tau} \{ \hat{\tau} \} \tau' \tau}$$

where the numerator stands for the collected total out-going valley flux while the denominator is the net charge transmission. This is plotted as the black disks in figure 5(d), whose values are calibrated on the left black vertical axis. The quality of the collected valley fluxes can be quantified by the valley polarizations.

Figure 4. Results for graphene with the interface oriented in the armchair direction, verifying the general points raised previously. In (a) and (b) we show the valley fluxes $\mathbf{S}_\tau^\mathbf{K}$ (the red solid line) and $\mathbf{S}_\tau^\mathbf{K}$ (the black long-dashed line). (a) is in the filter-dominating regime with $U_g = -0.97$ and (b) in the source-dominating regime, is with $U_g = -2.8 \text{ eV}$ being the hopping between neighboring sublattices [39]. (c) shows various contributions to angle-integrated valley fluxes, $\mathbf{S}_\tau^\mathbf{K}$ (the black circles), $\mathbf{S}_\tau^\mathbf{K}$ (the red squares), $\mathbf{S}_\tau^\mathbf{K}$ (the blue triangles), $\mathbf{S}_\tau^\mathbf{K}$ (the orange diamonds). In (a)--(c), we use $E_{\text{in}} - E_{\text{F}} = 0.08$ and other parameters are $S_b = 10$ and $W = 260$ for the lattice constant of graphene.

Figure 5. Chiral oriented interface results in separation between the directions of the valley and charge fluxes. (a): portions (differently colored) on the fermi contours upon which the incident carrier is allowed to be scattered into the opposite valley. (b): out-going fluxes carrying valleys K (blue) and K' (red), showing the deviation of the direction of valley flux from the biased direction. (c): a possible design of valley antenna by cross-bar geometry, where the bias is applied in the vertical direction while the valley fluxes are collected by horizontal electrodes. (d): the efficiency, $\eta_{\tau'}$ (the black disks), the polarizations of the reflected ($P_{\tau'}^R$ the red squares) and the transmitted ($P_{\tau'}^T$ the blue triangles) fluxes within the collectable angular ranges. In (a), incidence (as the right moving states) in $\mathbf{K}$ ($\mathbf{K}'$) is allowed to be scattered to the green (light-orange) sector in $\mathbf{K}'$ ($\mathbf{K}$). The green and the light-orange colored portions in (a) are correspondingly shaded in (b). In (b) and (d), the incident energy is $E_{\text{in}} - E_{\text{F}} = 110.6 \text{ meV}$ while $U_g = -400 \text{ meV}$ is used in (b). Here we take the (1, 2) direction.
The valley polarizations of the collected fluxes as $P^R_n$ and $P^T_n$ are plotted in figure 5(d), calibrated by the purple vertical axis on the right. The performance evaluation is done with $\alpha = \pi/6$. When the well is tuned into the source regime (here around $-U_g = 400$ meV), one of the collecting electrode can receive fluxes with valley polarization over 60%. Such considerable content of valley polarization without interference from bias driven charge current may be useful for further applications. The effect of concentrating valley currents into angular intervals separated from the bias direction is not restricted to the specific chiral direction used in figure 5. We provide another example using a different chiral orientation showing similar results in figure 6, evidencing its generality. Note that we do not further discuss the case of zigzag-oriented interface since no inter-valley scattering can be induced by such interface (see figure 1(d)).

### 3. Conclusions

The $n - n^- - n$ junction realizes a quantum well scattering potential, where the magnitude of the band offset between the $n$ and the $n^-$ regions corresponds to the strength of this scattering potential. The distinct needs for small and large band offsets for the two respective valleytronic functions can be intuitively understood from the essential differences between the mechanisms these two functions rely on. For the angle-dependent valley filtering, it is the effective breaking of the symmetry between the two valleys caused by the oblique incident angles that give rise to valley-dependent intra-valley scattering effect. At small band offset (weak scattering potential), larger oblique incident angles can readily lead to pronounced filtering effect. The valley source function arises from the difference between the two inter-valley backscattering channels, which is present under normal incidence as well. Such effect becomes significant only under a sufficiently strong scattering potential (i.e. large band offset).

Here we summarize our main findings and their general implications on valleytronics for 2D materials. (i): 2D valley filters, operated by valley-dependent intra-valley scattering, give vanishing angle-integrated valley flux, due to the nature of the time-reversal pairing between the two valleys. On the other hand, 2D valley sources, operated by significant inter-valley scattering, can generate sizable angle-integrated valley flux. (ii): the gate-tunable band-offset of 2D $n - n^- - n$ junctions adjusts the relative importance between intra-valley and inter-valley scattering. The functionalities of valley filters and valley sources can thus be switched by changing the band-offset of 2D $n - n^- - n$ junctions. These valley-related effects are demonstrated in both TMDs with the finite bandgap and in gapless graphene. (iii): the orientation of 2D $n - n^- - n$ junctions determines the incident angles by which inter-valley scattering is allowed. Therefore, by orienting the junction in chiral directions, the directions of valley fluxes can be deviated from the biased direction of charge fluxes. Combining such 2D junctions with extra electrodes to form cross-bar geometries, the valley fluxes generated by the valley sources can be separately harvested by the collecting electrodes. The valley filter and valley source effects of these 2D $n - n^- - n$ junctions are also anticipated in other materials with time-reversal paired valleys. The investigations carried out here also show that the benefits of using 2D materials as platforms for valleytronic operations are not only provided by the easily accessible valleys but also by the nature of valleys as momentum index whose 2D nature can be manipulated.

The conduction band for TMDs also has local energy minima at Q points, which has an energy around 100 meV higher than the band edge at K points depending on the compounds [30–32]. The scattering between any pair of momenta in the Brillouin zone is restricted by the energy and momentum conservations between the two $n$ regions on the two sides of the line scatterer.
Therefore, scattering involving the Q valleys in the conduction band could be allowed only at sufficiently large Fermi energy (exceeding the Q point energy). The inclusion of the Q valleys opens new inter-valley scattering channels among the Q valleys and between K and Q valleys, which will lead to new scenarios for valleytronic manipulations.

Appendix A. Equilibrium valley current

Here we extend our analysis in the main text for deducing that the vanishing of the angle-integrated valley flux for 2D valley filters. We apply similar analysis to inspect the net valley flux under the equilibrium condition, namely, the condition where no charge current flows, in order to see if it gives sensible conclusion. Below we show that the net valley flux under equilibrium is reasonably zero.

The equilibrium situation is attained by injecting equal amount of carriers from both sides of the interface such that the net charge flux is zero. We denote the probabilities of scattering the in-coming carrier, injected from the left/right side of the interface at angle \( \theta \) and valley \( \gamma \), to valley \( \gamma' \), by \( R^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} \) (as reflection) and \( T^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} \) (as transmission). Let us consider a specific carrier from the left side at valley \( \gamma \) with angle \( \bar{\theta}_{\gamma, \tau} \). This in-coming momentum is denoted by \( \mathbf{k}^{\gamma, \bar{\theta}} \). According to momentum conservation, the out-going momenta can be explicitly determined. We denote the out-going momenta reached by forward/backward intra-valley and inter-valley scattering by \( k^{\gamma', \bar{\theta}} \) and \( k^{\gamma', -\bar{\theta}} \) respectively. Note that due to the obliqueness of the incidence, the momenta \( k^{\gamma, \bar{\theta}} \) and \( k^{\gamma', \bar{\theta}} \) no longer make a time-reversal pair. By time-reversal symmetry, the momentum \( k^{\gamma, \bar{\theta}} \) is paired with \( \mathbf{k}^{\gamma', \bar{\theta}} \) for \( \bar{\theta} \in \{K, K'\} \). Automatically, the momenta denoted by \( k^{\gamma', \bar{\theta}} \) share the same projection along the interface. Denoting the associated angle of a momentum \( \mathbf{k}^{\gamma, \bar{\theta}} \) by \( \bar{\theta} \), the time-reversal symmetry applied to the intra-valley backscattering reads

\[
R^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}) = R^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}'), \quad (A.1a)
\]

and

\[
T^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}) = T^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}'), \quad (A.1b)
\]

for forward scattering. These scattering probabilities are subjected to normalization, namely, \( 1 = \sum_{\tau \in \{K, K'\}} [R^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}) + T^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta})] = \sum_{\tau \in \{K, K'\}} R^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}) + T^{\gamma' \rightarrow \gamma}_{\gamma, \theta, \tau} (\bar{\theta}) \) for \( \tau \in \{K, K'\} \).

By simultaneously injecting carriers with momenta \( k^{+\alpha}, k^{+\alpha}, k^{+\alpha}, k^{+\alpha} \) from the left and momenta \( k^{-\alpha}, k^{-\alpha}, k^{-\alpha}, k^{-\alpha} \) from the right, the subsequent flux that carriers valley \( K' \) flowing on the left side reads

\[
\tilde{J}^{\tau}_{K'} = \sum_{\sigma \in \{a, b\}} \sum_{\tau \in \{K, K'\}} [1 - R^{\tau+ \sigma}_{K' \rightarrow K}(\theta^{+\sigma})] - \sum_{\sigma \in \{a, b\}} \sum_{\tau \in \{K, K'\}} T^{\tau+ \sigma}_{K' \rightarrow K}(\theta^{+\sigma}). \quad (A.2)
\]

The first term, \( (1 - R^{\tau+ \sigma}_{K' \rightarrow K}(\theta^{+\sigma})) \), in equation \( (A.2) \) describes that the injection at valley \( K' \) from the left side is backscattered to the same valley, resulting in a net valley current that is the injected one subtracting the reflected one. The second term \( -R^{\tau+ \sigma}_{K' \rightarrow K}(\theta^{+\sigma}) \) contributing to the flux carrying valley \( K' \) comes from the inter-valley backscattering of an injection from the left side at valley \( K \). The last term \( T^{\tau+ \sigma}_{K' \rightarrow K}(\theta^{+\sigma}) \) is contributed by the scattering of the injected the carriers at valley \( \tau \) from the right side to valley \( K' \) on the left side. The minus sign stands for flowing toward the left. Similar expressions can be obtained for the net flux that carriers a particular valley flowing on either side of the interface.

Applying equation \( (A.1a) \) to equation \( (A.2) \) leads to \( \tilde{J}^{\tau}_{K'} = 0 \) and similarly all other valley–carrying fluxes on either side of the interface vanish. One can extend the above procedure to include all possible incident angles and the angle-integrated valley fluxes at equilibrium condition are just zero. The time-reversal symmetry, equation \( (A.1a) \), manifested for discrete set of incident angles is also confirmed numerically. Note that in obtaining equation \( (A.1a) \) and the consequences \( \tilde{J}^{\tau}_{\sigma} = 0 \) for \( \tau \in \{1, 2\} \) and \( \sigma \in \{K, K'\} \), both the intra- and inter-valley scattering have been taken into account.

Appendix B. Methodology

B.1. General approach

A general two-dimensional system is described by the following tight-binding model,

\[
H = \sum_{\tau} \sum_{\delta \in D_{\alpha, \beta}} \sum_{\gamma, \gamma'} c_{\tau, \alpha} h_{\gamma, \beta}(\delta) c_{\tau+\delta, \beta} + \sum_{\tau} \sum_{\alpha} c_{r, \alpha} U_{\alpha}(\delta) c_{r+\delta, \alpha} \quad (B.1)
\]

where \( r \) denotes the position vectors of the lattice sites and \( \alpha, \beta \) the internal orbitals. The displacement vectors are summed over neighbouring lattice sites, \( D = \{0, \pm \alpha_1, \pm \alpha_2, \pm (\alpha_1 + \alpha_2), \pm (\alpha_1 - \alpha_2)\} \), where \( \alpha_1 \) and \( \alpha_2 \) are the two lattice vectors. The operator \( c_{r, \alpha} \) (\( c_{r, \alpha} \)) then creates (annihilates) an electron on the orbital \( \alpha \) belonging to the lattice site at \( r \). The energy matrix, \( h_{\gamma, \beta}(\delta) \), describes the on-site orbital energies \( (\alpha = \beta) \) and their mixing \( (\alpha \neq \beta) \) for \( \delta = 0 \) and
hopping between neighbouring lattice sites for $\delta \in D$ with $\delta = 0$. The hermiticity of the Hamiltonian is given by $h_{\alpha \beta}(\delta) = [h_{\beta \alpha}(-\delta)]^\dagger$. An external potential is applied, specified by $U_\alpha(r)$, to shift the energy of orbital $\alpha$ residing on the lattice site $r$. The external potential $U_\alpha(r)$ is zero except for a certain region called the scattering area. For numerical calculations performed here, the parameters in equation (B.1) are taken from the $ab\text{ initio}$ justified three-band tight-binding models fitted to a series of transition-metal dichalcogenides in [30] for MoS$_2$.

A widely applied approach to derive reflection/transmission coefficients for nanoribbons/tubes (as quasi-one-dimensional systems) intercepted in the middle by a scattering area is based on a mode-matching technique, initially prescribed for square lattice [33] and later generalized to arbitrary lattice [34]. For generic two-dimensional systems, it is widely assumed that the potential along a chiral direction shows translational invariance (see [8–12]). Such invariance can be utilized to transform the two-dimensional scattering problem into a quasi-one-dimensional problem. Therefore, in principle, the methods developed in [33, 34], can be applied after the transformation. For pedagogical purposes, we provide an alternative route of deriving the required quantities following the line of thoughts used in quantum mechanics textbooks. We point out its benefits for dealing with the scattering problem in which the two-dimensional nature of the involved momenta is important.

Below, we first introduce effective lattices useful for transforming the problem at hand to a quasi-one-dimensional equivalence in section B.1.1. The approaches used in [33, 34] rely on constructing Bloch matrices from a set of eigenvalues and non-orthogonal eigenvectors. They are obtained through solving the tight-binding equation by imposing the Bloch symmetry to determine the properties of the involved modes. In section B.1.2, we show that the properties of the involved modes can also be directly obtained from the eigen-equation leading to the dispersion relation. The physical meanings of these eigenvalues and eigenvectors can be directly interpreted from this precursor of dispersion relation. The non-orthogonality of the eigenvectors also naturally appear there. Instead of getting the scattering states by constructing the Bloch matrices, we closely follow the usual textbook approach of matching wavefunctions at the boundaries of the scattering area. From the scattering states, the next step is to obtain the transmission and the reflection coefficients. In [33, 34], the physical transmission is obtained by normalizing the generalized transmission matrix elements with respect to the current, defined from the Bloch velocities in terms of the above mentioned eigenvalues and eigenvectors. Here we wish to remind that the fulfillment of current conservation testifies the scattering states as the eigenstates. In section B.1.3, the reflection and transmission coefficients are then subsequently deduced from the current conservation law, in which the expression of the Bloch velocity naturally emerges.

### B.1.1. Effective lattice for interface oriented at a chiral direction

We consider the situation in which the scattering area is formed by virtually cutting a nanoribbon from the two-dimensional crystal. The longitudinal direction of the ‘ribbon’ is described by a chiral vector,

$$A_2 = n_2 a_1 + n_3 a_2,$$  \hspace{1cm} (B.2)

where the integers $n_2$ and $n_3$ do not have common divisor, except one. The transverse direction of the ‘ribbon’ defines another vector, denoted by

$$A_1 = n_1 a_1 + n_2 a_2,$$  \hspace{1cm} (B.3)

where $n_1$ and $n_2$ are integers that do not have common divisor. The armchair orientation is then done by using $(n_1, n_2) = (1, 1)$. Other chiral directions follow different choices of $(n_1, n_2)$ specified in the relevant parts of discussions. We use $(n_1, n_2) = (1, -1)$ for the transverse direction in all cases to shrink the number of original lattice sites in an effective lattice point (see explanation for effective lattice below).

The chiral orientation of the interface can thus be handled by defining a new effective lattice whose lattice points are composed of the original lattice sites. The lattice vectors for the effective lattice are thus given by equations (B.2) and (B.3). The Hamiltonian equation (B.1) rewritten in the new basis becomes

$$H = \sum_\delta \sum_{\mathbf{r} \in D} \sum_{\alpha \beta} c_\mathbf{r}^\dagger \delta_{\alpha \beta} (\delta) \hat{h}_{\alpha \beta} \delta_{\mathbf{r} + \delta} + \sum_\mathbf{r} \sum_\alpha c_\mathbf{r}^\dagger \delta_{\mathbf{r} \alpha} \hat{U}_\alpha (\mathbf{r}) \delta_{\mathbf{r}, \alpha}$$  \hspace{1cm} (B.4)

where the vectors $\mathbf{r}$ now enumerate the positions of the sites of the effective lattice and $\delta_{\alpha \beta}$ the effective orbital, comprising the original lattice position and its orbital. The set of vectors connecting neighbouring sites on the effective lattice is given by $\mathbf{D} = \{0, \pm A_1, \pm A_2, \pm (A_1 + A_2), \pm (A_1 - A_2)\}$. The energy matrices $\hat{h}_{\alpha \beta} (\delta)$ as well as the potential $\hat{U}_\alpha (\mathbf{r})$ represented in this new basis can be constructed directly from the original ones given in equation (B.1). Similar approaches of defining effective lattices (supercells) to deal with boundaries formed along chiral directions are applied to study properties of edge states along the boundaries [35].

### B.1.2. Scattering states

The reflection and the transmission probabilities are obtained from the scattering states as the eigenstates of the Hamiltonian for given energies $\varepsilon$ lying in the band of the bulk part. We denote the eigenstate of $H$ by $|\Psi\rangle$ and $|\phi_n (\mathbf{r})\rangle$ the basis localized at $\mathbf{r}$ labeled by orbital $\alpha$. The potential term that defines the scattering area obeys $\hat{U}_\alpha (\mathbf{r}) = \hat{U}_\alpha (\mathbf{r} + A_2)$ such that the system is invariant along the $A_2$ direction. Therefore, writing generally,
\[ \Psi = \sum_n \tilde{\psi}_n(\tilde{r}) \phi_n(\tilde{r}) \]

where the spatial dependence of the wavefunction \( \tilde{\psi}_n(\tilde{r}) \) can be factorized into,

\[ \tilde{\psi}_n(\tilde{r}) = \tilde{\psi}_n(m_1, m_2) = e^{i m_1 \phi_1 \psi_2(m_1)} \]

(\( B.5 \))

where we have used \( t = (m_1, m_2) = m_1 A_1 + m_2 A_2 \) with \( m_1 \) and \( m_2 \) the integers specifying the spatial coordinate. The constant phase \( \Phi_2 \) will be determined later.

We divide the wavefunction into three regions, the left side (L), the central scattering region (CSR), and the right side (R), namely,

\[ \psi_n(m) = \begin{cases} 
\psi_n^L(m), m \leq m^L, \\
\psi_n^C(m), m^L < m \leq m^L + 1, \\
\psi_n^R(m), m \geq m^R, 
\end{cases} \]

(\( B.6 \))

where \( m^L \) and \( m^R \) mark the left and the right boundaries of the scattering area. For compactness, we denote \( \psi_n^X \) for \( X = L, C, R \), as a column vector whose components are \( \psi_n^X(m) \), through all the orbital \( \tilde{r} \). The Schrödinger equation, \( H\Psi = \epsilon \Psi \), for the segmented wavefunctions projected to the local basis then reads

\[ \epsilon \tilde{\psi}_m^C = (\tilde{H}^L + \tilde{u}(m) + \tilde{H}^R) \tilde{\psi}_m^C + [\tilde{H}^L]_m^C \tilde{\psi}_{m+1}^C + [\tilde{H}^R]_m^C \tilde{\psi}_{m-1}^C \]

(\( B.7a \))

\[ \tilde{H}^L = \tilde{h}^L(0) + e^{i \Phi_1} \hat{h}(A_1) + e^{-i \Phi_2} \hat{h}(A_2), \]

(\( B.7c \))

\[ \tilde{H}^R = \tilde{h}(A_3) + e^{i \Phi_3} \hat{h}(A_3) + e^{-i \Phi_4} \hat{h}(A_4), \]

(\( B.7f \))

where the evanescent field carry a phase. Notably even when the original energy matrices \( h_{\alpha, \beta} \) have all of their elements real (such that time-reversal symmetry is automatically satisfied), the effective quasi-one-dimensional system can have complex hopping matrix elements, as indicated by equation (\( B.7f \)). This is similar to the effect of a gauge field that makes the hopping carry a phase.

Following the textbook convention of solving purely one-dimensional scattering problem, we assume the wavefunctions for the bulk part that are to the left \( (S = L) \) and to the right \( (S = R) \) of the scattering area take the form,

\[ \psi_{\alpha}(m) = \sum_{l \in M} A_{l \alpha} e^{i m k \xi \cdot A_l}, \]

(\( B.8a \))

\[ \tilde{\psi}_n^R(m) = \sum_{l \in M} A_{l \alpha} \gamma_{l \alpha} e^{i m k \xi \cdot A_l}, \]

(\( B.8b \))

Here the notation \( M_S \) with \( S = L, R \) denotes the set of the delocalized basis. In a purely one-dimensional problem, \( M_S \) consists of only two delocalized modes, the familiar right-going and the left-going plane waves. As will see, evanescent modes emerge from orbital multiplicity.

The wave vectors \( k_{1/2} \), the amplitudes \( A_{1/2} \) and the coefficients \( \gamma_{1/2} \) in equation (\( B.8 \)) will be found by solving the Schrödinger equation using the above ansatz. Substituting equations (\( B.8 \)) into equation (\( B.7a \)) yields

\[ \tilde{H}(k_{1}) \psi_{1} = \epsilon \tilde{\psi}_{1}, \]

(\( B.9a \))

where \( \tilde{\psi}_{1} \) is a column vector of components \( \psi_{1} \) with

\[ \tilde{H}(k_{1}) = \tilde{h}^0 + e^{i k_{1} \cdot A_{1}} \hat{h}^1 + e^{-i k_{1} \cdot A_{1}} [\hat{h}^2]_{1} \].

(\( B.9b \))

Here equation (\( B.9a \)) is the usual eigen-equation for getting the dispersion relation for a quasi-one-dimensional crystal whose longitudinal direction is along \( A_1 \) with lattice constant \( |A_1| \).

By restoring \( \Phi_2 = \tilde{k}_{1} \cdot A_2 \) into equation (\( B.9b \)) leading to \( \tilde{H}(k_{1}) = \sum_{l \in \delta} e^{i k_{1} \cdot A_{1}} [\hat{h}^2]_{1} \), equation (\( B.9a \)) becomes the standard equation for obtaining the dispersion relation for two-dimensional crystals of lattice vectors \( A_1 \) and \( A_2 \). The involved modes of the scattering problem can be found from rearranging equation (\( B.9a \)) to

\[ \det [\mathbb{1} - \tilde{H}(k_{1})] = 0, \]

(\( B.10 \))

where \( \mathbb{1} \) is the identity matrix in the space of the effective orbitals. The determinant in equation (\( B.10 \)) results in a polynomial in \( e^{i k_{1} \cdot A_{1}} \) of degree \( 2N \), where \( N \) is the number of orbitals.

The solution to equation (\( B.10 \)) contains \( N \) right-going modes that include those decaying to the right and those propagating to the right and similarly there are \( N \) left-going modes. The propagating modes correspond to real wave vector \( k_{1} \), while the evanescent modes give a nonzero imaginary part of \( k_{1} \) whose sign determines to which direction (the left or the right) the wave decays. For a purely one-dimensional problem, with \( N = 1 \), equation (\( B.10 \)) dictates that no evanescent mode exists. The result equation (\( B.10 \)) is equivalent to the key formula, equation (2.12) in [33] and equation (4) in [34], obtained from relating the wavefunctions on neighbouring sites. Here we show...
that equation (B.10) can be directly arrived from the eigen-equation for getting the dispersion relation.

The eigenvectors $\psi_{\alpha}^{S,l}$ are the pseudo-spins for the mode of wave vector $k^l$ at the energy $\epsilon$. If one fixes $k^l$ in equation (B.9a), the resulting different pseudo-spin vectors are eigenvectors of different eigenenergies and they form an orthogonal set. In the present case, it is the energy $\epsilon$ that is fixed and the wave vectors (for propagating modes) are searched through the iso-energy contours provided by the dispersion relation. The non-orthogonality among $\bar{\psi}_{\alpha}^{S,l}$ for different $l$ is naturally anticipated. Therefore, once the incident energy is fixed and an incident wave vector is picked up, the value of $\Phi_\alpha = k^l \cdot A_l$ is then automatically determined and all the input required by equation (B.10) are fixed. The two-dimensional nature of the momenta can then be straightforwardly handled by equation (B.10) in combination of equation (B.9a).

From a scattering point of view, the wavefunctions on both sides of the scattering area actually contain propagating modes moving to both directions. The distinction lies in that only the right-going (left-going) propagating modes qualify to be in-coming modes for incident from the left (right). Therefore, the set of modes in $M^{in}_S$ obtained by solving equation (B.10), are categorized into $M^{in}_R$ and $M^{out}_S$. For $S = L$ ($S = R$), $M^{in}_S$ contains only the right (left)-going propagating modes and $M^{out}_S$ contains all the left (right)-going modes, both propagating and evanescent. After establishing the properties of the involved momenta $k^{l,R}_{\alpha}$ and pseudo-spins $\bar{\psi}_{\alpha}^{l,R}$ one can proceed to find the amplitudes $A^{l,R}_{\alpha}$. One can eliminate $\psi^C_{m}$ from equations (B.7c) and (B.7d), leading to

$$\psi^C_{m} = \sum_{S=L,R} G(m, m_{S}^C + \epsilon_S) [\hat{H}^C_{\delta}]_{m_{S}^C} \psi^S_{m_{S}^C}, \quad (B.11a)$$

where the Green function of the CSR is

$$G = \left[ \delta_{C} - \hat{H}_{C} \right]^{-1}, \quad (B.11b)$$

in which

$$\hat{H}^C_{\delta} = \delta_{m,m}(\hat{H}^0 + \hat{u}(m)) + \delta_{m+1,m,\delta} \hat{H}^l + \delta_{m-1,m,\delta} \hat{H}^r \quad (B.11c)$$

and $\delta_{C}$ is the identity matrix in both effective site and orbital space for the CSR. Inserting equation (B.11a) to equation (B.7b), which are then substituted by the ansatz equation (B.8), we are left with equations for the amplitudes $A^{l,R}_{\alpha}$. Defining

$$A^S_{\alpha} = e^{i k^l \cdot (m_{S}^C + \epsilon_S) A_l^S}, \quad (B.12)$$

we arrive at

$$\begin{pmatrix}
\vec{W}^{i,n}_{\text{out/}} \text{SS} \\
\vec{W}^{i,n}_{\text{out/}} \text{RL}
\end{pmatrix}
\begin{pmatrix}
\vec{A}^{l,\text{out}} \\
\vec{A}^{l,\text{out}}
\end{pmatrix}
= - \begin{pmatrix}
\vec{W}^{o,n}_{\text{in/}} \text{LL} \\
\vec{W}^{o,n}_{\text{in/}} \text{RL}
\end{pmatrix}
\begin{pmatrix}
\vec{A}^{l,\text{in}} \\
\vec{A}^{l,\text{in}}
\end{pmatrix}, \quad (B.13)$$

where $\vec{A}^{l,\text{out/in}}$ is a column vector of components $A^S_{\alpha}$ with $l \in M^{\text{out/in}}_S$ for $S = L, R$. The column vector $\vec{A}^{l,\text{out}}$ is of dimension $N$ while $\vec{A}^{l,\text{in}}$ is of dimension $N_p$, the number of right-going (left-going) propagating modes. The matrices $\vec{W}^{\text{SS}}_{\text{SS}}$ are $N \times N$ and $\vec{W}^{\text{SS}}_{\text{SS}}$ are $N \times N_p$ with $S, S' \in \{L, R\}$. They are explicitly given by

$$[\vec{W}^{\text{out/in}}_{\text{SS}}]_{ij} = g_{\delta} [\bar{G}^C_{\delta}]_{ij} [\bar{G}^S_{\delta}]_{ij}, \quad (B.14)$$

for $\delta$ enumerating the $N$ orbitals while the mode index $l$ in equation (B.14) is taken from $l \in M^{\text{out/in}}_S$. The notation $\bar{G}$ refers to the $\bar{G}$ component of the column vector obtained from the operations inside of the parenthesis.

The surface Green function of the CSR is abbreviated as $[\bar{G}(S, S')]_{m,\delta} = [G]_{m,\delta} (m_{S}^C + \epsilon_S m_{S'}^C + \epsilon_\delta)$ from equation (B.11b). The amplitudes for the out-going part of the wavefunction $A_S^{\text{out}}$ can thus be obtained from the amplitudes of the in-coming part $A_S^{\text{in}}$ through solving equation (B.13). This in turn fixes the coefficients in equation (B.8). With also the aid from equation (B.11a), the whole wavefunction in equation (B.6) is specified.

The above derivation though is for the case that the scattering area is defined by external potential that shifts the on-site energies of the lattice sites in a certain area, one can straightforwardly generalize it to the following situation: the composition of the orbitals as well as the hopping between neighbouring sites are also different from the rest part of the two-dimensional system. Such a generalization is done by replacing $(\hat{H}^0 - \hat{u}(m))$ and $\hat{H}^l$ in equation (B.7c) by $\hat{H}^{C\delta}_{\delta}(m)$ and $\hat{H}^{C\delta}_{\delta}(m)$ respectively, in which $\hat{H}^{C\delta}_{\delta}(m)$ represent the on-site energy matrix for the special set of orbitals on site $m$ and $\hat{H}^{C\delta}_{\delta}(m)$ the hopping from site $m$ to $m + 1$ in this region. Correspondingly, in equation (B.7d), the hopping $\hat{H}_{\delta}$ in front of $\psi^S_{m_{S}^C + \epsilon_S}$ is to be replaced by $\hat{H}^{C\delta}_{\delta}(m_{S}^C + \epsilon_S)$ for $S = L$ and by $\hat{H}^{C\delta}_{\delta}(m_{S}^C - 1)$ for $S = R$. The hopping $\hat{H}_{\delta}$ in front of $\psi^S_{m_{S}^C + \epsilon_S}$ in equation (B.7d) as well as its hermitian conjugate in front of $\psi^{S'}_{m_{S'}^C + \epsilon_{S'}}$ in equation (B.7b) is to be replaced by the new hopping that describes the junction between these two regions of properly different atomic structures. These situations can be realized by applying regional strains, formations of grain boundaries, or regional substitutions by foreign elements.

B.1.3. Current conservation and probabilities of reflections and transmissions

Being the eigenstate of $H$, the system prepared at $|\Psi\rangle$ will only evolve trivially to time $\tau$ by $e^{-iH\tau}|\Psi\rangle = e^{-i\hat{H}\tau}|\Psi\rangle$. The expectation value of any observable will just remain time-independent under such circumstance. Therefore, the charge and the current distribution in the state $|\Psi\rangle$ are stationary. Below we show how the reflection and transmission probabilities can be derived from this property.
The charge operator, \( Q_{en} \), for the charge occupation enclosed in certain area of the system is defined by,

\[
Q_{en} = \sum_{\vec{r} \in \Lambda} \sum_{\alpha} |\phi_{\alpha}(\vec{r})\rangle \langle \phi_{\alpha}(\vec{r})|.
\]  

(B.15)

In equation (B.15), \( B \) denotes the area bounded in the \( A_{1} \) direction between the positions \( \vec{r}(n_{1}^{L}, m_{2}) \) and \( \vec{r}(n_{1}^{R}, m_{2}) \) with no bounds on \( m_{2} \). The two integers \( n_{1}^{L} \) and \( n_{1}^{R} \) mark the bounds. From the Heisenberg equation, the current operator obtained by its definition as the time-changing-rate of charge, reads,

\[
I_{en} = -i [Q_{en}, H].
\]  

(B.16)

The expectation value of the current flowing out of \( B \) at time \( t \) evaluated on a certain state \( |\psi\rangle \) is given by

\[
\frac{d}{dt} \langle \psi | Q_{en} e^{-iHt} |\psi\rangle = \langle \psi | Q_{en} e^{-iHt} |\psi\rangle.
\]

If \( |\psi\rangle = |\Psi\rangle \) as an eigenstate of \( H \), then \( \langle \Psi | Q_{en} e^{-iHt} |\Psi\rangle \) becomes time-independent, leading to

\[
\langle \Psi | I_{en} |\Psi\rangle = 0.
\]  

(B.17)

By equation (B.4), we find from equations (B.15) and (B.16) that

\[
I_{en} = I_{en}^{L} + I_{en}^{R},
\]  

(B.18)

where

\[
I_{en}^{\pm} = \zeta \sum_{\alpha, \beta} \sum_{n_{1}=0, \pm 1} \sum_{m_{2}} \langle \psi_{\alpha}(n_{1}^{\pm}, m_{2}) | \hat{h}_{\alpha, \beta} (|\alpha\rangle \langle \beta| + |\beta\rangle \langle \alpha|) + \text{h.c.} \rangle,
\]  

(B.19)

for \( S = L, R \) in which we have explicitly written the integers for the position vectors of the local basis. The operators, equation (B.19), depend only on the hopping from the bounds marked by \( n_{1}^{L} \) and \( n_{1}^{R} \) to sites one step interior to the enclosed area. By choosing the area \( B \) wide enough such that the bounds of the CSR are within the bounds marked by \( n_{1}^{L} \) and \( n_{1}^{R} \), then the wavefunctions on the CSR do not contribute to the expectation value \( \langle \Psi | I_{en} |\Psi\rangle \). If further \( n_{1}^{L} \) and \( n_{1}^{R} \) are separated from \( m_{2}^{L} \) and \( m_{2}^{R} \) far enough such that the contributions from the evanescent modes to \( \langle \Psi | I_{en} |\Psi\rangle \) can be ignored, then \( \langle \Psi | I_{en} |\Psi\rangle \) will become independent of \( n_{1}^{L} \) and \( n_{1}^{R} \). Explicitly using the scattering state \( |\Psi\rangle \) discussed in section B.1.2 with equation (B.19), we obtain

\[
\langle \Psi | I_{en}^{\pm} |\Psi\rangle = \zeta \sum_{m_{2}} |\hat{A}_{\pm}^{\dagger} | \hat{T}_{\pm} |\Psi\rangle
\]  

(B.20)

where \( M_{\pm} \) contains all the propagating modes, both right-going and left-going ones and

\[
\hat{T}_{\pm} = -2i \text{Im} \{ e^{ik_{z}+A_{0^{\pm}}(\vec{k})} \hat{R}_{\pm}^{\mp} \hat{Y}(\vec{k}) \}.
\]  

(B.21)

is just the Bloch velocity. In equation (B.21), we have ignored the \( S \) superscript for designating the left or the right, \( k_{L} \rightarrow k_{L} \) and \( \hat{p}^{Z \pm} \rightarrow \hat{p}^{Z \pm} \), since \( k_{L} \) and \( k_{R} \) are the same for a given propagating mode \( l \). Using equations (B.20) with (B.17), we arrive at

\[
\sum_{l \in M_{\pm}} R_{\pm}^{l \rightarrow l'} + \sum_{l \in M_{\pm}} T_{\pm}^{l \rightarrow l'} = 1,
\]  

(B.22)

upon setting \( |\hat{A}_{\pm}^{\pm}| = 1 \) for incident from side \( S^{\pm} \) (with \( S^{+} = L \) and \( S^{-} = R \)) at the mode \( l_{0}^{\pm} \) (where the superscript \( + \) stands for right-going and - for left-going), in which

\[
R_{\pm}^{l \rightarrow l'} = |\hat{A}_{\pm}^{l'} |^{2} + \hat{T}_{\pm}^{l \rightarrow l'}, T_{\pm}^{l \rightarrow l'} = |\hat{A}_{\pm}^{l'} |^{2} + \hat{T}_{\pm}^{l \rightarrow l'}.
\]  

(B.23)

are the reflection and the transmission probabilities respectively. Note that the Bloch velocities of right-going modes are positive, namely, \( T_{R} > 0 \) while that of left-going modes are negative, \( -T_{R} > 0 \). Therefore, if the amplitudes, \( A_{\pm}^{l_{0}^{\pm}} \), obtained from equation (B.13), specify an eigenstate of \( H \), then substituting them into equation (B.23) shall lead to the fulfillment of equation (B.22). The current conservation stated in form of equation (B.22) can thus be used to justify the validity of the calculations, which has been ensured in all our numerical calculations.

B.2. Specification of computational setups

B.2.1. computation of incident and out-going angles

Due to the possible warping of the dispersion relation, the direction of the momenta on the fermi contour may not be aligned with the direction of actual motion of the electron in that momentum states. To unambiguously define the out-going angle as well as the incident angle, we need to compute the velocity expectation value for a given momentum.

In the above discussions, in order to describe scattering with a potential that has a chiral orientation, we have introduced the effective lattice. The in-coming states as well as the out-going states are well-defined momentum states of the original crystal system. Therefore, to find their velocity expectation values, we have to restore to the original two-dimensional crystal. The dispersion relation is then obtained from diagonalizing, \( \tilde{\mathcal{H}}(k) \), namely,

\[
\tilde{\mathcal{H}}(k) \psi(k) = \epsilon(k) \psi(k),
\]  

(B.24a)

where

\[
\tilde{\mathcal{H}}(k) = \sum_{\delta \in D} e^{ik_{z} \delta_{h}(\delta)}.
\]  

(B.24b)

in which the matrix elements \( [\delta_{h}(\delta)]_{\alpha, \beta} = h_{\alpha, \beta} \) and \( D \) are those in equation (B.1). Here \( \psi(k) \) is the pseudo-spin at moment \( k \) with component \( \psi_{\alpha}(k) \) at orbital \( \alpha \).

Since here we consider only intra-band elastic scattering, the velocity expectation value \( \nu(k) \) for \( k \) of the involved band is just the diagonal element indexed by the band of the usual velocity matrix \([36–38] \) (not to be

\[\text{1}\] The dispersion relation of the original crystal described by equation (B.24a) is well embedded in equation (B.9a) for the effective one. The pseudo-spins are connected by \( \nu_{\tilde{\alpha}} \), where \( \tilde{\alpha} \) points from the internal origin of an effective lattice site to the original lattice site specified by \( \alpha \) whose corresponding orbital is \( \alpha \).
confused with the quasi-one-dimensional Bloch velocity, equation (B.21), previously discussed), namely,
\[ \mathbf{v}(k) = |y(k)|^\dagger [\nabla k \gamma(k)] y(k). \] (B.25)

The two-dimensional vector \( \mathbf{v}(k) \) can thus be used to compute the angle \( \theta \) with respect to the normal of the interface for a given momentum \( k \), in one-to-one correspondence.

B.2.2. Characterisation of the potential structure

For clarity, we concentrate on the potential profiles that are step-like and we consider \( U_0(r) = U(r) \) for all \( \alpha \). Explicitly, we describe such a potential structure by the following (see also profiles in figure 1 of the main text),

\[
U(r) = \begin{cases} 
\frac{U_0}{2} \left[ 1 + \tan \left( \frac{\ln(2/\kappa - 1)}{2S}(r - n - x_{CL}) \right) \right], & \text{for } r \in C_L, \\
\frac{U_0}{2} \left[ 1 + \tan \left( \frac{\ln(2/\kappa - 1)}{2S}(r - n - x_{CR}) \right) \right], & \text{for } r \in C_R,
\end{cases}
\] (B.26)

where \( n = A_0/|A_0| \) and the regions separating the profiles of the potential along this lateral direction are \( C_L = [x_{CL}, x_{CL} + S] \), \( C_0 = [x_{CL} + S, x_{CL} + W] \) and \( C_R = (x_{CL} + W, x_{CL} + W + S] \) in which \( x_{CL} \) is the \( A_0 \) coordinate of the left boundary of the scattering area. The coordinate of the center of \( C_L \) is \( x_{CL} + S/2 \) and that of \( C_R \) is \( x_{CR} = x_{CL} + W + S/2 \). The parameter \( \kappa \) controls how fast the profile in \( C_L \) and \( C_R \) raises (lowers) to \( U_0 \). Here we set \( \kappa = 0.01 \) such that from the edge of \( C_{LR} \) it takes around a length of \( S \) to reach \( U_0 \). The potential \( U(r) \) is zero elsewhere when \( r \) is not in any of the regions \( C_L \), \( C_0 \), and \( C_R \).
