Objectives: The aim of this study was to determine the factors associated with the spatial distribution of the incidence of colorectal cancer (CRC) in the neighborhoods of Tehran, Iran using Bayesian spatial models.

Methods: This ecological study was implemented in Tehran on the neighborhood level. Socioeconomic variables, risk factors, and health costs were extracted from the Equity Assessment Study conducted in Tehran. The data on CRC incidence were extracted from the Iranian population-based cancer registry. The Besag-York-Mollié (BYM) model was used to identify factors associated with the spatial distribution of CRC incidence. The software programs OpenBUGS version 3.2.3, ArcGIS 10.3, and GeoDa were used for the analysis.

Results: The Moran index was statistically significant for all the variables studied (p < 0.05). The BYM model showed that having a women head of household (median standardized incidence ratio [SIR], 1.63; 95% confidence interval [CI], 1.06 to 2.53), living in a rental house (median SIR, 0.82; 95% CI, 0.71 to 0.96), not consuming milk daily (median SIR, 0.71; 95% CI, 0.55 to 0.94) and having greater household health expenditures (median SIR, 1.34; 95% CI, 1.06 to 1.68) were associated with a statistically significant elevation in the SIR of CRC. The median (interquartile range) and mean (standard deviation) values of the SIR of CRC, with the inclusion of all the variables studied in the model, were 0.57 (1.01) and 1.05 (1.31), respectively.

Conclusions: Inequality was found in the spatial distribution of CRC incidence in Tehran on the neighborhood level. Paying attention to this inequality and the factors associated with it may be useful for resource allocation and developing preventive strategies in at-risk areas.

Key words: Colorectal cancer, Spatial distribution, Incidence, Neighborhood, Besag-York-Mollié (BYM) model, Tehran, Iran

INTRODUCTION

Colorectal cancer (CRC) is one of the most important public health problems, and it is becoming more common worldwide [1]. CRC is the third most common cancer and the fourth leading cause of death from cancer in the world, and is responsible for 8% of all deaths from cancers. In 2012, approximately 1 361 000 new cases of CRC occurred, including 614 000 in women and
746,000 in men [1,2]. CRC is the third most common cancer in men and the second most common cancer in women, with a standardized incidence rate of 20.6 and 14.6 per 100,000, respectively [2,3]. CRC is one of the most common cancers in Iran, where it is the third most common cancer in men and the fourth most common cancer in women, with standardized incidence rates of 8.1–8.3 and 6.5–7.5 per 100,000, respectively; moreover, CRC is responsible for 8.4% of all cancers in Iran [4–6].

In general, considerable worldwide variation exists in the incidence and mortality of CRC. Approximately 55% of cases of CRC occur in developed countries. The highest age-standardized rate (ASR) in the world has been found in Australia/New Zealand (44.8 and 32.2 per 100,000 in men and women, respectively) and the lowest ASR has been reported in western Africa (4.5 and 3.8 per 100,000 in men and women, respectively) [7]. Moreover, studies have shown wide variation in the incidence of CRC in different regions of Iran [8,9].

Variation in the incidence of CRC can be caused by different distributions of risk factors, especially environmental risk factors such as socioeconomic, cultural, and behavioral factors [10]. Many studies have examined the incidence of CRC in Iran and its related factors, but these studies have generally been conducted on the individual level, whereas ecological studies have deliberately been carried out on the provincial level [11,12]. However, the ecological fallacy states that the distribution of disease in smaller geographic units may be different from the distribution in larger units [13]. In Iran, very few studies have investigated smaller geographic units, such as neighborhoods, and the effects of socioeconomic factors and risk factors on neighborhood-level geographical inequality. Nonetheless, creating knowledge in this field (disease mapping) can be very helpful for describing the geographical variation of risk factors (hypothesis generation), identifying high-risk regions, and forming a basis for the assessment of health inequalities in order to better allocate health and medical resources [14,15].

However, given the aging population and the increasing incidence of different types of cancer in Iran, especially CRC, and the importance of cancer prevention, it is necessary to identify neighborhoods with a high incidence of CRC in cities and to clarify the role of potentially relevant socioeconomic factors, health costs, and risk factors for the development of preventive strategies by using advanced statistical models. One of the most important of these advanced models is the Besag-York-Mollie (BYM) model. The BYM model has interesting features, such as being easy to interpret, having high precision, allowing the identification of geographical variations and patterns of spatial associations, and enabling the estimation of the relative weights of the risk factors for the outcome [12,16,17]. Therefore, based on the above considerations, the aim of this study was to determine the effect of factors (socioeconomic factors, health costs, and risk factors) associated with the spatial distribution of the incidence of CRC on the neighborhood level in Tehran (the capital of Iran) by using the BYM model.

**METHODS**

**Study Area**

This ecological study was conducted in the city of Tehran (the capital of Iran). The Tehran metropolitan area comprises 638 km², and is situated at the latitude of 35°45′N and the longitude of 51°25′E. The city has 22 districts. The geographical units of the study were 374 neighborhoods in the city of Tehran.

**Required Data for the Study**

**Demographic information**

In the present study, the demographic data of people aged 50 and older (the at-risk population for the incidence of CRC) were extracted from Iranian national censuses in 2006 and 2011. The population of people aged 50 and older for each neighborhood was calculated as follows:

\[
\text{population aged } \geq 50 \text{ in the 2006 census } + \text{ population aged } \geq 50 \text{ in the 2011 census} \div 2
\]

**Information regarding the incidence of colorectal cancer**

Data regarding the incidence of CRC from 2008 to 2011 were extracted from the population-based cancer registry data of the Iranian Ministry of Health and Medical Education. Then, according to the postal address of the patients, the number of CRC cases in each neighborhood was determined.

**Socioeconomic information, risk factors, and health expenditures**

We extracted socioeconomic variables, risk factors, and health expenditures from the Equity Assessment Study conducted in Tehran. The Equity Assessment Study was a cross-sectional study conducted in Tehran in 2011 to identify inequalities in physical, psychological, social, and environmental factors. For data collection in 22 municipalities and neighborhoods of Tehran, multi-stage sampling was performed. Each
district was considered independently to calculate the sample size based on the Cochrane formula, with 1535 households in each district based on variables with a prevalence of at least 10%, a margin of error (d) of 0.015, and a 95% confidence interval (CI). Then, to facilitate the allocation of samples to the 8-box table that had to be completed as part of the individual questionnaires and to achieve higher precision, the sample was expanded to 1600 households, regardless of the population size in each district. Then, 200 blocks were assigned to each district equally. In each block, 8 households were selected for a random systematic study. To allocate samples on the neighborhood level, the probability was proportional to the size of each district. Overall, 34,700 households (118,000 individuals) were studied in 22 municipalities of Tehran in 2011. The Equity Assessment Study utilized 2 types of questionnaires, consisting of 20 parts, 14 of which were applied at the household level for all 8 selected households in the block, and 6 of which (mental health, quality of life, social capital, physical pain, oral health, and physical activity) were completed for a selected household in each block (based on the age and gender table). The details of that study were fully described by Asadi-Lari et al. [18].

Statistical Analysis

The Besag-York-Mollie model

The lack of the assumption of independent observations and overdispersion are important challenges when the Poisson model is used for count data in a spatial analysis. To deal with these challenges, hierarchical models such as the BYM model have been introduced. The BYM model can be used to consider random spatial effects and/or any unstructured random effects [19]. As a hierarchical model, this model is suitable for explaining these 2 types of heterogeneity in different regions. In other words, the relative risk (RR) is divided into 3 components, as follows:

\[ y_i \sim \text{Poisson}(E_i \theta_i) \]

\[ \log(\theta_i) = \alpha + u_i + v_i \]

The hierarchical approach of the BMY model is as follows:

Level 1: It is assumed that the outcomes have a Poisson distribution and that the RRs \( \theta_i \) are independent of each other.

Level 2: The linear predictor variable assumes that \( \theta_i \) has the following form:

\[ \log(\theta_i) = \alpha + u_i + v_i \]

Where \( \alpha \) is the log-RR baseline, and \( v_i \) and \( u_i \) represent the spatial random structure and the non-spatial random structure, respectively. Spatial autocorrelation across neighborhoods \( (v_i) \) is induced by the conditional autoregressive (CAR) model. The CAR model represents risk factors with spatial structures, so that specific risk estimates of a given area will tend to shrink toward a local mean. The CAR model within the BYM model is as follows:

\[ v_i | v_j, i \neq j, \tau_v^2 \sim N(\bar{v}_i, \tau_v^2) \]

\[ \text{where } \bar{v}_i = \frac{1}{\sum w_{ij}} \sum_j v_j w_{ij} \text{ and } \tau_v^2 = \frac{\tau_v^2}{\sum w_{ij}} \]

If areas \( i \) and \( j \) are neighbors of each other, the weight is equal to 1, and otherwise it is 0.

The spatial heterogeneity model is dependent on the number of neighbors, and the assumption of independence is not always satisfied. To solve this problem, non-spatial random effects \( (u_i) \), which usually are called exchangeable random effects, are defined. Non-spatial random effects indicate that the specific risk estimates of a given area will tend to shrink toward the global mean of the study area. This component in the BYM model is as follows:

\[ u_i \sim N(0, \tau_u^2) \]

The parameters \( \tau_v^2 \) and \( \tau_u^2 \) control variability in \( v \) and \( u \).

Level 3: On this level, the prior distribution determines the precise parameters of 2 random effects from the second level. If \( G(\alpha, \beta) \) represents the gamma distribution with expected value \( \alpha \) and variance \( \beta \), for the 2 parameters of \( \tau_v^2 = \frac{\alpha_v}{\beta_v} \) and \( \tau_u^2 = \frac{\alpha_u}{\beta_u} \) 2 distributions—gamma \((\alpha_v, \beta_v)\) and gamma \((\alpha_u, \beta_u)\)—are defined [14,19,20]. To select the suitable gamma distribution, we used \( \alpha_v = 0.5 \) and \( \beta_v = 0.005 \) for spatially structured random effects and \( \alpha_u = 0.01 \) and \( \beta_u = 0.01 \) for non-spatially structured random effects, based on previous studies in this field. These values are equivalent to a non-informative prior distribution.

The inclusion of independent variables in the Besag-York-Mollie model

The BYM model is as follows when independent variables are added:

\[ \log \theta_i = \alpha + u_i + v_i + \sum \beta_i x_i \]

In this equation, \( v_i \) and \( u_i \) have a normal prior distribution and a normal conditional autocorrelation distribution, respectively. Additionally, \( \beta \) has a normal prior distribution.
A total of 2815 new cases of CRC occurred in Tehran from 2008 to 2011, of which 2491 (88.4%) were successfully geocoded to the neighborhood level. Figure 1A shows the geographical distribution of new cases of CRC at the level of neighborhoods of Tehran; as can be seen, new cases tended to be located in the northern and central areas of the city. Figure 1B shows the distribution of the population aged 50 years and older on the neighborhood level between the censuses of 2006 and 2011. The fewest inhabitants were found in the neighborhoods of districts 9, 18, 19, 21, and 22, which are deliberately sparsely inhabited and industrial.

Table 1 shows the mean and standard deviation (SD) and MI for all variables analyzed in the study (socioeconomic variables, health costs, and risk factors). The MI was statistically significant for all variables analyzed (p<0.05). This shows that there was spatial autocorrelation at the level of the neighborhoods of Tehran for all the variables included in this study. The MI was larger for women aged 17 years or older with a university education, households living in rental houses, and households without a car.

Figure 2A shows the estimated standardized incidence ratio (SIR) of CRC on the neighborhood level using the BYM model during 2008-2011. In general, the median (interquartile range) and mean (SD) values of the SIR of CRC, when there are no variables in the model, were 0.59 (1.02) and 1.06 (1.23), respectively. There was no neighborhood with a SIR of 0, and about 32.6% of the neighborhoods had a SIR greater than 1.

Table 2 shows the associations between the variables included in the study (socioeconomic variables, risk factors, and health costs) with the SIR of CRC according to the hierarchical BYM model. As can be seen, among the variables under investigation, 4 had a significant association with the SIR of CRC: a women head of household (median SIR, 1.63; 95% CI, 1.06 to 2.53), living in a rental house (median SIR, 0.82; 95% CI, 0.71 to 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96), no daily milk consumption in the household (median SIR, 0.96).
Spatial Inequalities of Incidence of CRC and Associated Factors

SIR, 0.71; 95% CI, 0.55 to 0.94), and higher household health expenditures (median SIR, 1.34; 95% CI, 1.06 to 1.68). For example, every 10% increase in having a women head of household and in household health expenditures led to a 63% and 34% increase in the SIR of CRC, respectively.

Figure 2B shows the SIRs of CRC at the neighborhood level in Tehran based on the BYM model, with all the socioeconomic variables, risk factors, and health costs entered into the BYM model for each neighborhood. As can be seen, the highest SIRs of CRC occurred in neighborhoods located in the northern and central regions of Tehran. Overall, the median (interquartile range) SIR of CRC was 0.57 (1.01), and 31.5% of the neighborhoods had an SIR greater than 1. Additionally, the mean (SD) SIR of CRC was 1.05 (1.31) based on the BYM model.

| Variables                        | Mean (SD) | MI   | p-value |
|----------------------------------|-----------|------|---------|
| People over 15 years old who were unemployed | 9.09 (1.94) | 0.08 | 0.01   |
| Women aged 17 years or older with a university education | 30.49 (13.17) | 0.53 | <0.001 |
| Women head of household | 11.13 (3.53) | 0.26 | <0.001 |
| Households without a car | 28.96 (7.64) | 0.47 | <0.001 |
| Households living in a rental house | 39.34 (15.29) | 0.14 | <0.001 |
| Households with an income below the poverty line | 19.28 (14.96) | 0.24 | <0.001 |
| People without insurance coverage | 28.44 (12.62) | 0.37 | <0.001 |
| Households without daily fruit consumption | 13.05 (7.36) | 0.23 | <0.001 |
| Households without daily milk consumption | 54.94 (13.00) | 0.28 | <0.001 |
| Overweight people aged 15 and older | 32.32 (5.13) | 0.08 | 0.02   |
| Smoking households | 24.11 (6.20) | 0.14 | <0.001 |
| Household health expenditures | 12.68 (6.94) | 0.06 | 0.02   |
| Household expenditures on diagnoses | 17.91 (9.70) | 0.06 | 0.1    |
| Household expenditures on medicine | 45.86 (14.03) | 0.07 | 0.02   |
| Household expenditures on hospitals | 9.67 (9.85) | 0.17 | <0.001 |
| Household expenditures on medical visits | 18.17 (8.35) | 0.07 | 0.03   |

MI, Moran index; SD, standard deviation.

Table 1. Mean values of variables relating to socioeconomic factors, risk factors, and health costs, along with the magnitude of the MI

Table 2. Associations of socioeconomic variables, risk factors, and health costs with the incidence of CRC by the BYM model

Figure 2. Estimation of the standardized incidence ratios (SIRs) for each neighborhood when there are no variables in the model (A) and with the inclusion of all the variables studied in the model (B) from the Besag-York-Mollié (BYM) model.
In the present study, the highest SIRs of CRC were found in neighborhoods that were located in the northern and central regions of Tehran. The people living in these areas generally have a higher socioeconomic status, have completed higher levels of education, pay more attention to their health, and undergo more screening tests. Therefore, more cases of cancer are diagnosed in them [23]. Additionally, CRC incidence may also be associated with lifestyle factors such as physical activity and diet, because people residing in urban areas, especially regions with a relatively high economic status, usually have less mobility and consume more fast food, both of which increase the SIR of CRC [7,24]. Additionally, supporting the above conclusions, the present study showed a statistically significant association between high household health expenditures (median SIR, 1.34; 95% CI, 1.06 to 1.68) and the SIR of CRC. This finding could reflect a tendency for households that pay more attention to their health to participate more in diagnostic and screening programs of cancer, meaning that more cases of CRC will be diagnosed in them. However, these diagnosed cases are more likely to be in the early stages of the disease and have a better prognosis [25-28].

A statistically significant association was found between having a woman head of household (median SIR, 1.63; 95% CI, 1.06 to 2.53) and the SIR of CRC. This is one of the most important indicators of socioeconomic status that is directly related to poverty. Households with a women head of household usually do not have a favorable socioeconomic status. Because of legal and cultural factors, they generally do not have the capability to provide for living expenses and emerge from poverty [28]. This finding is consistent with most studies that have been carried out in this field. For example, Karamifar et al. [29] found that the incidence of CRC was higher in people who had completed low levels of formal education and who lived in neighborhoods with lower socioeconomic status. In another study by Aarts et al. [30], individuals with a low socioeconomic status had a higher risk for CRC in the US and Canada, but this risk was lower in Europe. Kim et al. [31] also showed that living in neighborhoods with a high socioeconomic status and education levels may be a protective factor against CRC. In general, low socioeconomic status is an important risk factor for the development of several types of cancer. People with a lower socioeconomic status have less access to health care and diagnostic tests, and are also less likely to participate in screening programs due to an inability to pay the required fees; as a result, fewer cases of cancer may be reported in them. The cases that are diagnosed are more likely to be in the final stages and do not have a good prognosis [32,33]. Additionally, people with a lower socioeconomic status are more susceptible to several types of diseases for various reasons. For example, diet is an important factor for gastrointestinal cancers; people in lower socioeconomic strata are more likely not to consume a healthy diet that contains fiber and fruit, and may therefore have a higher risk of cancer.

In this study, living in a rental house (median SIR, 0.82; 95% CI, 0.71 to 0.96) was inversely associated with the SIR of CRC. Renters usually belong to lower socioeconomic strata, with the corresponding implications for cancer risk.

An inverse statistical association was found between the absence of daily milk consumption and the SIR of CRC (median SIR, 0.71; 95% CI, 0.55 to 0.94). This result is not consistent with most studies in this field. The meta-analysis conducted by Aune et al. [34] showed that milk and dairy products, with the exception of cheese, were associated with reduced CRC risk. A study conducted by Green et al. [35] showed that milk intake did not have a significant association with the risk of CRC. A study by Baena and Salinas [36] also found that milk intake of 525 mL/d was associated with a 26% risk reduction of CRC in men. In general, the protective effect of milk is mediated by calcium, because milk is a rich source of calcium. Perhaps the most important reason for this problem is the ecological fallacy, because in our research, the unit studied was the neighborhood [37,38]. This fallacy can also affect variables such as the lack of fruit consumption and overweight, which in the present study did not show a significant association with the SIR of CRC.

This study had a number of limitations and strengths. One of the strengths of this study is that it is the first ecological study in Iran to examines the simultaneous effect of various socioeconomic factors, health costs, and risk factors on the SIR of CRC on the neighborhood level using the BYM model. Its limitations include the ecological fallacy, which makes it impossible to speak with certainty about the results. Another issue that may affect the results is the edge effect, which refers to the fact that border neighborhoods can be affected by the size of adjacent regions. A further limitation is that the geocoding of CRC cases in some neighborhoods may have been accompanied by a certain degree of misclassification due to incomplete postal addresses.
In conclusion, all the variables analyzed in this study showed spatial autocorrelations at the level of the neighborhoods of Tehran. The results of the BYM model also showed that having a women head of household, living in a rental house, not consuming milk daily, and high household health expenditures had a statistically significant association with the SIR of CRC. In general, this study showed that inequality was present in the spatial distribution of the incidence of CRC on the neighborhood level in Tehran. Paying attention to this inequality and associated factors will be useful for resource allocation and the development of preventive strategies in at-risk areas.

ACKNOWLEDGEMENTS

This article was extracted from Kamyr Mansori’s PhD thesis in the Department of Epidemiology, School of Public Health, Iran University of Medical Sciences. We would like to express our sincere gratitude to the staff of the cancer office of Iran’s Ministry of Health and Medical Education for providing the data.

CONFLICT OF INTEREST

The authors have no conflicts of interest associated with the material presented in this paper.
