Research and Application of a Seismic Damage Classification Method of Concrete Gravity Dams Using Displacement in the Crest

Xiang Lu, Liang Pei *, Jiankang Chen, Zhenyu Wu and Chen Chen

Abstract: Concrete gravity dams are one of the most common water retention structures, some of which are located in seismically active regions. Determination of damage level after earthquakes plays an important role in assessing the safety behavior of concrete dams. Compared with the traditional performance parameters obtained from numerical simulations, such as the damage coefficient, energy dissipation, failure modes, and stress state, etc., the displacement of dams can be acquired from daily monitoring data conveniently and quickly. It is of great significance for the rapid and effective evaluation of dam properties after earthquakes. The residual displacement in the concrete gravity dam crest was adopted as the performance parameter in the paper, and the linear mapping function between the residual displacement and the damage coefficient was established based on the concrete damaged plasticity model (CDP). Based on the traditional classification method with damage coefficient, a residual displacement-based seismic damage classification method with corresponding level limits was proposed. The seismic fragility analysis of Guandi concrete gravity dam was conducted as an example to illustrate the presented methodology. The results indicate that the proposed method is reasonable, effective, and can be easily applied to different projects after slight modifications.

Keywords: concrete gravity dam; seismic fragility analysis; residual displacement; performance parameters; damage classification

1. Introduction

Concrete gravity dams are widely used due to their simple structure, safety, and reliability, strong adaptability to topographic and geological conditions. Numerous concrete gravity dams are in service in the world and are critical components of a nation’s infrastructure. However, some of them are located in seismically active regions. Earthquakes may cause varying degrees of damage in concrete gravity dams. The presence of damage impairs the durability and operational performance of concrete gravity dams. Determinations of damage level are closely linked with the performance assessment of concrete dams. Traditional seismic damage classification methods are promoted based on the performance parameters of damage coefficient, energy dissipation, failure modes, and stress state, etc. These parameters are widely used in the field of damage of dams from earthquake waves, there are still some problems that need to be improved. For example, the stress state-based method tends to be localized, and it is difficult to reflect the global damage level; the determination of conversion coefficient between the local and global damage coefficients has a certain degree of subjectivity, and the calculation of intermediate variables is easily influenced by numerical simulation model and its parameters. It is
well known that the displacement, as a daily monitoring physical quantity in dams, not only can reflect the behavior of dams directly but can be obtained conveniently and quickly. Therefore, establishing a classification method for evaluating the damage of dams based on the displacement is of great significance for the real-time assessment of dams after earthquakes.

Fragility analysis is one of the key methods to evaluate the state of structures after the earthquake waves and has been widely concerned [1–5]. Performance parameter selection of damage degree and corresponding damage classification are the critical points when analyzing the seismic fragility analysis of concrete dams [6,7]. Methods of failure modes-based [8], stress state on weak position-based [9], energy dissipation-based [10], performance-based [11] and the damage coefficient [12,13] have been introduced and applied to study seismic fragility of concrete dams, respectively. Four (intact, slight, moderate, and severe) or five levels (slight, moderate, severe, destruction, and complete destruction) of seismic damage are used commonly in some standards [14,15]. However, the determination of stress, energy dissipation, failure modes, and weight factors, and so on, may meet various challenges or not be readily available in time.

Changes in stress, damage degree, and strength degradation can be directly reflected in the physical quantity of displacement. The objective of this paper is to study (1) the relationship between the residual displacement and the damage coefficient and (2) the residual displacement-based seismic damage classification method for gravity dams. The remainder of this paper is organized as follows. In Section 2, methods for expressing the relationship between the displacement and the damage are presented, and the fragility analysis method and process of dams are showed. In Section 3, first, a finite-element model of Guandi gravity dam is established, then the variation curves of displacements with the peak ground acceleration (PGA) are analyzed and the linear functional relationship between the displacement and the damage coefficient is proposed, finally, the residual displacement-based seismic damage classification method is proposed and the seismic fragility is analyzed and compared. In Section 4, some conclusions are presented.

2. Methodology

2.1. Concrete Damaged Plasticity Model

Lubliner et al. [16] and Lee and Fenves [17] proposed the concrete damaged plasticity model (CDP), which can describe the nonlinear behavior of concrete with good convergence under unidirectional, cyclic, and dynamic loading. The model is a commonly used method to analyze the nonlinear seismic response of concrete gravity dams [18–22]. It is mainly used to simulate the non-recoverable degradation of material caused by damage under low hydrostatic pressure. The degradation is mainly manifested in a material’s tensile and compressive yield strengths on a macroscopic level. Different reduction factors of damage and stiffness are used for tension and compression.

In the CDP model, the total strain tensor \( \varepsilon \) is decomposed into elastic and plastic parts, \( \varepsilon^e \) and \( \varepsilon^p \), respectively, i.e.,

\[
\varepsilon = \varepsilon^e + \varepsilon^p
\]  

(1)

With this information, the stress tensor is given by

\[
\sigma = (1-d)\bar{\sigma} = E_0(\varepsilon - \varepsilon^p)
\]  

(2)

where \( d \) is the scalar stiffness degradation variable, \( \bar{\sigma} \) is the effective stress, and \( E_0 \) is the initial elastic stiffness of the material.

The stress-cracking strain curves for the uniaxial tension limit states and the stress-crushing strain in uniaxial compression limit states are needed to define the elastic, plastic, and damage behaviors of concrete, the stress-strain relationships under uniaxial tension and compression loading are

\[
\sigma_t = (1-d_t)E_0(\varepsilon_t - \varepsilon^p_t)
\]  

(3)
\[ \sigma_c = (1 - d_c)E_0(\varepsilon_c - \varepsilon_p) \] (4)

2.2. Relationship Determination of Residual Displacement and Damage Coefficient

The effect of various earthquakes on the nonlinear behavior of concrete gravity dams can be directly reflected in the residual displacement. Under the action of a seismic wave with a big PGA, the state (e.g., damage) of concrete gravity dams will be worse than that with a small PGA [23]. Wang et al. [24] concluded that the maximum displacement in the crest of the Pine Flat gravity dam is about between 30 mm to 480 mm with the PGA from 0.1 g to 0.8 g, the others are about 35 mm to 160 mm with the PGA from 0.1 g to 0.6 g in the Jin’anqiao concrete dam [25], about 23 mm to 329 mm with the PGA from 0.1 g to 1.0 g in the Koyna concrete gravity dam, and about 15 mm to 80 mm with the PGA from 0.1 g to 1.0 g [26]. Based on the research above, the displacement in concrete gravity dam crest and the damage degree of dams may have a certain correlation with the earthquake intensity, respectively. Therefore, the function to describe the potential and possible relationship between them under the \( i \)th earthquake wave can be expressed by

\[ R_i = f(D_i) \] (5)

where \( D_i \) and \( R_i \) are the dimensionless damage coefficient of dams and residual displacement in the dam crest under the \( i \)th earthquake, respectively; \( f(\cdot) \) is the function form.

Peak ground acceleration (PGA) is the commonly used ground motion parameter when studying the seismic fragility of dams. Each earthquake wave is standardized at different levels, and eight PGAs, ranging from \( 1 \) m/s\(^2\) to 8 m/s\(^2\) are obtained. So the dimensionless damage coefficient \( (D_{ij}) \) and residual displacement \( (R_{ij}) \) of dams under the \( i \)th earthquake can be calculated by

\[ D_{ij} = \frac{D_{ij}}{(D_{ij})_{\text{max}}}, \quad D_i = \{D_{i1}, D_{i2}, \ldots, D_{i8}\} \] (6)

\[ R_{ij} = \frac{R_{ij}}{(R_{ij})_{\text{max}}}, \quad R_i = \{R_{i1}, R_{i2}, \ldots, R_{i8}\} \] (7)

where \( D_{ij} \) and \( R_{ij} \) are the damage coefficient of dams and residual displacement in the dam crest under \( i \)th earthquake with a PGA of \( j \) m/s\(^2\), with \( j = 1, 2, \ldots, 8 \); \( (D_{ij})_{\text{max}} \) and \( (R_{ij})_{\text{max}} \) are the maximum values of \( D_{ij} \) and \( R_{ij} \); \( D_i \) and \( R_i \) are the sets of dimensionless damage coefficients and residual displacement under the \( i \)th earthquake; The damage coefficient of dams \( (D) \) can be calculated by Equation (8) [21], where \( l_{dp} \) is the length of the damage path in crack path \( p \); \( L_p \) is the total length to which crack path \( p \) is expected to grow; \( E_p \) is the damage dissipation energy at the crack path \( p \); and \( q \) is the number of crack paths.

\[ D_I = \sum_{p=1}^{q} \left( \frac{l_{dp}}{L_p} \right) E_p \sum_{p=1}^{q} E_p \] (8)

Then, the parameters need to be solved in Equation (5) can be calculated based on the sets of \( D_i \) and \( R_i \) in Equations (6) and (7).

In the field of the damage coefficient-based seismic damage classification analysis in gravity dams, the level limits of different damage degrees have been studied and lots of results have been made. Therefore, the residual displacement-based level limits under the \( i \)th earthquake can be determined based on the Equations (5)–(8) and the known level limit \( D_{i}^k \) obtained by the damage coefficient-based seismic damage classification, that is

\[ R_{i}^k = (R_{ij})_{\text{max}} \cdot f\left( \frac{D_{i}^k}{(D_{ij})_{\text{max}}} \right) \] (9)
where \( k \) is the classification level of seismic damage, \( k = 1, 2, 3, 4 \) stands for the damage state of “intact”, “slight”, “moderate,” and “severe” in concrete dams.

At last, the final level limits of the proposed classification method can be expressed by

\[
RD_k = \left( \frac{1}{n} \sum_{i=1}^{n} RD_k^i \right) / n
\]

(10)

where \( n \) is the number of earthquake waves.

### 2.3. Fragility Analysis of Dams

Based on the related research \[27\], the seismic fragility can be expressed by the following lognormal function,

\[
P_f = \Phi \left( \frac{\ln(x_d/x_c)}{\sqrt{\beta_d^2 + \beta_c^2}} \right)
\]

(11)

where \( x_d \) is the variable of dam response; \( x_c \) is the bearing capacity, \( \beta_d \) and \( \beta_c \) are the logarithmic standard deviations of \( x_d \) and \( x_c \), respectively.

According to Cornell’s study \[28\], there is an exponential regression relationship between ground motion parameters (PGA is selected in the paper) and the seismic response variables, which is called the probabilistic seismic demand model, and it has been adopted by the SAC-FEMA standard \[29\], that is

\[
x_d = a(IM)^b
\]

(12)

Equation (12) can also be given as,

\[
\ln(x_d) = b \ln(IM) + \ln(a)
\]

(13)

where \( a \) and \( b \) are the constants; \( IM \) is the ground motion parameters. The fragility of structure can be concluded by inserting Equation (13) into Equation (11):

\[
P_f = \Phi \left( \frac{b \ln(IM) + \ln(a) - \ln(x_c)}{\sqrt{\beta_c^2 + \beta_d^2}} \right)
\]

(14)

If

\[
\frac{\ln(a) - \ln(x_c)}{b} = m
\]

(15)

\[
\frac{\sqrt{\beta_c^2 + \beta_d^2}}{b} = n
\]

(16)

Equation (17) can be given by inserting Equations (15) and (16) into Equation (14):

\[
P_f = \Phi \left( \frac{\ln(IM) - m}{n} \right)
\]

(17)

Based on the Equation (17), seismic fragility curves of dams can be expressed.

### 3. Case Study

#### 3.1. Project Specifications

Guandi hydropower project is located in Liangshan, Sichuan Province. It is composed of a roller compacted concrete (RCC) dam, a flood discharge structure, an underground powerhouse on the right bank, and so on. The normal water level is 1330 m, with a corresponding capacity of 752.8 million m³. The maximum dam height is 168 m. The elevation of the barrage is about 1334.00 m. The dam crest
length is 516.00 m, the lowest base elevation 1166.00 m, and the maximum dam bottom width 153.2 m. Guandi hydropower project is located on the west margin of the Yangtze Paraplatform, with complex cracks under the dam, strong regional neotectonic movement, relatively stable zone in the near dam reservoir area.

3.2. Finite-Element Model and Material Parameters

A two-dimensional finite element model with the dam-foundation system is shown in Figure 1a. The width to the upstream or downstream and the depth of the foundation is two times of the dam height. The X-axis is pointing downstream, and the Y-axis is vertically upward. Rigid constraints were imposed on the three truncated boundaries of the foundation, and a massless foundation was adopted in the model. The upstream elevation of the dam foundation interface is 1190 m while the downstream elevation is 1180 m, and the corresponding dam heights are 144 m and 154 m, respectively. Except for the crest and foundation surface with normal concrete of C_I and C_II, the rest of the dam is poured with R_I~R_V RCC (as seen in Figure 1b). The dynamic elastic modulus and dynamic strength are increased by 30% on the basis of the corresponding static parameters. The foundation is mainly composed of grade III_1 and grade III_2 rocks and contains a small amount of grade II, grade III_3, and grade IV rocks. The fracture and disturbed belt are N40°~50° E/NW 15°~20° (A), N30°~40° E/SE 20°~25° (B), N10°~35° W/NE 15°~20° (C) and N35° E/NW 25°~30° (D).

![Finite element model of Guandi concrete gravity dam](image_url)

**Figure 1.** Finite element model of Guandi concrete gravity dam: (a) dam-foundation system; (b) materials of the dam

Related material parameters are shown in Tables 1 and 2. The modulus and strength of the dam were increased by 30% to account for the effect of the strain rate. The Rayleigh damping method can be expressed as [30]:

$$
C = \alpha M + \beta K
$$

(18)
where \( M \) is the mass matrix, \( K \) the stiffness matrix, \( \alpha \) and \( \beta \) are the damping coefficients, and can be defined as,

\[
\alpha = \frac{2f_1 f_2 \xi}{f_1 + f_2}, \quad \beta = \frac{2\xi}{f_1 + f_2}
\]

where \( f_1 \) is the first natural frequency, \( f_2 \) is the second natural frequency, the damping ratio \( \xi \) is 5%.

### Table 1. Performance parameters of concrete material.

| Region | Density/kg·m\(^{-3}\) | Dynamic Elastic Modulus/GPa | Dynamic Tensile Strength/MPa | Dynamic Compressive Strength/MPa | Poisson Ratio |
|--------|------------------------|-----------------------------|-----------------------------|----------------------------------|--------------|
| R\(_{III}\) | 2552 | 37.7 | 1.45 | 14.53 |
| R\(_{II}, R_{IV}\) | 2515 | 53.43 | 2.15 | 21.45 |

### Table 2. Performance parameters of foundation material.

| The Structural Plane and Classification of Rock Mass | Density kg·m\(^{-3}\) | Elastic Modulus/GPa | Poisson Ratio |
|-----------------------------------------------------|------------------------|---------------------|--------------|
| II | 2750 | 18 | 0.22 |
| III\(_1\) | | 10 |
| III\(_2\) | 2700 | 8 | 0.28 |
| III\(_3\) | | 6 |
| IV | 2100 | 3 | 0.33 |
| A,B | 0 | 1.5 | 0.25 |
| C,D | 0 | 2.5 | |

### 3.3. Loadings

The calculation loads include the weight of the dam body, upstream hydrostatic pressure, dynamic water pressure, uplift pressure, and seismic load. The upstream water table is assumed to be 130 m. Westergaard added mass [31] is employed to include the hydrodynamic effects and was computed as

\[
P = \frac{7}{8} \ddot{V}_n(t) \rho \sqrt{h_w(h_w - y)}
\]

where \( P \) is the hydrodynamic pressure, \( \ddot{V}_n(t) \) is the ground acceleration, \( \rho \) is the water density, \( h_w \) is the depth of water, and \( y \) is the height of the point from the foundation.

Twenty-eight earthquake waves are selected as the excitations for fragility analysis of Guandi dam based on the site conditions with epicentral distances (EpiD) of 5.7 to 30.3 km and magnitudes ranging from 5.2 to 7.36, as shown in Table 3. The horizontal and vertical seismic actions are considered and the amplitude of acceleration in the vertical direction takes two-thirds of that in the horizontal direction. Additionally, the PGA of each earthquake wave is treated to eight grades with 0.1 g, 0.2 g, 0.3 g, 0.4 g, 0.5 g, 0.6 g, 0.7 g, and 0.8 g (a total of 224 groups). Figure 2 shows the horizontal and vertical acceleration time-histories curves of Whittier Narrows-01.
Table 3. Earthquake waves.

| Code | Name             | Magnitude | EpiD (km) | Code | Name             | Magnitude | EpiD (km) |

| 6    |                  |           |           | 20   |                  |           |           |
| 7    |                  |           |           | 21   |                  |           |           |
| 8    |                  |           |           | 22   |                  |           |           |
| 9    |                  |           |           | 23   |                  |           |           |
| 10   | San Fernando     | 6.61      | 92.59     | 24   |                  | 7.01      | 28.78     |
| 11   |                  |           |           | 25   |                  |           |           |
| 12   |                  |           |           | 26   |                  |           |           |
| 13   |                  |           |           | 27   |                  |           |           |
| 14   |                  |           |           | 28   | Tabas_Iran       | 7.35      | 28.79     |

Figure 2. Acceleration time-histories curves of the Whittier Narrows-01 wave.

3.4. Analysis and Results

(1) Function relation between the residual displacement and the damage coefficient.

Typical damage modes of Guandi dam under selected 28 earthquake waves are concluded in Figure 3. The upstream crest corner was called point A. As shown in Figure 3, the main damaged locations are as follows: (Location 1) neck area at the change of downstream face slope; (Location 2) along lift joints at various elevations, the change of upstream face slope and around the drainage gallery; (Location 3) along with dam-foundation interface at the toe and heel of the dam.

Figure 3. Typical damage modes of the Guandi gravity dam.
Figure 4 shows the graph of the relation between the residual displacement in point A and the PGA. It can be seen that the residual displacement of point A increases with increasing PGA. Specifically, as the PGA of earthquake wave 10 increases from 0.1 g to 0.8 g, the residual displacement increases from 2.23 mm to 644.45 mm. The residual displacement has a fluctuation range under different earthquake with the same PGA. Figure 5 shows the scatter diagram of the dimensionless damage coefficient of dams (D) and the dimensionless residual displacement in the dam crest (R) under 28 earthquake waves. To study the correlation between D and R variables, Pearson’s correlation coefficient is adopted in the paper, as seen in Equation (21). Results show that the Pearson’s correlation coefficient between D and R in the dam under 28 seismic waves is 0.93, indicating that there is a strong correlation between D and R.

\[ r(X, Y) = \frac{Cov(X, Y)}{\sqrt{Var[X]Var[Y]}} \]  

where \( r(X, Y) \) is the correlation coefficient between X and Y variables; \( Cov(X, Y) \) is the covariance; \( Var[X] \) and \( Var[Y] \) are the variances of X and Y variables, respectively.

The best-fit curves are shown in Figure 6 for the relationship between the D and R under earthquake waves 1–4. It can be seen that there is an approximately linear functional relationship between the D and R under these earthquake waves. For earthquake waves 1–4, the best-fit equations are linear functions as follows,

\[ R_1 = -0.010 + 1.051D_1 \]  \( (R^2 = 0.97) \)  
\[ R_2 = 0.013 + 1.023D_2 \]  \( (R^2 = 0.98) \)  
\[ R_3 = 0.137 + 0.882D_3 \]  \( (R^2 = 0.95) \)  
\[ R_4 = 0.072 + 0.909D_4 \]  \( (R^2 = 0.95) \)  

Taking the residual displacement obtained from the fitting functions between D and R under 28 earthquake waves as the prediction value, the average relative error under 28 earthquake waves is 13.52%, with the fluctuation of 4.95%–25.04%. The relative error shows that the relationship between D and R in the Guandi concrete gravity dam can be described by a linear function with high accuracy. Therefore, the linear functions of the D and R can be defined by

\[ R_i = a_i + b_iD_i \quad (i = 1, 2, \cdots, 28) \]  

Therefore, the residual displacement-based level limits are as follows

\[ RD^k_i = (RD^k_i)_{\text{max}} \left( a_i + b_i \frac{D^k_i}{(D^k_i)_{\text{max}}} \right) \quad (i = 1, 2, \cdots, 28; k = 1, 2, 3) \]  

\[ RD^k = \frac{\sum_{i=1}^{28} RD^k_i}{28} \quad (k = 1, 2, 3) \]
Figure 4. Graph of the relation between the residual displacement in point A and the peak ground acceleration (PGA).

Figure 5. Scatter diagram of R and D under 28 earthquake waves.
Figure 6. Correlation of R and D under various earthquake waves. (a) Correlation of R and D under wave 1; (b) Correlation of R and D under wave 2; (c) Correlation of R and D under wave 3; (d) Correlation of R and D under wave 4.

(2) Classification of seismic damage

Damage-based classification of seismic damage has been commonly used in the field of concrete dams. According to the related researches [8,23,32], the damage-based classification is shown in Table 4. According to Equations (27) and (28), the residual displacement-based level limits can be calculated with $\text{DI}_1 = 0.05$, $\text{DI}_2 = 0.15$ and $\text{DI}_3 = 0.40$ (as seen in Table 5). Table 6 shows the residual displacement-based classification of seismic damage of the Guandi gravity dam. As shown in Table 5, the residual displacement level limits of the intact, slight, moderate, and severe state are 13.29 mm, 39.60 mm, and 105.38 mm, respectively, and the level limits account for 0.009%, 0.027% and 0.073% of dam height. In addition, the coefficient of variations is between 34.17% and 55.47% due to the randomness of earthquake waves. The dam structure is a highly nonlinear system, it is reasonable that the response characteristics of the dam under different earthquake actions are quite different, so the average value of displacements under various earthquake waves is adopted for the further analysis.

Table 4. Damage-based classification of damage states for gravity dams.

| Symbol | Damage State | Damage Index Range |
|--------|--------------|--------------------|
| DS1    | Intact       | $0.00 < \text{DI} < 0.05$ |
| DS2    | Slight       | $0.05 < \text{DI} < 0.15$ |
| DS3    | Moderate     | $0.15 < \text{DI} < 0.40$ |
| DS4    | Severe       | $\text{DI} \geq 0.40$    |

Note: DS, damage state; DI, damage coefficient.
Table 5. Residual displacement-based level limits under various earthquakes.

| Code | DI<sub>1</sub> = 0.05 | DI<sub>2</sub> = 0.15 | DI<sub>3</sub> = 0.40 | Code | DI<sub>1</sub> = 0.05 | DI<sub>2</sub> = 0.15 | DI<sub>3</sub> = 0.40 |
|------|------------------------|------------------------|------------------------|------|------------------------|------------------------|------------------------|
| 1    | 13.27                  | 46.59                  | 129.91                 | 14   | 23.14                  | 53.40                  | 129.06                 |
| 2    | 24.19                  | 64.31                  | 164.60                 | 15   | 11.84                  | 41.22                  | 114.67                 |

Table 6. Residual displacement-based classification of seismic damage.

| Symbol | Damage State | Residual Displacement Range (mm) |
|--------|--------------|----------------------------------|
| DS1    | Intact       | 0.00 < RD < 13.29                |
| DS2    | Slight       | 13.29 < RD < 39.60               |
| DS3    | Moderate     | 39.60 < RD < 105.38              |
| DS4    | Severe       | RD ≥ 105.38                      |

Note: DS, damage state; RD, Residual displacement.

(3) Comparative fragility analysis

Based on the seismic fragility analysis method of dams, a series of functions between the probability and the logarithm of PGA are as follows

\[
P_f^{DS2} = \Phi(1.609 \ln(PGA) - 1.912)
\]

(29)

\[
P_f^{DS3} = \Phi(3.004 \ln(PGA) - 2.268)
\]

(30)

\[
P_f^{DS4} = \Phi(3.564 \ln(PGA) - 1.734)
\]

(31)

Figure 7 shows the seismic fragility curves of the Guandi dam. Generally speaking, Concrete gravity dams are designed based on two earthquake levels, the operating basis earthquake (OBE) and the maximum creditable earthquake (MCE), to ensure the seismic safety. The PGAs of OBE and MCE for the Guandi dam are 0.352 g and 0.415 g.

Figure 7a shows the seismic fragility curves defined by the residual displacement-based classification of damage for the Guandi dam, and Figure 7b shows the seismic fragility curves defined by the damage-based classification of damage. Figure 7a shows that the probabilities of slight and moderate damage under the OBE are 59.2% and 19.3%, while the severe damage is only 2.3%. It indicates that the Guandi dam under the OBE is mainly the slight damage. The corresponding probabilities under the MCE are 69.0%, 35.4%, and 8.1%, respectively. The proportion of moderate damage probability has increased. In contrast to Figure 7a, the probabilities of different damage states under the OBE (MCE) in Figure 7b are 32.3% (51.9%), 22.7% (40.4%) and 2.2% (7.8%), respectively.

Obviously, the difference between probabilities based on the residual displacement, and the damage is very small. It indicates that the residual displacement-based performance parameter and the corresponding classification method of seismic damage are reasonable and feasible. Displacements of dams are the must-be-monitored physical quantity, thereby making it easier to acquire the monitoring.
data. Residual displacement-based seismic evaluation procedures can be implemented conveniently and quickly.

### 4. Conclusions

In the present study, the following conclusions can be drawn:

1. A linear mapping function between the residual displacement and the PGA under various earthquakes is obtained. Results show that residual displacement increases with increasing PGA, and the rate of increase varies with earthquake waves.

2. Based on a series of linear mapping functions, equations for residual displacement-based level limits are established. The corresponding classification of seismic damage is made combined with the damage-based method.

3. Seismic fragility analysis results of the Guandi concrete gravity dam show that the damage degree under the OBE is mainly slight. The proportion of moderate damage probability is much larger under the MCE. The probability of severe damage or even dam failures is very small with the two levels. It indicates that the proposed method is reasonable and feasible.

4. Displacement is a must-be-monitored physical quantity in the field of concrete dams. Selecting displacement as the performance parameter to assess the safety behavior of dams makes the evaluation process timely and the results effective.
