(Received 12 December 2014; published 23 April 2015)

In many of the experimental systems that may host Majorana zero modes, a so-called chiral symmetry exists that protects overlapping zero modes from splitting up. This symmetry is operative in a superconducting nanowire that is narrower than the spin-orbit scattering length, and at the Dirac point of a superconductor-topological insulator heterostructure. Here we show that chiral symmetry strongly modifies the dynamical and spectral properties of a chaotic scatterer, even if it binds only a single zero mode. These properties are quantified by the Wigner-Smith time-delay matrix $Q = -i\hbar S^\dagger dS/dE$, the Hermitian energy derivative of the scattering matrix, related to the density of states by $\rho = (2\pi\hbar)^{-1}\text{Tr}Q$. We compute the probability distribution of $Q$ and $\rho$, dependent on the number $\nu$ of Majorana zero modes, in the chiral ensembles of random-matrix theory. Chiral symmetry is essential for a significant $\nu$ dependence.

In classical mechanics the duration $\tau$ of a scattering process can be defined without ambiguity, for example as the energy derivative of the action. The absence of a quantum mechanical operator of time complicates the simple question, “By how much is an electron delayed?” [1,2]. Since the action, in units of $\hbar$, corresponds to the quantum mechanical phase shift $\phi$, the quantum analogue of the classical definition is $\tau = \hbar d\phi/dE$. In a multichannel scattering process, described by an $N \times N$ unitary scattering matrix $S(E)$, one then has a set of delay times $\tau_1, \tau_2, \ldots, \tau_N$, defined as the eigenvalues of the so-called Wigner-Smith matrix

$$ Q = -i\hbar S^\dagger (dS/dE).$$

(For a scalar $S = e^{i\phi}$ the single-channel definition is recovered.)

This dynamical characterization of quantum scattering processes goes back to work by Wigner and others [3–5] in the 1950s. Developments in the random-matrix theory of chaotic scattering from the 1990s [6,7] allowed for a universal description of the statistics of the delay times $\tau_n$ in an ensemble of chaotic scatterers. The inverse delay matrix $Q^{-1}$ turns out to be statistically equivalent to a so-called Wishart matrix [8]: the Hermitian positive-definite matrix product $WW^\dagger$, with $W$ a rectangular matrix having independent Gaussian matrix elements. The corresponding probability distribution of the inverse delay times $\gamma_n \equiv 1/\tau_n > 0$ (measured in units of the Heisenberg time $\tau_H = 2\pi\hbar/\delta_0$, with mean level spacing $\delta_0$), takes the form [9,10]

$$ P(\gamma_n) \propto \prod_{j>i=1}^N |\gamma_i - \gamma_j|^{\beta} \prod_{k=1}^N \gamma_k^{N/2} e^{-\beta \gamma_k N/2}. $$

The symmetry index $\beta \in \{1, 2, 4\}$ distinguishes real, complex, and quaternion Hamiltonians. This connection between delay-time statistics and the Wishart ensemble is the dynamical counterpart of the connection between spectral statistics and the Wigner-Dyson ensemble [11,12] —discovered several decades later although the Wishart ensemble [13] is several decades older than the Wigner-Dyson ensemble.

The delay-time distribution (2) assumes ballistic coupling of the $N$ scattering channels to the outside world. It has been generalized to coupling via a tunnel barrier [14,15], and has been applied to a variety of transport properties (such as thermopower, low-frequency admittance, charge relaxation resistance) of disordered electronic quantum dots and chaotic microwave cavities [16–29]. Because the density of states $\rho(E)$ is directly related to the Wigner-Smith matrix,

$$ \rho(E) = (2\pi\hbar)^{-1}\text{Tr}Q(E) = \sum_n (2\pi\hbar\gamma_n)^{-1}. $$

the delay-time distribution also provides information on the degree to which levels are broadened by coupling to a continuum.

The discovery of topological insulators and superconductors [30,31] has opened up a new arena of applications of random-matrix theory [32,33]. Topologically nontrivial chaotic scatterers are distinguished by a topological invariant $\nu$ that is either a parity index, $\nu \in \mathbb{Z}_2$, or a winding number, $\nu \in \mathbb{Z}$. In the spectral statistics, topologically distinct systems are immediately identified through the number of zero modes, a total of $|\nu|$ levels pinned to the middle of the excitation gap [34,35]. If the gap is induced by a superconductor, the zero modes are Majorana, of equal electron and hole character [36–38].
These developments raise the question of how topological invariants connect to the Wishart ensemble: How do Majorana zero modes affect the dynamics of chaotic scattering? That is the problem addressed and solved in this Letter, building on two earlier works [39,40]. In Ref. [39] it was found that a $\mathbb{Z}_2$ invariant (only particle-hole symmetry, symmetry class D in the Altland-Zirnbauer classification [41]) has no effect on the delay-time distribution for ideal (ballistic) coupling to the scatterer: The distribution is the same with or without an unpaired Majorana zero mode in the spectrum. Here we show that the $Z$ invariant of $|\nu|$-fold degenerate Majorana zero modes does significantly affect the delay-time distribution. This is symmetry class BDI, with particle-hole symmetry as well as chiral symmetry [42,43]. Chiral symmetry without particle-hole symmetry, symmetry class AIII, was considered in Ref. [40] for a scalar $S = e^{i\phi}$, with a single delay time $\tau = \hbar d\phi/dE$. While our interest here is in Majorana modes, for which particle-hole symmetry is essential, our general results include a multichannel generalization of Ref. [40] and also cover class CII.

Majorana zero modes are being pursued in either two-dimensional (2D) or one-dimensional (1D) systems [36,37,44,45]. In the former geometry the zero modes are bound to a magnetic vortex core, in the latter geometry they appear at the end point of a nanowire. Particle-hole symmetry by itself can only protect a single zero mode, so even though the Majoranas always come in pairs, they have to be widely separated. The significance of chiral symmetry is that it provides additional protection for multiple overlapping Majorana zero modes [46–49]. The origin of the chiral symmetry is different in the 1D and 2D geometries. By definition, chiral symmetry means that the Hamiltonian $H$ anticommutes with a unitary operator. The 1D realization of chiral symmetry relies on the fact that the Rashba Hamiltonian of a nanowire in a parallel magnetic field is real—if its width $W$ is well below the spin-orbit scattering length. Particle-hole symmetry $H = -\tau_x H^\dagger \tau_x$ then implies that $H$ anticommutes with the Pauli matrix $\tau_x$, that switches electrons and holes. It follows that a nanowire with $W \lesssim l_0$ (the typical regime of operation) is in the BDI symmetry class and supports multiple degenerate Majorana zero modes at its end [50–52].

The Andreev billiard of Fig. 1 illustrates a 2D realization on the surface of a topological insulator. The massless Dirac fermions on the surface have a chiral symmetry at the charge-neutrality point (the Dirac point), because the 2D Dirac Hamiltonian

$$H_0 = v(p_x - eA_x)\sigma_x + v(p_y - eA_y)\sigma_y$$

anticommutes with the Pauli spin-matrix $\sigma_z$. The coupling to a superconducting pair potential $\Delta$ introduces particle-hole symmetry without breaking the chiral symmetry, since the Bogoliubov–de Gennes Hamiltonian

$$H = \begin{pmatrix} H_0 - \mu & -i\sigma_z\Delta \\ i\sigma_z\Delta^* & \mu - H_0 \end{pmatrix}$$

still anticommutes with $\sigma_z$ for $\mu = 0$.

Therefore, overlapping Majorana zero modes in a superconductor–topological insulator heterostructure (the Fu–Kane model [53]) will not split when the chemical potential is tuned to within a Thouless energy $N\delta_0$ from the Dirac point [54–56]. In this 2D geometry one needs random scattering by disorder to produce a finite density of states at $E = 0$, but in order to preserve the chiral symmetry the disorder cannot be electrostatic ($V$ must remain zero). Scattering by a random vector potential is one possibility [57,58], or alternatively scattering by random surface deformations [59–61]. To be definite, we will refer to the 2D Andreev billiard geometry in the following, but our results apply as well to 1D nanowires [62].

The unitary scattering matrix $S(E)$ of the Andreev billiard is obtained from the Green’s function $\mathcal{G}(E) = K(E - H)^{-1} K^\dagger$ via

$$S(E) = \left[1 - i\pi\mathcal{G}(E)\right]\left[1 + i\pi\mathcal{G}(E)\right]^{-1}.$$

The matrix $K$ describes the coupling of the quasibound states inside the billiard to the continuum outside via $2N$ scattering channels [63]. We assume that $K$ commutes with $\sigma_z$ so as not to spoil the chiral symmetry of the Green’s function and scattering matrix,

$$\sigma_z\mathcal{G}(E) = -\mathcal{G}(-E)\sigma_z \Rightarrow \sigma_z S(E) = S^\dagger(-E)\sigma_z.$$

It follows that the matrix product $S_0 = \sigma_z S(0)$ is both Hermitian and unitary, so its eigenvalues can only be $+1$ or $-1$. There are $N_{\pm} = N \pm \nu_0$ eigenvalues equal to $\pm 1$, where the so-called matrix signature $\nu_0$ is determined by the number of Majorana zero modes [64].
\[ \nu_0 = \frac{1}{2} \Tr S_0 = \begin{cases} \nu & \text{if } |\nu| \leq N, \\ N(\text{sign } \nu) & \text{if } |\nu| \geq N. \end{cases} \] (8)

At the Fermi level, the time-delay matrix (1) depends on \( S_0 \) and on the first-order energy variation, \( \sigma_{S}(E) = S_0[1 + iE S_1 + O(E^2)] \). Unitarity requires that \( S_1 \) is Hermitian and the chiral symmetry (7) then implies that \( S_1 \) commutes with \( S_0 \). Since \( Q(0) = Q_0 = h S_1 \), the same applies to the time-delay matrix at the Fermi level: \( S_0 Q_0 = Q_0 S_0 \). This implies the block structure
\[
S_0 = U_0 \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} U_0^\dagger, \\
Q_0 = U_0 \begin{pmatrix} Q_+ & 0 \\ 0 & Q_- \end{pmatrix} U_0^\dagger, \] (9)

with \( 1_n \) the \( n \times n \) unit matrix, \( U_0 \) a \( 2N \times 2N \) unitary matrix, and \( Q_\pm \) a pair of \( N_+ \times N_- \) Hermitian matrices. There are therefore two sets of delay times \( r_n^\pm \), \( n = 1, 2, \ldots, N_\pm \), corresponding to an eigenvalue \( \pm 1 \) of \( S_0 \).

After these preparations we can now state our central result: For ballistic coupling the two matrices \( Q_1^- \) and \( Q_1^- \) are statistically independent, each described by its own Wishart ensemble [65] and eigenvalue distribution \( P_\pm_{\gamma_\pm} \) of \( \gamma_n^\pm = 1/r_n^\pm \) given by
\[
P(\{\gamma_\pm\}) \propto \prod_{j=1}^{N_\pm} \gamma_j^\pm - \gamma_j^\mp \beta \prod_{k=1}^{N_\pm} (\gamma_j^\pm)^{\beta/2-1} e^{-\beta \gamma_j^\pm /4} \times (\gamma_j^\pm)^{\beta/2(|\nu|+N)}, \] (10)

with symmetry index \( \beta = 1 \) for the class BDI Hamiltonian (5). The distribution (10) holds also for \( |\nu| \geq N \), when the scattering matrix signature (8) is saturated. In that case a single Wishart ensemble remains for all \( 2N \) delay times, with distribution
\[
P(\gamma_n) \propto \prod_{j=1}^{2N} |\gamma_j - \gamma_j'|^{\beta / 2} \gamma_j^{\beta / 2 - 1} e^{-\beta \gamma_j /4} \times \gamma_j^{(\beta / 2)(|\nu|+N)}, \quad |\nu| \geq N. \] (11)

The derivation of Eq. (10) starts from the Gaussian ensemble for Hamiltonians with chiral symmetry [8,43],
\[
H = \begin{pmatrix} 0 & \mathcal{A} \\ \mathcal{A}^\dagger & 0 \end{pmatrix}, \quad P(\mathcal{A}) \propto \exp \left( -\frac{\beta \pi^2}{8 \delta_0^2 N} \Tr \mathcal{A} \mathcal{A}^\dagger \right). \] (12)

The rectangular matrix \( \mathcal{A} \) has dimensions \( N \times (N + \nu) \), so \( H \) has \( |\nu| \) eigenvalues pinned to zero. The matrix elements of \( \mathcal{A} \) are real (\( \beta = 1 \), symmetry class BDI, chiral orthogonal ensemble), complex (\( \beta = 2 \), class AIII, chiral unitary ensemble), or quaternion (\( \beta = 4 \), class CII, chiral symplectic ensemble).

The coupling matrix \( K = K_1 \oplus K_2 \) is composed of two rectangular blocks of dimensions \( N \times N \) and \( N \times (N + \nu) \), having nonzero matrix elements
\[
(K_1)_{nn} = (K_2)_{nn} = \kappa_n, \quad n = 1, 2, \ldots, N, \] (13)

with \( \kappa_n = \sqrt{2N \delta_0 / \pi^2} \equiv \kappa_0 \) for ballistic coupling. These matrices determine the time-delay matrix (1) via Eq. (6). At the Fermi level one has
\[
Q_0 = 2\pi h \Omega \Omega^\dagger, \quad \Omega = K(H + i\pi K^\dagger K)^{-1}. \] (14)

We seek the distribution of \( Q_0 \) given the Gaussian distribution of \( \nu \), in the limit \( N \to \infty \) at fixed \( \nu \).

The corresponding problem in the absence of chiral symmetry was solved [9,39] by using the unitary invariance of the distribution to perform the calculation in the limit \( S \to 1 \), when a major simplification occurs. Here this would only work in the topologically trivial case \( \nu = 0 \), so a different approach is needed. We would like to exploit the block decomposition (12) of the Hamiltonian, but this decomposition is lost in Eq. (14).

Unitary invariance does allow us to directly obtain the distribution of the eigenvectors of \( Q_0 = U_{\pm} \text{diag}(|r_1^\pm|, r_2^\pm, \ldots, U_{\pm}^\dagger \). From the invariance \( P(S_0, Q_0) = P(V S_0 V^\dagger, V Q_0 V^\dagger) \) under joint unitary transformations of \( S_0 \) and \( Q_0 \) we conclude that the matrices of eigenvectors \( U_0, U_+, U_- \) are all independent and uniformly distributed in the unitary group for \( \beta = 2 \), and in the orthogonal or symplectic subgroups for \( \beta = 1 \) or \( \beta = 4 \).

The “trick” that allows us to obtain the eigenvalue distribution is to note that \( Q_0 = 2\pi h \Omega \Omega^\dagger \) has the same nonzero eigenvalues as \( Q_0 \)—but unlike \( Q_0 \) it is block diagonal:
\[
\tilde{Q}_0 = 2\pi h \begin{pmatrix} \Lambda_-^{-1} & 0 \\ 0 & \Lambda_+^{-1} \end{pmatrix}. \] (15a)

\[
\Lambda_- = \pi^2 K_1^1 K_1 + \mathcal{A}(K_1^2 K_2 + \epsilon)^{-1} \mathcal{A}_1, \] (15b)

\[
\Lambda_+ = \pi^2 K_1^3 K_2 + \mathcal{A}^\dagger(K_1^4 K_1 + \epsilon)^{-1} \mathcal{A}. \] (15c)

The infinitesimal \( \epsilon \) is introduced to regularize the inversion of the singular matrices \( K_1^3 K_1 \), \( K_1^4 P_n \), where \( (P_n)_{ij} = 1 \) if \( 1 \leq i = j \leq N \) and zero otherwise. In the limit \( \epsilon \to 0 \) some eigenvalues of \( \Lambda_\pm \) diverge, while the others converge to the inverse delay times \( \gamma_n^\pm \).

The calculation of the eigenvalues of \( \Lambda_\pm \) in the \( \epsilon \to 0 \) limit is now a matter of perturbation theory [67]. This is a degenerate perturbation expansion in the null space of \( \mathcal{A}^\dagger(1_{N+\nu} - P_2) \mathcal{A}_1 \) for \( \Lambda_- \), and in the null space of \( \mathcal{A}^\dagger(1_{N+\nu} - P_1) \mathcal{A} \) for \( \Lambda_+ \). The small perturbation (an order \( \epsilon \) smaller than the leading order term) is \( \pi^2 \kappa_0^2 P_1 + \kappa_0^{-2} \mathcal{A} P_2 \mathcal{A}^\dagger \) and
From the discrete spectrum of zero modes that are not states contains additionally a contribution to the continuous spectrum. For states in the Andreev billiard. This is the density of states in a representative plots for distribution to determine the density of states.[73] In contrast, the class-BDI distribution (10) is sensitive to the number $|\nu|$ of Majorana zero modes,

$$P_{BDI}(\tau_1, \tau_2) \propto e^{-(\tau_\mu/4)(1/\tau_1+1/\tau_2)} \times \begin{cases} (\tau_1 \tau_2)^{-2} & \text{for } \nu = 0, \\ (\tau_1 \tau_2)^{-2-|\nu|/2}|\tau_1-\tau_2| & \text{for } |\nu| \geq 1. \end{cases}$$

The corresponding probability distributions of the Fermi-level density of states $\rho_0 = \tau_1/\delta_0 + \tau_2/\delta_0$ are plotted in Fig. 3. Chiral symmetry has a strong effect even for unpaired Majorana zero modes: While away from the Dirac point (class D) the distribution $P(\rho_0)$ is the same

$$P_D(\tau_1, \tau_2) \propto (\tau_1 \tau_2)^{-3}|\tau_1-\tau_2| e^{-(\tau_\mu/2)(1/\tau_1+1/\tau_2)}.$$  

In contrast, the class-BDI distribution (10) is sensitive to the number $|\nu|$ of Majorana zero modes,

$$P_{BDI}(\tau_1, \tau_2) \propto e^{-(\tau_\mu/4)(1/\tau_1+1/\tau_2)} \times \begin{cases} (\tau_1 \tau_2)^{-2} & \text{for } \nu = 0, \\ (\tau_1 \tau_2)^{-2-|\nu|/2}|\tau_1-\tau_2| & \text{for } |\nu| \geq 1. \end{cases}$$

The corresponding probability distributions of the Fermi-level density of states $\rho_0 = \tau_1/\delta_0 + \tau_2/\delta_0$ are plotted in Fig. 3. Chiral symmetry has a strong effect even for unpaired Majorana zero modes: While away from the Dirac point (class D) the distribution $P(\rho_0)$ is the same

$$P_D(\tau_1, \tau_2) \propto (\tau_1 \tau_2)^{-3}|\tau_1-\tau_2| e^{-(\tau_\mu/2)(1/\tau_1+1/\tau_2)}.$$  

In contrast, the class-BDI distribution (10) is sensitive to the number $|\nu|$ of Majorana zero modes,
for $\nu = 0, 1$, at the Dirac point (class BDI) these two distributions are significantly different.

In conclusion, this Letter presents the solution to a long-standing problem in the theory of chaotic scattering: the effect of chiral symmetry on the statistics of the Wigner-Smith time-delay matrix $Q$. The solution completes a line of investigation in random-matrix theory started six decades ago [11,12], by establishing the connection between $Q$ and Wishart matrices for the chiral counterparts of the Wigner-Dyson ensembles [42,43]. The solution predicts an effect of Majorana zero modes on the quantum delay times with significant consequences for the density of states (Fig. 3). Because the experimental search for chaotic scattering, with significant consequences for the effect of Majorana zero modes operates on 1D and 2D systems with chiral symmetry, the general and exact results obtained here are likely to provide a reliable starting point for more detailed investigations.

We have benefited from discussions with P. W. Brouwer. This research was supported by the Foundation for Fundamental Research on Matter (FOM), the Netherlands Organization for Scientific Research (NWO/OCW), and an ERC Synergy Grant.

The distribution (2) is known as a Laguerre distribution in random-matrix theory. It represents the eigenvalue distribution of a Wishart matrix $WW^\dagger$ for $\beta = 1$ [when $W$ is a real Gaussian $N \times (2N + 1)$-dimensional matrix] and for $\beta = 2$ (complex Gaussian $N \times 2N$ matrix $W$). For $\beta = 4$ there is no corresponding Wishart ensemble.

The number $2N$ of scattering channels includes a factor of 2 from the electron-hole degree of freedom. For $\beta = 4$ each scattering channel (and hence each delay time $\tau_n$) has a twofold Kramers degeneracy from the spin degree of freedom, while for $\beta = 1, 2$ the spin degree of freedom is counted separately in $N$. The mean level spacing $\delta_0$ refers to distinct levels in the bulk of the spectrum (away from $E = 0$), including electron-hole and spin degrees of freedom but not counting degeneracies.

The Laguerre distributions (10) and (11) are the eigenvalue distributions of a Wishart matrix $WW^\dagger$ when $W$ has dimension $\left(\frac{N}{\nu}\right) \times 2N$ for $|\nu| < N$ and dimension $2N \times (N + |\nu|)$ for $|\nu| \geq N$.

This complication was explained to us by P. W. Brouwer.

See Supplemental Material at http://link.aps.org/supplemental/10.1103/PhysRevLett.114.166803 for details of the calculation.

The $|\nu| - N$ uncoupled zero modes in the Andreev billiard, not broadened by the $2N$ scattering channels into the continuum, span the null space of $\mathcal{H} + i\pi K^\dagger K$. For $|\nu| \leq N$ all zero modes are broadened by coupling to the continuum.
