ABSTRACT

Purpose The objectives of the ongoing Canadian longitudinal cohort called the Alberta Pregnancy Outcomes and Nutrition (APrON) study are to: (1) determine the relationship between maternal nutrient intake and status before, during, after pregnancy, and (a) maternal mental health, (b) pregnancy and birth outcomes, and (c) infant/child neurodevelopment and behavior; (2) identify maternal mental health and nutrient predictors of child behaviour; and (3) establish a DNA biobank to explore genomic predictors of children’s neurodevelopment and behavior. The purpose of this paper is to describe the participants, measures, and key findings on maternal and paternal mental health, maternal nutrition, and child outcomes to when children are 3 years of age.

Participants Participants included mothers and their children (n=2189) and mothers’ partners (usually fathers; n=1325) from whom data were collected during the period from pregnancy to when children were 3 years of age, in Alberta, Canada. More than 88% of families have been retained to take part in completed data collection at 8 years of age.

Findings to date Data comprise: questionnaires completed by pregnant women/mothers and their partners on mothers’, fathers’ and children’s health; dietary interviews; clinical assessments; linkage to hospital obstetrical records; and biological samples such as DNA. Key findings on mental health, nutrition and child outcomes are presented. APrON women who consumed more selenium and omega-3 were less likely to develop symptoms of perinatal depression. Higher prenatal consumption of choline rich foods such as eggs and milk were recommended as was vitamin D supplementation for both mothers and children to meet guidelines. Couples in which both mothers and fathers were affected by perinatal depression reported lower incomes and higher maternal prenatal depressive symptoms and lower support from fathers postnatally and their children presented with the most behavioural problems. Maternal experiences of early adversity predicted increased likelihood of perinatal depression and anxiety and children’s behavioural problems.

Future plans The APrON cohort offers a unique opportunity to advance understanding of the developmental origins of health and disease. There is a planned follow-up to collect data at 12 years of age.

Strengths and limitations of this study

► APrON is a large, ongoing longitudinal study designed to understand the early origins of health and disease.
► APrON has collected data to 8 years of age and has planned follow-up at 12 years of age.
► APrON has retained more than 88% of participants at the 8-year data collection.
► A limitation is that the cohort is largely low-risk, limiting generalisability of study findings to higher-risk populations.

WHY WAS THE APRON COHORT SET UP?
The Alberta Pregnancy Outcomes and Nutrition (APrON) study is a longitudinal cohort of pregnant women, their partners, and their children, in Alberta, Canada. Women in our study are biological mothers, and partners typically self-identify as fathers of their children whether biological or not. The APrON study was designed to investigate the effect of nutrient intake and status during pregnancy on maternal mental health and children’s neurodevelopment and behaviour by meeting three objectives. First, the APrON team sought to determine the relationship between maternal nutrient intake and status before, during, and after pregnancy, and (a) maternal mental health, (b) pregnancy and birth outcomes, and (c) infant/child neurodevelopment and behaviour. Second, the team sought to identify maternal mental health and nutrient predictors of child behaviour over time. Third, the team sought to establish a DNA biobank to explore genomic predictors of children’s neurodevelopment and behaviour. An original grant of $5 million provided the foundation for the APrON study, which has subsequently been awarded additional funds to continue the study up to 12 years of age.
expanded its focus and contributed to over 50 additional projects on the psychobiology of stress, parent–child relationships and attachment, neurotoxicant exposure, genetics, epigenetics, inflammation and immune activity, probiotics, the microbiome, and children’s brain development. To date, the APrON study has received over $15 million in additional funding. This funding enables follow-up of APrON families until children reach 12 years of age to understand the impact of medical, biological and environmental factors on children’s development, behaviour and mental health. Data collection for the 5-year and 8-year follow-up questionnaires is completed, with the data currently being cleaned for analysis and the 12-year follow-up to begin in 2022. Papers have been published detailing how women and their partners were recruited and describing the APrON cohort at enrollment during pregnancy and up to 12 months postpartum; however, a summary of key findings has not been reported. Thus, drawn mostly from data collected during the period from pregnancy to when children are 3 years of age, the objectives of this paper are to describe the: (1) participants, (2) measures, and (3) key findings on maternal mental health, maternal nutrition and child outcomes.

**WHO IS IN THE APRON COHORT?**

Women were recruited into the cohort if they were 16 years of age or older, able to speak and read English, <27 weeks gestation and willing to come for on-site clinic visits at the University of Calgary, in Calgary or University of Alberta, in Edmonton, Alberta. Partners were eligible if they were cohabitating with the participating woman. Participants were excluded if they planned to move out of the region during the clinic visit timeframe of pregnancy to 3 months postpartum. A total of 2189 pregnant women (aged 16–44) and 1325 men (aged 18–52), residing around Calgary or Edmonton, were enrolled in the study between May 2009 and June 2012. To assess the representativeness of the APrON cohort (see table 1), socio-demographic characteristics of participants at the time of recruitment were compared with characteristics of women with children in Calgary, Alberta and Canada. A greater proportion of women in the cohort (28.0%) were over 34 years old compared with women in Calgary (20.0%), Alberta (16.0%) and Canada (18.0%). More APrON women were married (95%) compared with women in Calgary (73.0%), Alberta (70.0%) and Canada (60.0%). A greater proportion of women had household incomes of $60 000 or more (77.0%) compared with Calgary (65.0%), Alberta (61.0%) and Canada (58.0%). More APrON women completed post-secondary education (87.0%) compared with women in Calgary (69.0%), Alberta (70.0%) and Canada (72.0%). The proportion of APrON women who were born outside of Canada (22.0%) was similar to the proportions in Calgary (25.0%), Alberta (22.0%) and Canada (20.0%) (see figure 1).

**Patient and public involvement**

APrON cohort participants were not involved in the development of the initial study design or in the recruitment of participants. However, APrON established a parent advisory committee (PAC) shortly after recruitment ended in 2012. Over time, 70 parents have participated on the PAC, with approximately 10–15 parents taking part in twice yearly meetings to advise the principal and co-investigators on a variety of topics, for example, how to keep participants engaged and interested in APrON research, priorities for future APrON research, and feedback on laymen research summaries posted to APrON’s website. APrON has also extensively disseminated knowledge to the public via various modalities including: multiple presentations to various stakeholders, APrON’s Newsletter, website (https://apronstudy.ca/) and conferences. Held via Zoom due to COVID-19 on 29–30 October 2020, APrON hosted an online conference titled *Celebrating 10 Years: Alberta Pregnancy Outcomes and Nutrition (APrON) Achievements & Evolution*, that attracted over 300 attendees, many who were APrON participants. The APrON cohort PAC members held their own panel session where they spoke to the attendees about their experiences with APrON, why they think the research is important, and how we can continue for years to come.

**How often have APrON families been followed up?**

Between 2009 and 2012, the initial cohort completed questionnaires and clinical assessments three times during pregnancy, and at 3 months postpartum. Hospital delivery records were also accessed to record birth information. Follow-up questionnaires were provided when children were 6 months, and 1, 2, 3, 5 and 8 years of age (see figure 2). We plan a 12-year follow-up beginning in 2022.

In total, 2189 women and 1325 men completed at least one questionnaire. Of the women and their children (88.9%) are continuing participants, defined as those who did not become ineligible or were lost to follow-up. Participants who discontinued the study included women who miscarried, had a stillbirth, lost custody of their child or for whom a maternal/child death was reported (n=52, 2.4%); moved out of Calgary or Edmonton before 3 months postpartum (n=43, 2.0%) or withdrew from the study citing loss of interest (n=149, 6.8%). The demographic characteristics of participants who continued in APrON compared with those that discontinued are provided in table 2.

Continuing participants were more likely to be older, married and to have higher education and household incomes (all p’s <0.05). The proportion of continuing participants born in Canada was similar to discontinuing participants. When mothers were lost to follow-up, so too were fathers and children.

**WHAT HAS THE APRON STUDY MEASURED?**

Expectant women and later mothers were asked to complete questionnaires three times during pregnancy...
Letourneau N, et al. BMJ Open 2022;12:e047503. doi:10.1136/bmjopen-2020-047503

(<14, 14–26 and 27–40 weeks gestation; number of scales administered was 37) and seven times postnatally (3 and 6 months, 1, 2, 3, 5 and 8 years; number of scales administered was 77). Their partners (usually self-reported fathers) were asked to complete questionnaires at 14–26 weeks gestational age (number of scales
administered was 16) and two times postnatally (3 months and 5 years; number of scales administered was 14). Questionnaires administered during pregnancy measured previous and current mental and physical health status, nutritional, medication and supplement intake, lifestyle choices, healthcare services used, social support, attitudes towards breast feeding and sociodemographic variables. The follow-up postpartum questionnaires collected information about labour and delivery, postpartum medical problems, maternal and paternal mental health and stress, nutrition, medication and supplement intake, lifestyle choices, food security, parenting, experiences in close relationships, adverse childhood experiences, and sociodemographics (see figure 2). Measures were selected based on several synergistic priorities. First, the APrON team had to judge measures to be reliable and valid indicators of the constructs of interest. Second, measures had to minimise burden to participants in terms of time and difficulty to complete, for example, measures with fewer items and more accessible language were valued most. Finally, an APrON team member had to express an interest in using the measure. Full details and documentation of all APrON measures are available on request.

Clinic visits were undertaken to gather maternal anthropometric measurements during pregnancy and at 3 months postpartum. These measures included height, pre-pregnancy and current weight, highest weight during pregnancy, circumference measurements (i.e., mid-upper arm, waist, hip, thigh) and skinfold thickness (i.e., biceps, triceps, subscapular, suprailiac, thigh). Each measurement was taken three times and averages were reported for analyses. Maternal height and weight were collected during the prenatal period. As an objective of APrON was to establish a biobank for future research on genetics, epigenetics,1 nutrient exposures and neurotoxins, biosamples were also collected from mothers, their partners and infants during clinic visits. Midstream random urine samples (10mL) were collected from expectant mothers at 14–26 weeks gestation and 3 months postpartum. A breast milk sample was collected from breastfeeding mothers to determine fatty acid composition. Maternal non-fasting venous blood samples were collected from mothers at <14, 14–26 and 27–40 weeks gestation, and at 3 months postpartum. Maternal blood collection provided whole blood, plasma and serum, which were used for DNA, RNA, cytokines, haemoglobin measures, thyroid hormones and measures of heavy metals (e.g., mercury, lead) and perfluorinated chemical exposure. Buccal cell samples were also collected at 14–26 weeks gestation from partners for DNA extraction and future genetic and epigenetic studies. From infants, buccal and/or blood samples were collected at 3 months of age for DNA extraction. Purified DNA is available at the Gene Expression Omnibus data repository (https://www.ncbi.nlm.nih.gov/geo/). A detailed list of data collected up to 8 years of age on the full sample is provided in table 3 for mothers, table 4 for fathers and table 5 for children.

Numerous substudies, employing portions of the APrON sample, have utilized the originally collected biosamples in related research; for example, the Neurotoxicant

Figure 2  Data collection to 8 years of child age.
Study (n=546) that examined maternal exposure to endocrine hormone disrupting chemicals (i.e., bisphenol A and phthalates) on child outcomes8–13 and the Parenting Research on Mental Illness, Stress and Epigenetics (PROMISE; n=276) Study of gene-by-environment interactions.14–18 Another substudy, called the Fetal Programming Study19–27 (n=276) collected additional data such as maternal and infant saliva for cortisol assessment, infant heart rate variability, and parent-infant interactions via videotaped observations.

WHAT HAS APRON FOUND?
A complete list of publications from APRON can be found at http://www.apronstudy.ca. Key findings from the full sample on maternal and paternal mental health, maternal nutrition and child outcomes have been summarised in box 1.

MENTAL HEALTH OUTCOMES
Drawn from the full APRON cohort, three key papers28–30 reported on perinatal depression and anxiety symptom prevalence and risk factors and specifically, the impact of adverse childhood experiences on outcomes. Many more papers report on parental mental health in substudies. See APRONstudy.ca for details.

Predictors of depression
Maternal prenatal depression is known to have negative impacts on pregnancy and maternal postnatal mental health and neonatal outcomes,31 32 and the psychosocial predictors of maternal postpartum depression are well known.33 34 However, less well known is whether mothers and fathers in partnered, cohabitating couples (e.g., married, common-law) share common predictors and experiences of depressive symptoms in the perinatal period. Further, whether maternal prenatal nutrition impacts postpartum depressive symptoms is less well studied. Thus, using APRON data, Leung and colleagues30 reported on the prevalence of depressive symptoms in couples. For partnered mothers’ depressive symptoms, using the recommended Edinburgh Depression Scale (EDS) cut-off score of ≥10,35 findings revealed that 15.2% and 11.18% of mothers had significant symptoms prenatally and at 3 months postpartum, respectively. For fathers in couples, the cut-off of EDS ≥9 was used as

| Characteristic                  | Continuing participants n (%) | Discontinuing participants n (%) | Lost to follow-up, n (%) | Dropped out, n (%) | P value |

ACEs, Adverse Childhood Experiences Questionnaire; CCHSC, Canadian Community Health Survey Cycle 2.2, modified; CES-D, Centre for Epidemiologic Studies Depression Scale; ECR, Experiences in Close Relationship Scale; EDS, Edinburgh Depression Scale; FFQ, Food Frequency Questionnaire, adapted from the Canadian version of the Diet History Questionnaire; GLTE, Godin Leisure-Time Exercise Questionnaire; OECD, Organization for Economic Cooperation and Development Guidelines on Measuring Subjective Wellbeing; PDSQ, Psychiatric Diagnostic Screening Questionnaire; PSS, Perceived Stress; PUQE, Pregnancy-Unique Quantification of Emesis and Nausea Questionnaire; SCL-90-R, Symptom Checklist-90-Revised; SF-8, Short Form Health Survey-8; SLEQ, Stressful Life Events Questionnaire; SSI, Social Support Index; SSQ, Social Support Questionnaire; STAI, State-Trait Anxiety Inventory; TIPI, Ten-Item Personality Inventory.
per recommendations revealing that 14.0% and 12.1% of fathers had significant symptoms prenatally and at 3 months postpartum, respectively. These rates are consistent with other large samples. Further, 2.3% of couples experienced perinatal depressive symptoms in both mothers and fathers, 78.5% of couples did not experience depressive symptoms in either partner, 9.5% of couples experienced depressive symptoms in mothers only and 9.8% of couples experienced depressive symptoms in fathers only. Leung and colleagues determined the predictors of depression at 3 months postpartum from second trimester data. Risk factors for maternal postpartum depressive symptoms included low household income, high prenatal depressive symptoms, low postnatal support from fathers and high stressful life events. Risk factors for paternal postpartum depressive symptoms included low household income, prenatal depressive symptoms, postpartum stressful life events and smoking. For couples in which both partners were depressed, risk factors included low income, high maternal depressive symptoms and low prenatal social support from fathers. Postpartum social support was found to be a protective factor associated with decreased risk of maternal and paternal postpartum depressive symptoms.

Additionally, Leung and colleagues examined nutritional predictors of maternal postpartum depression, focusing on APrON mothers’ reports of their multivitamin and mineral intake in each trimester of pregnancy. Almost all women (99%) took some type of micronutrient supplement during the prenatal period, with the most commonly consumed being vitamins B6, B9 (folate), B12 and E, with more than 90% of mothers consuming above recommended dietary allowances. With respect to predictors of postpartum depression, findings revealed that mothers who experienced postpartum depressive symptoms (EDS ≥ 10) were statistically less likely to take the supplemental micronutrients selenium and omega-3, compared with mothers who reported no postpartum depressive symptoms (EDS < 10). Selenium intake above the recommended dietary allowance appeared to be

X refers to investigator-developed measures. BMI, body mass index; EDS, Edinburgh Depression Scale; GLTE, Godin Leisure-Time Exercise Questionnaire; SLEQ, Stressful Life Events Questionnaire; SSQ, Social Support Questionnaire.
Letourneau N, et al. BMJ Open 2022;12:e047503. doi:10.1136/bmjopen-2020-047503

Protective, and other research suggests that this micro-nutrient has a role in normal brain function and in the pathway between dopamine and the pathophysiology of depression. The supplement taken the least was omega-3; however, 68.5% of women with low depressive symptoms (EDS <10) did not take omega-3, versus 78.0% of women with high depressive symptoms (EDS ≥10), a finding consistent with other research. The mean intakes of other nutrients were more likely to be higher in women with low depressive symptoms than those with high symptoms, although not statistically significant. The authors conclude with a call for more study into the value of selenium and omega-3 in the prevention of postpartum depression.

### Associations with adverse childhood experiences

Adverse childhood experiences are defined as a set of exposures to personal abuse, neglect and household dysfunction prior 18 years of age that includes physical, sexual and emotional abuse, domestic violence, and parental mental illness, substance use and incarceration. A graded relationship has been repeatedly observed between the number of adversities experienced in childhood and later increased risk for poor health, including depression and other mental health outcomes. However, whether such adversities affect perinatal mood more broadly including anxiety was less studied. Felitti and colleagues' classic measure of adverse childhood experiences was administered to APron mothers, revealing that while 55% reported...
Letourneau N, et al. BMJ Open 2022;12:e047503. doi:10.1136/bmjopen-2020-047503

Maternal experiences of early adversity associate with maternal infants' vitamin D status increases in direct proportion to mothers' requirements. Approximately 70% of women who entered pregnancy with a body mass index (BMI) >25 kg/m² were likely to exceed gestational weight gain guidelines in the beginning of the second trimester. Women with excessive weight gain also gained higher amounts of body fat and retained higher amounts of fat compared with women who gained within the guidelines. Women who consumed a healthy diet pattern prior to pregnancy were less likely to develop complications such as gestational hypertension.

The median vitamin D intake from diet and supplements was 600 IU/day during pregnancy, which was not enough to achieve a target plasma concentration. Women who gained in excess of weight gain guidelines, by about 19 weeks gestation. Women with excessive weight gain also gain higher amounts of body fat and retain higher amounts of fat compared with women who gain within the guidelines. Women who consumed a healthy diet pattern prior to pregnancy were less likely to develop complications such as gestational hypertension.

13% of mothers had a score of three or more adverse childhood experiences. Maternal exposure to early adversities predicted higher reported symptoms of perinatal depression and anxiety.

BOX 1

Mental health outcomes

In partnered couples, both mothers and fathers had depressive symptoms in 2.3% of couples. Low household income and prenatal maternal depression were associated with a higher probability of depressive symptoms in both partners. In 78.5% of couples, neither father nor mother experienced depressive symptoms. Postnatal social support was found to be a protective factor associated with decreased risk of maternal and paternal postpartum depressive symptoms. Risk factors for maternal postpartum depression symptoms included low household income, and prenatal symptoms of depression. For paternal postpartum depression symptoms, risk factors included low household income, prenatal depression symptoms, postpartum stressful life events, and smoking.

Women with higher postpartum depression symptoms were less likely to take micronutrients (eg, vitamins B6, B9, B12 and E; essential fatty acids; selenium) compared to those with fewer symptoms; however, only selenium and omega-3 were significantly different between symptomatically depressed and non-depressed groups, with non-depressed mothers consuming higher amounts.

13% of mothers had a score of three or more adverse childhood experiences. Maternal exposure to early adversities predicted higher reported symptoms of perinatal depression and anxiety.

Nutrition outcomes

Approximately 70% of women who entered pregnancy with a body mass index (BMI) >25 kg/m² were likely to exceed gestational weight gain guidelines in the beginning of the second trimester. Women with excessive weight gain also gained higher amounts of body fat and retained higher amounts of fat compared with women who gained within the guidelines. Women who consumed a healthy diet pattern prior to pregnancy were less likely to develop complications such as gestational hypertension.

The median vitamin D intake from diet and supplements was 600 IU/day during pregnancy, which was not enough to achieve a target plasma concentration. A significant relationship between maternal reported dietary vitamin D intake and plasma vitamin D concentration was identified. Only 23% of mothers met the adequate intake (AI) recommendations for choline; the number was even lower (19%) in the postpartum period. Consuming eggs and milk during pregnancy increased mothers' likelihood of meeting choline AI recommendations.

Child outcomes

Infants with higher birth weights and at 3 months of age had mothers with a higher pre-pregnancy BMI. Gestational weight gain above recommendations was associated with higher infant weight at birth and 3 months of age as well as more rapid postnatal growth.

Infants' vitamin D status increases in direct proportion to mothers' vitamin D intake. Given many mothers were found to be below recommended AI for vitamin D, both infants and breastfeeding mothers require vitamin D supplementation.

Maternal experiences of early adversity associate with maternal symptoms of anxiety and depression during the perinatal period as well as externalising behavioural problems in their 2-year-old children. Boys demonstrate greater vulnerability to the indirect effects of maternal adversity via both depression and anxiety.

Both mothers' perinatal depressive symptoms and mothers' and fathers' co-occurring perinatal depressive symptoms predicted more problematic emotionally reactive, withdrawn, and total internalising behaviours in their 2–3-year-old children. Children's aggression, attention problems and total externalising behaviours were only predicted by mothers' perinatal depressive symptoms.

NUTRITION OUTCOMES

Gestational weight gain and dietary intake, especially perinatal nutrient intake and status focused on vitamin D and choline were examined in eight key papers.44-51

Gestational weight gain and dietary intake

Gestational weight gain over or below Health Canada's Gestational Weight Gain Guidelines is associated with an increased risk of adverse outcomes for mother and infant.52 The APrON cohort was the first to provide evidence that more than half of women gain more than Health Canada's Guidelines, using prospectively collected body weights from across pregnancy.44 Since then, several studies have been completed with body weight or body composition in pregnancy or postpartum as a main outcome. Analysis of the APrON data by Jarman and colleagues46 provided a clear picture indicating that approximately 70% of women who become pregnant with a body mass index (BMI) >25 kg/m² are likely to exceed gestational weight gain guidelines, by about 19 weeks gestation. Women who gain in excess of weight gain also gain higher amounts of body fat and retain higher amounts of fat compared with women who gain within the guidelines.46 The detailed dietary intake information that was collected showed that women who consumed a healthy diet pattern prior to pregnancy were less likely to develop complications such as gestational hypertension.47 An individualised approach to supportive dietary counselling that considers pre-pregnancy BMI in addition to the woman's social and financial context may be key to helping women meet national recommendations for both diet and gestational weight gain in pregnancy.53

Nutrient intake and status

Vitamin D is critical for a healthy pregnancy and the major circulating form of vitamin D is 25-hydroxyvitamin D (25(OH)D); thus, the total serum 25(OH)D level is no early adverse childhood experiences, nearly 32% reported one or two adversities and 13% reported three or more. Employing data from each trimester of pregnancy and 3, 6 and 12 months postpartum, more reported early adversities predicted higher reported symptoms of perinatal and postnatal depression and anxiety.29 Routine screening for maternal childhood adversities may facilitate early identification and preventative interventions for perinatal mood disorders including depression and anxiety; however, this has been recently debated.43 In sum, the identified risks and protective factors provide opportunities for prevention of perinatal depression and anxiety.

Continued
was currently considered the best indicator of vitamin D supply. Three studies that included APrON participants examined the role of maternal vitamin D intake during pregnancy. Aghajafari and colleagues reported that the median vitamin D intake from diet and supplements was 600 International Units (IU)/day during pregnancy, which was not sufficient to achieve a target concentration of 25(OH)D. When the 3-epimer (3-epi-25(OH)D3) was included in the estimation of 25(OH)D3 concentration, the prevalence of vitamin D insufficiency (<75 nmol/L) was lower (33.0%) compared with when it was excluded (38.0%). Vitamin D supplementation (2000 IU/day) was associated with 25(OH)D3 sufficiency. A significant relationship between maternal reported dietary vitamin D intake and plasma 25(OH)D and 3-epi-25(OH)D3 concentration was identified.

Choline intake during pregnancy and lactation is critical to the offspring’s brain function. Lewis and colleagues reported that the mean choline intake in pregnant and lactating women ranged between 340 (SD 148) in the second trimester and 346 (SD 151) mg/day at 3 months postpartum. Only 25% of mothers met the adequate intake (AI) recommendations for choline; the number was even lower (10%) in the postpartum period. Consuming eggs and milk during pregnancy increased mothers’ likelihood of meeting choline AI recommendations. These findings contributed to the European Food Safety Authority dietary reference values for choline guidelines. To conclude, a significant number of women were not meeting recommendations for vitamin D and choline intake during pregnancy and postpartum. Increased consumption of these nutrients may be necessary for pregnant and lactating women to improve the health and development of their infants.

**CHILD OUTCOMES**

The impacts of maternal and infant nutrient intake, maternal BMI and gestational weight gain, and perinatal depression and maternal adverse childhood experiences on child outcomes were examined in four key papers. Many more papers will emerge as the cohort matures and data become available.

**Maternal BMI, gestational weight gain and vitamin D**

Subhan and colleagues described the effects of maternal pre-pregnancy BMI and gestational weight gain on infant anthropometrics at birth and 3 months and infant growth rates between birth and 3 months. Other research shows that children who are heavier at birth have an increased risk of high BMI in childhood, being overweight or obese as adults, a condition linked to increased risk for hypertension, type 2 diabetes and cardiovascular diseases. APrON findings revealed that infants with higher weight at birth and at 3 months of age had mothers with a higher pre-pregnancy BMI. Also gestational weight gain above recommendations was associated with higher infant weight at birth and 3 months of age as well as more rapid postnatal growth. The authors concluded that clinicians and healthcare professionals should encourage women to enter pregnancy with a healthy BMI and adhere to the current gestational weight gain recommendations.

Aghajafari and colleagues examined the association between APrON mothers’ vitamin D intake during breast feeding with their infants’ vitamin D status to determine whether infant supplementation was sufficient. Other research reveals that low vitamin D is associated with increased rates of infections, autoimmunity and allergies and poor bone health in children. Using plasma from a subset of breastfed infants, vitamin D status was measured by liquid chromatography–tandem mass spectrometry and mothers’ and infants’ dietary data were attained from questionnaires. Controlling for race, season, prenatal maternal vitamin D status, infant birth weight and daily infant vitamin D supplementation, infants’ vitamin D status increased in direct proportion to mothers’ vitamin D intake. Moreover, a quarter of mothers were below recommended AI for vitamin D. The authors concluded that to ensure optimal infant vitamin
D status, both infants and breastfeeding mothers require vitamin D supplementation.

**Perinatal depression and adverse childhood experiences**

Two studies addressed impacts of perinatal depression and adverse childhood experiences on children’s behaviour. It is well established that children’s internalising behavioural problems (e.g., emotional reactivity, anxiety, depression, somatic complaints and social withdrawal) and externalising behavioural problems (i.e., inattention, hyperactivity and aggression) predict adult mental health problems.

As indicated above, adverse childhood experiences increased risk for poor health over the lifespan, however, intergenerational impacts have also been noted with an incomplete understanding of the mechanism of transmission from one generation to the next. In examining intergenerational impacts, Letourneau and colleagues found that APrON mothers’ experiences of early adversity were associated with maternal symptoms of anxiety and depression during the perinatal period (discussed earlier) as well as externalising behavioural problems in their 2-year-old children. Indirect associations were observed between maternal adverse childhood experiences and children’s internalising and externalising problems via maternal anxiety and depression. Sex differences were also observed with boys demonstrating greater vulnerability to the indirect effects of maternal adversity via both depression and anxiety. The authors concluded that interventions may be targeted to women who have multiple adverse childhood experiences as well as mental health problems to prevent behavioural problems in their children. Letourneau and colleagues further examined perinatal depression in mothers, as well as fathers or both parents and how symptoms in one or both parents predict children’s behavioural problems. Other research has shown that fathers may buffer the impacts of maternal depression on children’s outcomes and thus this protective factor is likely undermined when fathers are depressed as well as mothers. Mothers’ and fathers’ depressive symptoms were measured during pregnancy and 3 months postpartum, and children’s behaviour was measured at 24 and 36 months of age. Results revealed that both mothers’ perinatal depressive symptoms and mothers’ and fathers’ co-occurring perinatal depressive symptoms predicted more problematic emotionally reactive, withdrawn and total internalising behaviours. In contrast, children’s aggression, attention problems and total externalising behaviours were only predicted by mothers’ perinatal depressive symptoms. The authors urge healthcare providers to consider the whole family, including fathers, when treating maternal symptoms of depression, aligned with review recommendations to also consider fathers.

**WHAT ARE THE MAIN STRENGTHS AND WEAKNESSES?**

The major strengths of APrON are recruitment and retention of the large community-based cohort during pregnancy, postpartum and early childhood. The APrON study used a detailed array of standardised validated psychological and physiological measures and biospecimens. The prospective data collection and follow-up enabled investigation of a wide range of maternal and paternal health outcomes. The APrON team has been successful in continuously engaging participants, as evidenced by high response rates over the years (see table 6).

The high response rates over time may be due to the recruitment of a relatively low-risk sample as sociodemographic characteristics are skewed toward a high percentage of well-educated, higher income, married participants. Consequently, generalisability of findings to those with different sociodemographic backgrounds should be made with caution. Further, the study likely included participants with healthier lifestyle behaviours or with more positive attitudes towards research, because such characteristics are associated with higher socioeconomic status. Selective attrition bias is likely operating in the cohort, which may lead to underestimation of the effect of parental mental health and lifestyle choices on children’s development. While attrition has been relatively low over time, differences in the sociodemographic characteristics of the continuing participants compared with discontinuing participants should be considered when interpreting the findings. There were also fewer fathers than mothers in the sample; thus, most developmental and behavioural outcomes are based on maternal reports.
