INTRODUCTION

Regulatory T cells (Tregs) are emerging as a new cell-based therapy in solid organ transplantation. Adoptive transfer of Tregs has been shown preclinically to protect from graft rejection, and the safety of Treg therapy has been demonstrated in clinical trials. Despite these successes, the in vivo distribution and persistence of adoptively transferred Tregs remained elusive, which hampers clinical translation. Here we isolated human Tregs using a GMP-compatible protocol and lentivirally transduced them with the human sodium iodide symporter to render them traceable in vivo by radionuclide imaging. Engineered human Tregs were characterized for phenotype, survival, suppressive capacity, and reporter function. To study their trafficking behavior, they were subsequently administered to humanized mice with human skin transplants. Traceable Tregs were quantified in skin grafts by non-invasive nano-single-photon emission computed tomography (nano-SPECT)/computed tomography (CT) for up to 40 days, and the results were validated ex vivo. Using this approach, we demonstrated that Treg trafficking to skin grafts was regulated by the presence of recipient Gr-1+ innate immune cells. We demonstrated the utility of radionuclide reporter gene-afforded quantitative Treg in vivo tracking, addressing a fundamental need in Treg therapy development and offering a clinically compatible methodology for future Treg therapy imaging in humans.

In transplantation, graft rejection is a detrimental process driven by alloreactive T cells that recognize donor major histocompatibility complex (MHC) antigens (alloantigens) via various pathways.3 In addition to maintaining tolerance to self-antigens, Tregs contribute to controlling responses to alloantigens, and a correlation between the proportion of Tregs within a transplanted organ (allograft) and graft survival has been observed.4,8 This has led to the pursuit of protocols designed to tip the balance between Tregs and effector T cells (Teffs) in favor of Tregs to induce transplantation tolerance. One strategy to increase Treg numbers is purification of Tregs from allograft recipients, expanding and potentially manipulating them in vitro before re-administration. In immunodeficient mice transplanted with human skin and reconstituted with peripheral blood mononuclear cells (PBMCs), adoptive transfer of human in-vitro-expanded polyclonal Tregs significantly prolonged the survival of skin allografts.7,8 Polyclonal Treg-based cell therapy approaches yielded early promising results for prevention of graft versus host disease (GVHD), after allogeneic hematopoietic stem cell transplantation9,10, and for maintenance of C-peptide levels in type I diabetes.11,12 We led two clinical phase I/II trials using adoptive transfer of polyclonal expanded Tregs to promote tolerance in kidney (ONE Study, NCT02129881) and liver (ThRIL, NCT02166177) transplant recipients.13-15 The resultant data...
suggested Treg therapy to be safe and well tolerated and showed some signs of efficacy.

Despite an increase in the numbers of clinical trials using human Treg therapy, important questions pertaining to their in vivo fate, distribution, and location of their function remain unclear. Recently, polyclonal Tregs labeled with [6,6-2H2]glucose were detected in the circulation of individuals with type 1 diabetes for up to one year. However, it remains a challenge to identify adoptively transferred Tregs in tissues non-invasively.

Non-invasive radionuclide imaging by single-photon emission computed tomography (SPECT) or positron emission tomography (PET) offers excellent sensitivity with absolute quantification and true 3D information while being translatable to the clinic. Cell labeling approaches can be direct or indirect, with each approach offering distinct advantages and disadvantages. We showed previously that direct radiolabeling of murine CD4+ T cells, with 99mTc-hexamethylpropyleneamine oxide, did not affect cell viability, but the radiolabeled cells could only be tracked for up to 24 h because of the short radioisotope half-life of 99mTc (6 h). This enabled assessment of Treg biodistribution within a day after administration but precluded the desired long-term tracking of Tregs, which would require longer half-life radioisotopes. Longer half-life radioisotopes are available (e.g., 111In and 89Zr) but also elicit a higher radioactive dose, limiting the study length. Using various T lymphocytes, recent studies involved tracking of about one week but not longer. In the context of transplant immunology, aiming to track Tregs to transplants, one week is a short observation time, and significantly longer cell tracking would be beneficial.

Long-term cell tracking can be achieved through indirect cell labeling, which involves genetic engineering to express a reporter and render the cells in vivo traceable by repeat imaging. Treg in vivo dynamics were assessed using bioluminescence approaches. However, bioluminescence imaging is not translatable to the clinic because of the non-human nature of luciferases, which also require luminogenic substrate administration, and the added disadvantages of optical imaging at depth (absorption, scatter) precluding reliable quantification. Radionuclide reporter genes are an alternative that enables 3D tomographic imaging, and they have also been shown to be clinically translatable. Host reporter genes are from the same species as cell tracking should occur in and should be endogenously expressed in only a very limited number of host tissues to ensure favorable contrast and overcome any immunogenicity issues intrinsic to foreign reporters. One of the most promising host reporter genes is the human sodium iodide symporter (NIS), which has been shown to be well tolerated in different cell types, including cancer cells, cardiomyocytes, stem cells, and T cells. In a proof-of-principle study employing retroviral transduction methodology, we demonstrated ex vivo engineering of murine Tregs to express NIS and detected the cells in vivo 24 h after administration by SPECT imaging. Importantly, it has also been shown recently that the radioactivity levels that can be expected to be taken up into T cells through NIS use during imaging did not cause lasting DNA damage in T cells. Moreover, the matching radiotracers required for NIS imaging have already been translated to humans (for thyroid imaging). These features make NIS a well-established reporter gene suitable for preclinical long-term cell tracking and a candidate reporter for the clinical setting. Notably, so far, long-term in vivo tracking of human Tregs has not been addressed using a reporter gene imaging approach that can be translated to the clinic.

Our goal was to genetically engineer GMP-isolated and in-vitro-expanded human Tregs, characterize the resultant traceable Tregs, and apply them to investigate their capacity to home to and reside within human skin transplants in a humanized mouse model. Because it has been reported that, during inflammation, soluble mediators (for example, chemokines produced by infiltrating granulocytes and monocytes) are critical for recruitment of adaptive immune cells to antigen-rich tissues, we applied our approach to investigate whether innate immune cells had an effect on Treg trafficking to skin grafts.

RESULTS

Generation of in-vivo-traceable Tregs

CD4+CD25high Tregs from donor blood were enriched using GMP protocols and stimulated with anti-CD3/CD28 beads in the presence of rapamycin and interleukin-2 (IL-2) (Figure S1). Three days after stimulation, Tregs were transduced with lentiviral particles transferring DNA encoding the radionuclide-fluorescence fusion reporter gene NIS-GFP (Figure 1A; monomeric GFP aids traceable Treg generation, purification, and ex vivo detection). Transduced NIS-GFP Tregs were purified by cell sorting (purity > 99%; Figure 1B), and NIS-GFP was found predominantly in the plasma membrane, suggesting correct intracellular reporter trafficking (Figure 1C). No significant changes in reporter expression levels were observed over six weeks, suggesting stable NIS-GFP expression (Figure 1D). Importantly, we also did not find differences in Treg expansion between untransduced and reporter-expressing Tregs (Figure 1E). NIS-GFP Tregs showed uptake of the radioactive NIS substrate [99mTcO4−] whereas untransduced Tregs did not (Figure 1F). The [99mTcO4−] uptake was also reduced significantly in NIS-GFP Tregs in the presence of excess amounts of the NIS co-substrate perchlorate, demonstrating radiotracer uptake to be specific for NIS-GFP expression (Figure 1F).

NIS-GFP Tregs maintain phenotype and function

To investigate whether reporter transduction and radiolabeling affect the Treg phenotype, we compared NIS-GFP Tregs with untransduced Tregs employing established Treg markers (CD25, FOXP3, and CTLA-4). This comparison was performed with identical Treg batches that had been exposed to [99mTcO4−] radiotracer or vehicle, and no significant effect of NIS transduction and NIS use (radiolabeling) was detected (Figures 2A and 2B; Figure S2). Next we assessed the suppressive capacity of NIS-GFP Tregs...
compared with untransduced Tregs based on their ability to suppress the proliferation of dye-labeled Teffs. No significant differences between NIS-GFP+ Tregs and untransduced Tregs were found, neither in the presence nor in the absence of exposure to the NIS radiotracer $[^{99m}Tc]TcO_4^-$ at different Teff:Treg ratios (Figure 2C; Figure S3). Importantly, these data demonstrated that (1) NIS-GFP+ Tregs maintained their suppressive function after lentiviral transduction and upon stable reporter expression, and (2) the amount of $[^{99m}Tc]TcO_4^-$ used, which is comparable to what NIS-GFP+ Tregs would experience upon reporter gene imaging in vivo, did also not impair their function.

These data showed that human Tregs genetically engineered via lentiviral transduction technology to stably express the radionuclide-fluorescence reporter NIS-GFP maintained their phenotype and suppressive function following labeling.

**In vivo detection of NIS-GFP+ Tregs in a humanized mouse model**

First we assessed the detection sensitivity of $[^{99m}Tc]TcO_4^-$-labeled NIS-GFP+ Tregs in our nanoSPECT/computed tomography (CT) instrument and found a limit of detection (LOD) of ~10,000 NIS-GFP+ Tregs per million untransduced cells (Figure S4). These data demonstrated the feasibility of Treg tracking by NIS reporter gene imaging.

Next we determined the traceability of NIS-GFP+ Tregs in vivo in a well-established human skin xenograft transplant model. Previously, we had demonstrated the efficacy of human polyclonal Tregs to reduce alloimmune human skin injury (30 days after administration).7,12 Therefore, human skin grafts were prepared using immunocompromised BALB/c recombination activating gene 2−/− γc−/− (BRG) mice as recipients. Six to seven weeks after skin engraftment, transplant-bearing mice were randomized, and allogeneic CD25-depleted PBMCs were administered intravenously alone or together with NIS-GFP+ Tregs. Importantly, murine granulocyte receptor 1 (Gr-1)-positive cells, including neutrophils and certain monocytes, were still functional in BRG mice. To achieve a higher level of immunocompromise, Gr-1+ cells were depleted using an antibody raised against Gr-1 as described previously (Figure 3A).7,12,38 It is noteworthy that despite this being an established approach to deplete the remaining Gr-1+ cells using the indicated antibody, we confirmed its success by histology (Figure S5). Treg in vivo detection was based on visualization of NIS-GFP+ Tregs by SPECT imaging with the NIS radiotracer $[^{99m}Tc]TcO_4^-$. Notably, the host reporter gene human NIS is homologous to murine NIS (mNIS), and the radiotracer detected both forms.7 This explained why we observed, in mice that did not receive NIS-GFP+ Tregs (Figure 3C), the following signals attributed to endogenously expressed mNIS: thyroid, salivary, and lachrymal glands; the stomach; and, at lower levels, the small intestine and the testes of male mice. Bladder signals were caused by the expected renal radiotracer excretion. Importantly, in animals that had received NIS-GFP+ Tregs, we detected the traceable therapeutic cells in the transplants (Figure 3D). Importantly, none of the aforementioned organs with endogenous mNIS expression or involved in renal radiotracer excretion contributed to any background signals in human skin grafts (cf. Figures 3C and 3D, insets), enabling quantification of NIS-GFP+ Tregs in the skin grafts.
Serial in vivo imaging revealed a role of Gr-1+ innate immune cells in Treg recruitment

Next we used serial SPECT/CT imaging to track NIS-GFP+ Tregs at different time points after intravenous administration into transplant-bearing immunocompromised mice lacking Gr-1+ innate immune cells. BRG mice received traceable NIS-GFP+ Tregs and were treated with the anti-Gr-1 antibody to deplete this cell compartment (Figure S5). We found that radiotracer uptake levels in their human skin grafts did not significantly differ from control animals (no NIS-GFP+ Tregs and only CD25-depleted PBMCs administered) for the first 2 weeks (cf. pink versus black lines in Figure 4). Notably, NIS-GFP+ Treg presence was elevated significantly compared with control animals at late time points, ranging 30–40 days after administration (Figure 4). Using non-obese diabetic (NOD) Cg-Pkd2<sup>−/−</sup> Il2rg<sup>−/−</sup> (NSG) mice, which have less and mostly dysfunctional innate immune cells<sup>39</sup> and thus did not receive the anti-Gr-1 antibody, we obtained similar results compared with those obtained in BRG mice with Gr-1+ cell depletion (Figure S6).

Next, to investigate the role of Gr-1+ innate cells on Treg recruitment to skin grafts, we determined the in vivo trafficking behavior of intravenously (i.v.) administered NIS-GFP+ Tregs in transplant-bearing BRG mice without anti-Gr-1 antibody administration (Figure 4; Figure S5). Interestingly, NIS-GFP+ Tregs were detectable at the skin
grafts as early as 3 days after administration. Their signals peaked at around 8 days and remained detectable in the transplants up to 40 days after administration (Figure 4C). Image quantification revealed significant differences between BRG mice without and with Gr-1⁺ cell depletion at early time points after Treg administration (Figure 4D). Early trafficking of Tregs to the skin in the presence of Gr-1⁺ cells suggested an active role of these cells in influencing Treg recruitment to the graft.

**Ex vivo validation of in vivo imaging**

Animals of each cohort were sacrificed at the indicated time points, and radioactivity in the graft tissues was quantified (by γ-counting). Human skin grafts were compared with mouse skin grafts using paired analyses. In control animals that did not receive traceable Tregs, no significant differences in tissue radioactivity between human grafts and mouse skins at any time point were observed (Figure 5A; solid versus dashed black lines), demonstrating no human graft-specific radiotracer accumulation. In BRG mice that had also received anti-Gr-1 antibody treatment, we observed no significant differences between human and mouse tissues for the first 2 weeks but identified a significant difference between the two skin types on day 40 (p = 0.0309; Figure 5A, compare solid versus dashed pink lines). Importantly, in BRG mice with Gr-1⁺ cells present, the radioactivity found in human skin grafts was higher than in mouse skin at all time points (p = 0.0016; Figure 5A, solid versus dashed blue lines). These comparisons of human skin grafts with mouse skin from the same animals clearly demonstrated a preference for traceable human Tregs to accumulate at human skin grafts.

Human skin grafts from different animal cohorts were compared using unpaired statistical analysis. The radioactivity levels in human skin grafts on day 8 were significantly higher in BRG mice with Gr-1⁺ cells present compared with BRG mice lacking Gr-1⁺ cells and control cohorts (Figure 5A). Notably, there were no differences between mouse skins of the same three animal cohorts. On day 40, the situation had changed, with both experimental cohorts (BRG with Gr-1⁺ cells and BRG without Gr-1⁺ cells) showing significantly elevated radioactivity in human skin grafts compared with control animals (p = 0.0340 and p = 0.0071, respectively; Figure 5A; ANOVA with Holm-Sidak multiple comparison correction). These data further confirmed our in vivo imaging data.

Moreover, we used immunofluorescence histology to independently validate the NIS-GFP⁺ Treg presence in human skin grafts. First, in control animals that had received only CD25-depleted human PBMCs, we found human CD3⁺ (Figure 5B), whereas in additional control mice that had received only saline, we did not observe the presence of any human CD3⁺ cells (Figure 5C). In BRG mice that were treated with the anti-Gr-1 antibody, we detected human CD3⁺FOXP3⁺ Tregs alongside human CD3⁺ in the skin grafts on day 40 (Figure 5D). Importantly, we also found human CD3⁺FOXP3⁺ Tregs in the human skin grafts of BRG mice with Gr-1⁺ cells present on day 8 and day 40 (Figures 5E and 5F), again confirming our previous results. We also obtained ex vivo results in line with in vivo imaging data for NSG mice (Figures S5D and S5E).

In summary, our in vivo imaging data were confirmed by two independent ex vivo tissue analyses and demonstrated murine Gr-1⁺ cells to affect human Treg arrival in human skin graft models.
Human Treg migration is enhanced by murine neutrophils/monocytes in vitro

To gain more mechanistic insights into the role of innate immune cells on Treg recruitment, we tested whether murine neutrophils and/or monocytes could affect human Treg migration using in vitro transmigration assays.

First we analyzed whether human Tregs responded to the murine chemokines CCL17/CCL22. It has been reported previously that Tregs are responsive to gradients of chemokines engaging CCR4,40,41 and we confirmed here that human Tregs expanded in vitro according to our GMP protocol continued to express high levels of CCR4 (Figure S7). The same human Treg preparations used for in vivo tracking experiments (see Figure S8A for individual donors) were seeded into the top well of a Transwell system, and their migration through a 3 μm porous membrane was quantified, with the bottom chamber containing medium with the indicated admixtures. Under some conditions, Tregs were pre-treated with pertussis toxin (PTX). The murine chemokines CCL17/CCL22 were able to increase human Treg migration (p < 0.0001, two-way ANOVA), an effect that was reversed by PTX pre-treatment of Tregs (Figures 6A and 6B), suggesting G-protein-coupled receptor (GPCR) involvement.

Having established that human Tregs responded to murine pro-migratory stimuli, we then investigated whether isolated murine neutrophils and/or monocytes (Figures S8B and S8C) could induce human Treg migration. To exclude any direct cell-cell interactions, neutrophils/monocytes were provided in the bottom chambers, whereas human Tregs were added to the top well of the Transwell system. Notably, neutrophils and monocytes as well as their combination significantly increased human Treg migration (Figures 6C and 6D; p = 0.0112, two-way ANOVA). A synergistic effect of neutrophils and monocytes was not observed. Notably, enhancement of human Treg motility was reduced when they were pre-treated with PTX, with no significant migration differences detected between the presence or absence of the indicated cell types (Figures 6E and 6F; p = 0.2478, two-way ANOVA).

Taken together, murine Gr-1+ cells accelerated human Treg recruitment to inflammatory sites (such as human skin graft models) by production of GPCR ligands, likely chemokines, which cross-reacted with GPCRs on human Tregs.

DISCUSSION

Previously, we have demonstrated the efficacy of human polyclonal Tregs at reducing alloimmune injury in a human skin xenograft model. Here, we tested whether in vitro transmigration assays could be used to determine the ability of murine neutrophils and/or monocytes to enhance human Treg migration. Our results show that murine neutrophils and monocytes can indeed enhance human Treg migration in vitro. Furthermore, we observed that the enhancement of Treg migration by neutrophils and monocytes was reversed by PTX pre-treatment of Tregs, suggesting GPCR involvement. These findings suggest that murine neutrophils and monocytes may play a role in enhancing human Treg migration in vivo, potentially contributing to the recruitment of Tregs to inflammatory sites.

Figure 5. Ex vivo tissue analysis of transplanted tissues

(A) Ex vivo radioactivity analysis of harvested tissues. Mouse skin was harvested from a region above the lower spine. Human skin grafts were compared with mouse skin from the same animal using paired t-tests. No Treg/PBMC-only control: not significant over all time points (p = 0.2506), solid versus dashed black lines; BRG without Gr-1+ cells: not significant for early time points (p = 0.4850) but significant on day 40 (p = 0.0309), solid versus dashed pink lines; BRG with Gr-1+ cells present: significant over all time points (p = 0.0018), solid versus dashed blue lines. Human skin grafts from different animal cohorts were compared using unpaired ANOVA on day 8 or day 40, with p values shown in (A). Cumulative data; n = 2 (days 3 and 15) and n = 4 (days 8 and 40); error bars indicate SEM. (B–E) Immunofluorescence staining of harvested tissues with anti-human CD3 (red in merged images) and anti-FOXP3 antibodies (green in merged images). Indicated times refer to days after adoptive Treg transfer as in Figure 4. Shown are (B) untreated mice that received only PBMCs or (C) no cells (saline only). (D) Representative confocal micrographs of Gr-1+ cell-depleted mice, which received PBMCs and NIS-GFP+ Tregs. (E) Experiments as in (C) but performed in BRG mice without Gr-1+ cell depletion. CD3 staining is indicative of administered PBMC-derived human T cells and Tregs, whereas FOXP3 staining identified administered human Tregs only. Scale bars are 100 μm.
transplant model. However, little was known about the in vivo distribution and fate of administered Tregs, and it remained extremely challenging to track adoptively transferred Tregs non-invasively in solid tissues. We previously attempted to assess the in vivo distribution of murine Tregs by whole-body imaging within a day of administration. What remained elusive was long-term tracking as well as tracking of human Tregs in skin transplant models to quantify their arrival at transplant sites.

Therefore, we used the well-established dual-mode reporter NIS-GFP to enable long-term in vivo tracking. The Achilles heel of all reporter gene-afforded cell tracking is the additional regulatory hurdle upon clinical translation because of the need to genetically engineer the cell product. However, chimeric antigen receptor (CAR) Treg therapy has recently emerged as the next-generation strategy for Treg therapy. We and others have already successfully generated and characterized prototype CAR Tregs for various indications, including colitis and multiple sclerosis and in humanized mouse models of xenogenic GVHD and human skin transplantation. We performed gene transfer into Tregs using lentiviral technology, which has been used successfully for genetic engineering of cell-based therapeutic agents in the clinic before (e.g., anti-cancer CAR T cell therapeutic agents). The first CAR Treg clinical trial has been granted by UK Medicines and Healthcare products Regulatory Agency (MHRA) authorization: a phase I/II clinical trial (STEADFAST) for kidney transplant patients. Therefore, investigation of the suitability of reporter gene technology for therapeutic Tregs was worthwhile because it provided another mosaic piece in the journey to further develop and translate Treg/CAR Treg therapy for human use.

The most promising host reporters available for our purpose were NIS and prostate-specific membrane antigen (for a review of host reporter genes for immune cell tracking, see Ashmore-Harris et al., neither of which was expressed in human or mouse dermis or epidermis. NIS offered the local technical advantage of a generator-produced radiotracer (\[^{99m}\text{TcO}_4^-\]) for SPECT imaging, avoiding radiotracer synthesis on each imaging day. Preclinically, the sensitivity advantages of PET over SPECT are not so pronounced on high-quality instrumentation; however, clinically, PET is superior to SPECT.
to SPECT in sensitivity. Importantly, a clinical PET tracer for NIS is already available ([18F]BF4−)26,33 and will be particularly useful in the future when combined with new total-body PET instrumentation that has been shown to offer further significant sensitivity improvements (i.e., 40-fold improvement of total-body PET over existing clinical PET). Moreover, NIS has been reported to be very sensitive to cell viability because of its dependence on the cellular Na+/K+ gradient,27 enabling reliable imaging of live cells only. The fluorescent co-reporter GFP in our fusion reporter NIS-GFP helped streamline generation of traceable cells for preclinical experimentation.27,28,36 Notably, NIS-fluorescent protein fusion reporters have been shown previously (1) to be correctly localized to the plasma membrane and function in several different cell types (rodent and human cancer cells,27,28,29,36 human CAR T cells,49 and hepatocyte-like cells28) and (2) to mediate uptake of various substrates similarly to unmodified NIS (for similar relative substrate uptake of NIS substrates, compare Figure S9A, Diouc et al.38, and Khoshnevian-san et al.29 with Portulano et al.37 and Dohan et al.;31 for comparative considerations relating to the NIS Michaelis-Menten constant for tetrahedral substrates, see Figure S9B). Importantly, although NIS-GFP was practical for preclinical experimentation, removal of GFP will be required to render our Treg tracking approach fully compatible with the workflows required for human application. Consequently, selection conditions will need to change, but suitable NIS antibodies or alternative selective expansion strategies27 are already available.

One apparent shortcoming of radionuclide reporter gene imaging approaches is their limited spatial resolution (low millimeter range). This can be overcome by combining them with technologies that provide routinely about an order of magnitude higher resolution and anatomical context, such as X-ray CT or magnetic resonance imaging (MRI).23 Because this generally leads to better interpretability of obtained co-registered images by combining the best of both worlds, we also adopted a multi-modal SPECT-CT imaging approach throughout this work.

In this work, we generated Tregs stably expressing NIS-GFP for a minimum of 6 weeks (Figure 1); we did not detect any negative effect of lentiviral transduction on Treg expansion (Figure 1) or on Treg phenotypes or suppressive function (Figure 2). Importantly, there was also no negative effect of radiolabeling NIS-GFP+ Tregs with the SPECT radiotracer [99mTc]TcO4− followed by full radioactivity decay (Figure 2), lending credibility to the overall reporter imaging strategy to be safe for long-term monitoring of Tregs (in line with previous observations that it is safe in Teffs).25 We found the LOD for NIS-GFP+ Tregs in our instrument to be ~10^5 cells/million (Figure S4), roughly one order of magnitude lower than what we found previously for cancer cells;27 we attributed this to the Tregs being about ~2-fold smaller in diameter (amounting to ~1/6 in volume, taking up at least 8-fold less radiotracer per cell). In this setting, we were able to track NIS-GFP+ Tregs for 40 days after administration, only limited in time by animal license regulations, and ex vivo data confirmed in vivo results (Figures 4 and 5). Future work will need to focus on more in-depth analysis of potential reporter gene effects and put emphasis on potential transcriptomic, proteomic, and metabolomic changes.

Previous work in mice (for example, in an islet allograft model) demonstrated that Tregs migrated from the blood stream first to inflamed allografts and subsequently to draining lymph nodes.54,55 The latter phenomenon was not detected in our studies, not because of limited detection sensitivity but because of the lack of functional lymph nodes in the immunocompromised mice used in this humanized model. Several studies in cancer and pregnancy research have suggested roles of neutrophils or monocyte-derived suppressor cells (MDSCs) in induction and recruitment of Tregs to tumors.56–58 Notably, MDSCs were first identified to play an important role in tolerance induction in a rat kidney transplant model.59 There are two MDSC subtypes, monocytic (M)-MDSCs and polymorphonuclear/granulocytic (PMN/G)-MDSCs, which show some phenotypic similarity to monocytes or neutrophils, respectively, and both present with immune-suppressive functions. Furthermore, adoptive transfer experiments with M-MDSCs and PMN-MDSCs in a heart transplant model demonstrated a role of these MDSC in Treg expansion in the transplant and for prolonged allograft survival.60 Despite much research, not least in human transplantation, where a positive correlation between MDSCs and Tregs has been observed51,62, the detailed mechanisms by which MDSCs induce Tregs still remain unclear. Treg migration to inflamed islet allografts, however, has been found to depend on CCR2, CCR5, and, importantly, CCR4.64 Neutrophils and MDSCs produce the chemokines CCL17/CCL22, which are ligands for CCR4 (Iellem et al.;40 Figure S7), and expression of this chemokine receptor by Tregs has been implicated previously in their migration to allografts.62 Furthermore, CCL17 has also been shown to be involved in neutrophil-mediated Treg recruitment to tumors.65 Gr-1+ murine innate immune cells comprise neutrophils and subsets of monocytes and dendritic cells. A Gr-1+ monocyte subset has been observed previously in a cardiac transplant model,65 and Gr-1+ monocytes have also been shown to differentiate into tolerogenic dendritic cells that produced IL-10 and induced Treg responses in vivo in tumors.64 We hypothesized that murine Gr-1+ cells might also affect Treg recruitment in human skin transplant models. In vivo tracking of NIS-GFP+ Tregs in human skin transplant-bearing BRG mice that were either left untreated or depleted of Gr-1+ murine cells revealed significant differences in NIS-GFP+ Treg recruitment to the grafts (Figures 4 and 5). These results were supported by data from NSG mice (Figure S6), which have reduced amounts of functional innate immune cells, including Gr-1+ cells,69 and corroborated by subsequent in vitro assays demonstrating enhanced migration of human Tregs toward Gr-1+ murine neutrophils and monocytes (Figure 6B). We further confirmed that human Tregs were responsive to murine CCL17/CCL22 (Figure 6A), and our results are in line with previous data.67 Our finding that murine Gr-1+ cell depletion resulted in delayed Treg detection at the human transplant (~3–4 weeks of delay; Figures 4 and 5) further suggested a major role of the CCR4-CCL17/CCL22 axis and warrants future investigations. Although use of human Tregs in mice could have been a limitation in understanding the migration of human Tregs, our results further demonstrated...
that human Tregs are attracted in vitro and in vivo by murine Gr-1+ cells. Notably, the work presented here in the context of transplantation suggests that, for Tregs that lack antigen specificity, the speed of migration to the transplant is controlled by the level of inflammation. In contrast, if Tregs present with donor-specificity, then their speed of migration is dictated by recognition of the donor antigen on endothelial cells, and they have been shown to migrate to the respective skin graft within a week, even in the absence of innate immune cells. This is in agreement with the important role of antigen recognition on endothelial cells for recruitment of T cells into tissue that has been reported previously. Recently, we extended this observation to CAR-expressing Tregs in the same humanized mouse model described in this study. Recognition of human leukocyte antigen (HLA)-A2 by A2-specific CAR Tregs favored migration of these cells to human skin.

The results of our study demonstrate that NIS is a suitable radionuclide reporter gene for non-invasive long-term tracking of Tregs. The Treg therapy field is currently moving toward CAR Tregs, not least supported by several newly formed companies concerned with CAR development and optimization specifically for CAR Treg therapy. Importantly, like for anti-cancer CAR T cell therapy intended to treat tumors, there is also a requirement to monitor (CAR) Treg distribution and fate in therapy recipients. Here we provide a preclinical proof of principle to support translation of long-term tracking of (CAR) Tregs for future clinical application. Our methodology is well suited to support future CAR Treg tracking work because it relies on genetic engineering, which is a prerequisite for CAR Treg therapy, and therefore no major additional regulatory burden is added to enable imaging/monitoring. Further steps on the path to clinical translation include first convincing others that the added cost of including imaging in trials is low compared with the production cost and value of this cell therapy type and second combining CAR and the NIS reporter into the same final vector for human cell therapy. Besides aspects relating to clinical translation of Treg therapy, our work provides a strategy to implement quantitative 3D tomographic imaging into the workflows of preclinical Treg therapy development, and, not least, we contribute, with our findings regarding the role of innate immune cells, to the increasing understanding of human Treg migration to human skin grafts.

MATERIALS AND METHODS
Information regarding lentivirus production, flow cytometry marker analysis and fluorescence microscopy of cells, radiotracer uptake into cells, and determination of detection sensitivity of cells is detailed in the Supplemental Materials and Methods.

Ethics statement
The study involved human samples as well as animals. All procedures related to animal work were performed in accordance with all legal, ethical, and institutional requirements (PPL70/7302). Sample sizes of in vivo experiments were based on prior work from our laboratories and kept to a minimum in line with law and ethical guidelines for animal research in the United Kingdom, as were the in vivo endpoints. Human skin and blood were obtained with ethics approval (institutional review board reference 09/H0707/86). Transplant-bearing animals were randomized before PBMC/Treg administration.

Reagents
Standard reagents were from Corning, Merck, Sarstedt, Thermo Fisher Scientific, TPP, or VWR. [99mTc]TcO4⁻ was generator-eluted as a sodium salt solution and used within 12 h of elution.

Animals
BRG mice (from A. Hayday, King’s College London) were bred at licensed in-house animal facilities. NSG and C57BL/6 mice were purchased from Charles River Laboratories UK. All mice used were male and between 6 and 8 weeks old at the beginning of the experiment. Mice were maintained within the King’s College London Biological Services Unit under specific pathogen-free conditions in a dedicated and licensed air-conditioned animal room (at 23°C ± 2°C and 40–60% relative humidity) under light/dark cycles lasting 12 h every day. They were kept in individually ventilated standard plastic cages (IVCs; 501 cm² floor space, Tecniplast) including environmental enrichment and bedding material in the form of sterilized wood chips, paper strips, and one cardboard roll per cage. Maximum cage occupancy was five animals, and animals were moved to fresh cages with fresh environmental enrichment and bedding material twice per week. Sterilized tap water and food were available ad libitum; food was PicoLab Rodent Diet 20 (LabDiet) in the form of 2.5 x 1.6 x 1.0 cm oval pellets that were supplied at the top of the cages. For imaging, animals were anesthetized using isoflurane (1.5% [v/v] in pure O₂). After imaging, mice were left to recover from anesthesia (by withdrawal of anesthetic) in a pre-warmed chamber or sacrificed under anesthesia by cervical dislocation. No adverse events were associated with the procedures performed in this study, and animals put on weight in line with strain expectations (data from Charles River UK) throughout. Sentinel animals were kept on the same IVC racks as experimental animals and were confirmed to be healthy after completion of the studies.

Purification and culture of human PBMCs, Tregs, and Teffs
Cells were isolated from peripheral blood donated by anonymous healthy volunteers via the National Blood Service with informed consent according to our GMP protocols. PBMCs were separated by Lymphoprep density gradient centrifugation (PAA Laboratories). CD4⁺ T cells were enriched using RosetteSep (STEMCELL Technologies), followed by selection and separation of CD4⁺CD25⁺ Tregs and CD4⁺CD25⁻ Teffs using CD25 microbeads (Miltenyi Biotec). PBMCs were also depleted of CD25⁺ cells by using CD25 microbeads (Miltenyi) and are referred to hereafter as CD25⁻ PBMCs. Aliquots of CD25⁻ PBMCs, Tregs, and Teffs were cryopreserved in 5% (v/v) human serum (BioSera) containing 10% (v/v) DMSO. Tregs were activated with anti-CD3/CD28 beads (1:1 bead:cell ratio, Miltenyi) and cultured in X-Vivo15 medium (Lonza) supplemented with 5% (v/v) human AB serum (BioSera; Treg medium) and 100 nM rapamycin (LC-Laboratories). 1,000 U/mL recombinant human IL-2
Generation of NIS-GFP-expressing Tregs

Tregs (3 days after isolation) were transduced with lentiviral particles transferring NIS-GFP as described previously.\(^7\) Briefly, tissue culture plates were coated with 50 µg/µL retronectin (TakaraBio) overnight at 4°C before concentrated lentivirus particles and Tregs were added. Treg medium contained anti-CD3/CD28 beads, IL-2, and rapamycin. After 72 h, virus-containing medium was washed off, and Tregs were maintained with fresh Treg medium every 48 h for seven days until fluorescence-activated cell sorting (FACS; BD FACS Aria II, GFP channel). After sorting, NIS-GFP\(^+\) Tregs were re-stimulated in Treg medium containing anti-CD3/CD28 beads, IL-2, and rapamycin.

Suppression assay

10\(^7\) cells/mL HLA-A2-mismatched CD4\(^+\)CD25\(^+\) Teffs were resuspended in staining solution containing 5 µM CellTrace Violet (CT-V) and incubated at 37°C for 15 min prior to co-culture. Tregs and labeled Teffs were co-cultured in X-Vivo medium at the indicated ratios in the presence of anti-CD3/CD28 beads. Teff proliferation was assessed after five days by quantifying cellular CT-V using flow cytometry. Results are shown as percent suppression (the inverse of percent Teff proliferation) relative to Teffs cultured alone.

Transwell migration assay

Female 8- to 10-week-old C57BL/6 mice received 1 mg/mL of zymosan intraperitoneally (i.p.) and were culled 4 and 18 h later to obtain neutrophils and monocytes from peritoneal cavities (via PBS washes), respectively. For monocytes, cells were left for 1 h at 37°C in RPMI medium without serum, allowing monocytes to adhere. Non-adherent cells were discarded. Cells were harvested, washed twice in cold PBS, counted, resuspended (RPMI medium containing 2% [v/v] fetal calf serum [FCS]), and 3 × 10\(^5\) cells/700 µL were plated per 24 wells, forming the bottom wells of the migration assay. Some wells received admixtures of CCL17 and CCL22 (PeproTech, 1 ng/mL each).

Human Tregs were isolated/purified as described above. Prior to plating, some Tregs were treated for 1 h with 0.1 ng/mL PTX. Tregs were counted, resuspended at 3 × 10\(^5\) Tregs/300µL in Treg medium and added to the top of the Transwell chambers (3-µm pore size). The Tregs that migrated to the bottom chamber within 2 h were counted while discriminating potentially present floating neutrophils or monocytes based on cell size.

Human skin xenograft transplant model

Human skin was obtained from routine abdominoplasty with informed consent and ethical approval (reference 06/Q0704/18). Donor HLA-A2\(^+\) split-thickness skin grafts were transplanted onto 10- to 12-week-old recipient BRG or NSG mice as described previously.\(^7\) Briefly, split-thickness (500–700 µm) skin explants were harvested with a dermatome (Zimmer), and ~1.5-cm\(^2\) pieces were transplanted into graft beds on the indicated animals. Human skin grafts were fixed, epidermal side up, onto similarly sized defects on recipient backs with an absorbable tissue seal (Vet-Bond, Braun Medical). Grafts were covered with Fucidin microbead (Leo Laboratories), secured with Tegaderm film dressing (3M) for seven days, and skin was allowed to engraft for 5 weeks in total before initiation of experiments.

5–6 weeks after skin transplantation, 5 × 10\(^6\) PBMCs that were depleted of CD25\(^+\) cells (see above) were then administered i.v. with or without 5 × 10\(^6\) Tregs. No animals developed symptoms of xenogeneic GvHD, which was confirmed by maintenance of stable body weight. Skin grafts were subjected to visual and tactile inspection weekly for evidence of graft injury, and experiments ended 5–6 weeks after Teff transfer at the latest. As indicated in the experimental schemes, some BRG mice received 100 µg anti-mouse Gr-1 (RB6-8C5, Bio X Cell, 1 mg/mL in saline) i.p. every two days (Figure 3A).\(^{38}\)

In vivo imaging and image analysis

Mice were anesthetized with 2% (v/v) isoflurane/O\(_2\), SPECT/CT imaging was performed on animals that had received NIS-GFP\(^+\) Tregs. 20 MBq \([\text{TcO}_4]\) (in 100 µL sterile PBS) was administered i.v. into anesthetized animals, and SPECT scans were acquired 40 min later (NanoScan SPECT/CT from Mediso equipped with high-resolution multi-pinhole collimators for mouse imaging; \(99m\text{Tc}\) SPECT resolution, ~0.7 mm; CT resolution, sub-100 µm isotropic voxel). CT (55 kVp tube voltage, 1,200 ms exposure time, 360 projections) was performed after tracer administration but before SPECT. Repeat imaging with the same radiotracer was not affected by tracer amounts from prior imaging sessions.\(^{36}\)

SPECT/CT data were reconstructed using Tera-Tomo (Mediso) with corrections for attenuation, detector dead time, and radioisotope decay in place as needed. All images were analyzed using VivoQuant software (inviCRO), enabling delineation of regions of interest (ROIs) for quantification of activity. CT images were used to draw ROIs and provide the volumes required for standard uptake value calculations. The total activity in the whole animal (excluding the tail) at the time of tracer administration was defined as the injected dose (ID).

Ex vivo analyses of tissues

For analysis of radioactivity in harvested tissues, tissues were weighed, and radioactivity was quantified using a γ- counter (1282-Compugamma, LKB-Wallac) together with calibration standards. Data were expressed as %ID/g.

Skin grafts were harvested alongside normal mouse skin of similar size (from the lower back) for histology and frozen in Optimal Cutting Temperature (OCT) compound followed by tissue sectioning (8 µm). Thawed sections were fixed in 4% paraformaldehyde/PBS for 10 min, permeabilized (0.2% [v/v] Triton X-100/PBS), washed,
and blocked (20% [v/v] goat serum/PBS containing 0.1% fish skin gelatin and 0.25% [v/v] Tween 20) before being stained with the following primary antibodies (2 µg/mL) overnight at 4°C: anti-human CD3 (polyclonal rabbit, A0452, Dako), anti-FOXP3 (monoclonal rat, clone PCH101, ebioscience), anti-Gr-1 (monoclonal rat, RB6-8C5, ebioscience), and anti-GFP (monoclonal mouse, 3E6, Invitrogen). After washing, sections were stained with secondary antibodies: goat anti-mouse-AlexaFluor 555, anti-rabbit-AlexaFluor 568 (Invitrogen), and anti-rat-Cy5 (Jackson ImmunoResearch). Nuclei were stained with 4,6-diamidino-2-phenylindole (DAPI; 10 µg/mL PBS). Samples were mounted using fluorescence mounting medium (Dako) and imaged on a NikonA1 confocal microscope. Fiji/ImageJ v.1.5 software was used for analysis.

Statistical analysis
Statistical analysis was performed using Prism v.7 software (GraphPad); details are given in the text and figure legends. Generally, the significance level α was set to 0.05.
