ABSTRACT

We report the discovery of the likely white dwarf companions to radio millisecond pulsars 47 Tuc Q and 47 Tuc S in the globular cluster 47 Tucanae. These blue stars were found in near-ultraviolet images from the Hubble Space Telescope for which we derived accurate absolute astrometry, and are located at positions consistent with the radio coordinates to within 0\textquoteleft\textquoteleft0.016 (0.2$\sigma$). We present near-ultraviolet and optical colors for the previously identified companion to millisecond pulsar 47 Tuc U, and we unambiguously confirm the tentative prior identifications of the optical counterparts to 47 Tuc T and 47 Tuc Y. For the latter we present its radio timing solution for the first time. We find that all five near-ultraviolet counterparts have $U_{300} - B_{390}$ colors that are consistent with He white dwarf cooling models for masses $\sim 0.16 - 0.3$ $M_\odot$ and cooling ages between $\sim 0.1 - 6$ Gyr. The $H\alpha - R_{625}$ colors of 47 Tuc U and 47 Tuc T indicate the presence of a strong $H\alpha$ absorption line, as expected for white dwarfs with a H envelope.

Key words: Binaries: general - globular clusters: individual (47 Tucanae) - pulsars: general - pulsars: individual (PSR J0024–7204Q, PSR J0024–7204S, PSR J0024–7204T, PSR J0024–7203U, PSR J0024–7204Y)

1 INTRODUCTION

Millisecond pulsars (MSPs) are rapidly spinning neutron stars with spin periods of 20 ms or less, magnetic field strengths $B \approx 10^{8-9} \text{ G}$, and characteristic spin-down ages $\tau_c \approx 10^{9-10} \text{ yr}$ (see e.g. the review by Ransom 2008). Their properties can be explained by the recycling formation scenario (Alpar et al. 1982), in which an old neutron star is spun up by the accretion of mass from a companion star in a low-mass X-ray binary (LMXB) phase.

Up to now, more than 200 MSPs have been discovered in the Galaxy, and a large fraction of these reside in globular clusters (GCs). The number of MSPs per unit mass is higher in GCs than in the Galactic disk by two to three orders of magnitude (Freire 2013). In the context of the recycling scenario, this overabundance is no surprise. The LMXB progenitors of MSPs have long been known to occur in GCs with a much higher frequency than in the rest of the Galaxy (Clark 1975) as a result of the high stellar encounter rates that favor their formation in dense clusters.

Most MSPs are found in binary systems. Studies of
Table 1. Parameters of the millisecond pulsars in 47 Tuc whose companions are discussed in this paper, for a reference epoch MJD 51600. Positions, spin periods \( (P_s) \), orbital periods \( (P_o) \), limits on companion masses \( (m_c) \) for an assumed neutron star mass of 1.35 \( M_\odot \), and characteristic ages \( (\tau_c) \) are from Freire et al. (in preparation). X-ray luminosities in the 0.1 – 10 keV band \( (L_X) \) were taken from Bogdanov et al. (2006). Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds. Numbers in parentheses are 1σ uncertainties in the last significant digit, errors in \( P_s \) are in thirteenth decimal, while errors in \( P_o \) are in the ninth decimal or smaller. Values of \( \tau_c \) are lower limits based on the 2σ upper limit for the spin-period derivatives.

The identification of MSPs at other wavelengths enables a range of studies into the physical processes that govern the evolution of the MSP binaries. In GCs, the spatial resolution of the Chandra X-ray Observatory and the Hubble Space Telescope (HST) is a necessity to overcome the crowding. Indeed, the first unambiguous X-ray identification of MSPs in globular clusters was made with the first Chandra observation of 47 Tuc, in which fifteen of the 23 MSPs then known were first detected and precisely located in X-rays (Grindlay et al. 2003). So far, HST counterparts to globular-cluster MSPs have been found for only twelve systems, two of which are tentative identifications (47 Tuc T and Y; Edmonds et al. 2003a). The other ten systems in GCs are 47 Tuc U and W (Edmonds et al. 2001, 2002), NGC 6397 A (Ferraro et al. 2001), NGC 6752 A (Bassa et al. 2003; Ferraro et al. 2004), M4 A (Sigurdsson et al. 2003), NGC 6266 B (Coccioza et al. 2008), M28 H and I (Pallanca et al. 2014, 2013), M5 C (Pallanca et al. 2014) and M71 A (Cadelano et al. 2013). Clearly, more identifications are needed to get a better understanding of the possible differences between MSP properties in GCs and in the field.

Right after Terzan 5, 47 Tucanese (47 Tuc) is the GC where most radio MSPs have been identified so far: a total of 23 were discovered (Manchester et al. 1990a, 1993). Robinson et al. (1995), Camilo et al. (2000), fifteen of which are in binary systems. To date, accurate radio-timing positions have been derived for thirteen of the 47 Tuc binary MSPs (Freire et al. 2003, and in preparation), which allows a search for their counterparts at ultraviolet and optical wavelengths. So far, secure identifications have been found for only two of them. The companion of PSR J0024–7204W, or 47 Tuc W in short, is a non-degenerate star that may be (close to) filling its Roche lobe (Edmonds et al. 2002; Bogdanov et al. 2003); it was among the first MSP binaries to be classified as a “redback” system. The companion of 47 Tuc U, on the other hand, is typical for a system that is the outcome of the canonical recycling scenario. Edmonds et al. (2001; E01 hereafter) found that it is likely a He WD with a mass of \(~0.17 M_\odot\). Edmonds et al. (2003a; from now on E03a) suggested identifications for two more systems, 47 Tuc Y and T, but from their data they could only derive upper limits on the \( U – V \) colors of the proposed blue counterparts.

We have carried out a search for counterparts to the 47 Tuc MSPs using new near-ultraviolet (NUV) imaging data obtained with the HST Wide Field Camera 3 (WFC3), and optical data (including deep Hα imaging) from the Advanced Camera for Surveys (ACS). The NUV data are particularly useful for looking for WD companions, whose blue spectral energy distribution yields a high contrast against the typically red cluster stars. Here we present the results of our search, which includes the discovery of the counterparts to 47 Tuc Q and S, and the corroboration of the suggested identifications of 47 Tuc T and Y. We find that, like in 47 Tuc U, the MSP companion in all four systems is likely a low-mass \((0.16 – 0.3 M_\odot)\) He WD.

---

2 http://www.naic.edu/~pfreire/GCpsr.html

3 He WDs are low-mass \((\lesssim 0.45 M_\odot)\) white dwarfs with He-rich cores. They are thought to have formed as a result of a mass-transfer episode in a close binary before He ignition, removing much of the He WD-progenitor’s envelope and exposing its He-rich core.

4 The optical counterpart to 47 Tuc Y was originally reported as the counterpart to the Chandra source W 82 by E03a. This source was classified as a candidate cataclysmic variable, as the radio position for 47 Tuc Y was unknown at the time. After the position became available, Bogdanov et al. 2006 reported its association with W 82, implying the detection of the MSP companion by E03a.
This paper is structured as follows. In Section 2 we describe the HST observations, and the X-ray data used in this work. The HST data analysis is described in Section 3. In Section 4 we present the search for counterparts to the 47 Tuc MSPs in the HST data, and we show our results for the new identifications and the known WD companion of 47 Tuc U. Finally we discuss our results in Section 5.

2 OBSERVATIONS

The NUV companions to millisecond pulsars in 47 Tuc with radio-timing positions, nineteen are covered by the UVIS and WFC images; only 47 Tuc X, a binary MSP, was missed.

In this work we make use of the catalog of X-ray sources in 47 Tuc from H05 (see that paper for details about the data reduction), which was obtained from deep observations (281 ks in total) with Chandra. All nineteen MSPs covered by our NUV/optical data are matched to an X-ray source in this catalog.

3 DATA REDUCTION AND ANALYSIS

The data reduction of our UVIS data starts with the flat-fielded images produced by the standard UVIS pipeline (CALWF3 version 3.1.2). To correct for the charge transfer efficiency (CTE) degradation of the UVIS detectors, we used the CTE correction software provided by the Space Telescope Science Institute (STScI). The resulting images still suffer from geometric distortion, which we corrected for with the DrizzlePac software (Gonzaga et al. 2012). Astrometric alignment of the individual images was performed with the TWEAKREG task in DrizzlePac. Subsequently, the ASTRODRIZZLE task was used to combine the aligned images into one stacked master frame in each filter that is distortion free, and cleaned of cosmic rays and detector artifacts like hot pixels or bad columns. The resulting master images in F390W and F300X are twice-oversampled to a pixel scale of 0′′.02 pixel$^{-1}$.

The reduction steps for the WFC images are similar to those for the UVIS data, except that the images produced by the ACS calibration pipeline (CALACS version 8.2.0) are already corrected for CTE losses. The stacked master images in F435W, F658N, and F625W have a final pixel scale of 0′′.025 pixel$^{-1}$.

3.1 Astrometry

The radio coordinates of the 47 Tuc MSPs were derived using the Solar System ephemeris DE/LE 405. This is specified in the International Celestial Reference Frame (ICRF), which is aligned to the International Celestial Reference System (ICRS). To facilitate the identification of NUV/optical counterparts we also aligned our UVIS and WFC images to the ICRS using stars in the UCAC2 catalog (Zacharias et al. 2004). Since isolated and unsaturated UCAC2 stars are scarce in the HST images of the cluster core, we derived secondary astrometric standards from a ground-based image of 47 Tuc as an intermediate step. We obtained from the ESO archive a 30s V image taken with the 2.2m/Wide Field Imager (WFI) at La Silla, Chile on 2002 October 29. An astrometric solution of the part of the image that contains the cluster center was derived using 225 UCAC2 stars; fitting for zero-point offset, rotation, pixel scale, and distortions gives rms residuals of about 0′′.035 in right ascension and declination. We then selected 126 secondary standards from the WFI image to calibrate a 10s F435W exposure.

---

5 We have not analyzed the existing STIS far-ultraviolet data of the center of 47 Tuc, because the five objects studied in this paper are not included in the small field of view of that data set.

8 http://drizzlepac.stsci.edu
Table 2. Astrometric and photometric results for the MSP companions discussed in this paper. Errors in the absolute astrometry of the celestial positions are $0'.074$ ($1\sigma$). Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds. Columns 4 to 8 give the calibrated photometry on the Vega-mag system and the errors from DAOPHOT. The projected distance of the companions from the cluster center ($\delta_{c}$) was calculated using the coordinates of the center of 47 Tuc as reported by Goldsbury et al. (2011). The offsets between the X-ray and NUV positions (last column) were determined using the positions from H05. The value of $\sigma_X$ is the combined error in the NUV and X-ray positions.

| MSP companion | R. A. (J2000) | Decl. (J2000) | $U_{300}$ | $B_{390}$ | $B_{435}$ | $R_{625}$ | $H_{0}$ | $\delta_{c}$ (arcsec) | Radio offset (arcsec/$\sigma$) | X-ray offset (arcsec/$\sigma_X$) |

1 Using the nomenclature in H05.

2 The X-ray position used for 47 Tuc S corresponds to the position of a single detected X-ray source that is the combination of X-ray emission from 47 Tuc F and 47 Tuc S. This explains the apparent large X-ray astrometric offset.

from our GO 9281 program, which resulted in rms residuals of about $0'.027$ in each direction. Finally, this solution was transferred to our stacked WFC images with negligible errors using >10,000 stars, and to our stacked UVIS images with rms residuals of about $0'.027$ in each direction using >11,700 stars. The final 1 sigma error in the absolute astrometry of our images is the quadratic sum of all the aforementioned errors, plus a term that represents the error with which the UCAC2 is tied to the ICRS. The latter is dominated by the estimated systematic error in UCAC2 positions of 10 mas (Zacharias et al. 2004). For the WFC and UVIS images this results in an error of $0'.064$ and $0'.074$, respectively. Errors in the radio positions are negligible.

H05 aligned the astrometry of their X-ray source catalog to the radio positions of seventeen MSPs detected by Chandra. Therefore, we can indirectly check the alignment between our NUV and radio positions by comparing the NUV and Chandra astrometry. We have done this by comparing the NUV and X-ray positions of seventeen sources with published finding charts in E03a and Edmonds et al. (2003b). We find that the NUV/X-ray offset is very small, about $0'.023$+$0'.008$ in right ascension and $0'.003$+$0'.009$ in declination in both filters, so about one oversampled pixel.

3.2 Photometry

Given that the images of the core of 47 Tuc are very crowded, we carried out point spread function (PSF) photometry for the stacked UVIS and WFC frames by using standard IRAF and DAOPHOT tasks. We used isolated stars to build a variable PSF for each filter. The obtained PSF was fitted to all detected stars in each stacked frame. Photometric calibration of the extracted magnitudes was performed onto the Vega-mag system using the zero points given at STScI’s web page for UVIS and E03a for the UVIS images. For the WFC images we used the zero points provided for $0'.4$ apertures. In the remainder we denote calibrated magnitudes in the F300X, F390W, F435W, F625W, and F658N filters by $U_{300}$, $B_{390}$, $B_{435}$, $R_{625}$, and $H_{0}$, respectively. The absolute magnitudes were calculated for an adopted distance modulus ($m-M$)$_{0} = 13.36 \pm 0.02 \pm 0.06$, corresponding to the 47 Tuc distance of 4.69$ \pm $0.04$ \pm $0.13 kpc (Woodley et al. 2012). The first error term corresponds to the random error, and the second to the systematic error of the distance determination.

The UVIS data were also independently analyzed using software based on the program developed for the ACS Globular Cluster Treasury Project, described in Anderson et al. (2008), which gave consistent results with the DAOPHOT analysis. The reductions were done using the latest version of this software known as KS2. Star finding required that stars be detected in both the F300X and F390W frames. Photometry was performed by PSF fitting using library PSFs with perturbations to better match the specific PSF in each exposure. The final KS2 photometry comes from averaging the fluxes from the individual images, with sigma clipping applied to remove outlying values due to cosmic rays, defective pixels, etc. A total of 148,717 stars were detected in the region covered by the UVIS imaging. Color-magnitude diagrams were constructed to choose the best KS2 options for photometry of the faint stars (e.g. the fitting radius), from the tightness of the fiducial sequences, and to identify the counterparts for the MSPs. Drizzle-combined mosaic images of this region were also produced using the STScI PyRAF routine ASTRODRIZZLE from the Drizzlepac package. The drizzle-combined images were oversampled by a factor of two, in order to increase the effective resolution. Calibration of the KS2 photometry to the Vega-mag system was performed by doing aperture photometry on moderately bright, isolated stars in the image mosaics within a $0'.1$ radius aperture, finding the aperture correction to an infinite radius aperture from ISR WFC3 2009-34 calculating the median offset between the KS2 photometry and the aperture photometry for these stars, and applying the zeropoints from the HST WFC3 zero point website.

To take into account the effect of extinction on the UVIS photometry, we converted the reddening towards 47 Tuc of $E(B-V) = 0.04 \pm 0.02$ (Salaris et al. 2002) to the extinction in the F300X and F390W filters using the UVIS Exposure Time Calculator of HST. We obtained extinction values of $A(F300X) = 0.26 \pm 0.13$ and $A(F390W) = 0.18 \pm 0.09$.

© 2015 RAS, MNRAS 000, 000
respectively. To compute the extinction in the WFC filters, we used the conversions in Sirianni et al. (2005). This yields A(F435W)=0.16±0.08, A(F658N)=0.10±0.05, and A(F625W)=0.11±0.05.

4 RESULTS

The search for MSP counterparts was done in the astrometrically calibrated NUV images. These frames are less crowded than the optical images, and contain fewer bright and saturated stars that could affect the detection of faint counterparts. We looked for counterparts within 3σ (0''.22) of the radio positions.

We found blue stars inside the match circles of the binary MSPs 47 Tuc Q, S, T, U, and Y. These objects are excellent astrometric matches with the radio positions, with offsets that are smaller than 0''.016 (0.2σ). All other stars inside the 3σ error circles lie further from the radio positions, and do not have blue U300−B390 colors.

The blue stars that match with 47 Tuc T, Y and U are the likely WD counterparts proposed by E01, E03a and Bogdanov et al. (2006), while for 47 Tuc Q and S these are new discoveries. Based on the similar locations in the $B_{390}$ versus $U_{300}−B_{390}$ color magnitude diagram (CMD), and the good alignment with the radio positions, we consider the stars near 47 Tuc Q and S to be the likely counterparts, and WD companions, to these MSPs, as well. A more detailed discussion of the individual systems is given in Sections 4.1 to 4.5. In the remainder of the text we use capital letters (without subscript) to refer to the MSPs detected at radio wavelengths, while we add the subscript ”UV” to refer to the NUV counterparts, e.g. 47 Tuc Q versus QUV. Finding charts in the F300X and F390W filters are presented in Figure 1.

Figures 2 and 3 are NUV and optical CMDs for 47 Tuc that show the photometry for QUV, SUV, TUV, UUV and YUV. In Table 4 we summarize the properties of the five MSPs as determined from radio and X-ray observations, while our astrometric and photometric results can be found in Table 2.

We have estimated the parameters of QUV, SUV, TUV, UUV and YUV assuming that they are He WDs. In Figures 2 and 3 we have included new evolutionary tracks for He WD cooling models as described in Serenelli et al. (2002), but with a metallicity as appropriate for 47 Tuc of $Z = 0.003 ([Fe/H] = −0.78$, Thygesen et al. 2013). Masses were estimated by determining the mass range that corresponds to the two cooling tracks that bracket the location of the companion in the NUV CMD, including 1σ error bars. Errors include the DAOPHOT uncertainties, errors in the calibration, and in the adopted distance modulus and extinction (see Section 4.2). The corresponding ranges in age, effective temperature $T_{\text{eff}}$, surface gravity log $g$, and bolometric luminosity $L$ were determined by interpolating linearly along the two bracketing tracks using the absolute magnitude in the F390W filter ($M_{F390W}$) as the independent variable. Table 3 summarizes the results.

Cooling ages derived from our models (column 3 in Table 3) represent the time since the point of highest temperature in the cooling track until the observed location along the track. Prior to this time lapse is the time between Roche-lobe detachment (when the mass transfer from the He WD

**Figure 1.** Finding charts of the companions to MSPs 47 Tuc Q, S, T, U and Y. Images in the filter F300X are shown on the left side while images in F390W are shown on the right. The solid red lines show the 3σ match circles centered on radio positions of the pulsars, which take into account the astrometric UVIS errors. The dashed cyan circles are the 3σ match circles of *Chandra* sources. The companion candidates are indicated by solid orange circles. Each image is 1′′ × 1′′ in size.
progenitor to the neutron star stops) until the point where the highest $T_{\text{eff}}$ is reached. This phase lasts only a few Myr for masses $0.25 \, M_\odot$ and higher, but can amount to $\sim 1.5$ Gyr for the $0.16 \, M_\odot$ model, $\sim 1$ Gyr for $0.175 \, M_\odot$, and $\sim 500$ Myr for $0.2 \, M_\odot$. The exact value depends on the uncertain details of the binary evolution, and sets a lower limit to the total age. Istrate et al. (2014) have derived a general expression for the duration of this “proto-WD” phase ($\Delta t_{\text{proto}}$) in terms of the He WD mass, which for our MSP companions is given in the last column of Table 3. We find that the proto-WD time scale in our models and the value of $\Delta t_{\text{proto}}$ are in general agreement.

We have estimated the number of He WD-like objects that we expect to find by chance within a separation of...
Figure 3. $B_{435} - R_{625}$ versus $R_{625}$ (left) and $H_{\alpha} - R_{625}$ versus $R_{625}$ (right) CMDs from our WFC DAOPHOT photometry. MSP counterparts are plotted with filled red circles. Calibrated Vega-mag magnitudes were converted to dereddened absolute magnitudes using a distance to 47 Tuc of 4.69 kpc (Woodley et al. 2012) and reddening $E(B-V) = 0.04$ (Salaris et al. 2007). We include He WD cooling tracks (Serenelli et al. 2002) for masses in the range $0.16 - 0.45 M_\odot$ and an initial metallicity of $Z = 0.003$.

Photometry errors include the DAOPHOT uncertainties, and errors in the distance modulus and $E(B-V)$.

0.′016 (i.e. the largest offset among the suggested matches for 47 Tuc Q, S, T, U, and Y; see Table 3) from the radio positions. To this end, we determined the density of blue objects (stars arcsec$^{-2}$) enclosed by the cooling tracks for masses $0.16 \leq M_{WD}/M_\odot \leq 0.30$ and absolute magnitudes $6 \leq M_{B_{390}} \leq 11$ (see Figure 2). For the total area of the 3σ match circles of nineteen MSPs, the expected number is very small, $9.5 \times 10^{-5}$. This suggests that our five identified MSP counterparts are indeed not chance coincidences.

For the binary MSP 47 Tuc I we find a very blue object at 0.′12 (1.6σ) with a $U_{300} - B_{390}$ color that puts it on or very close to the CO WD sequence (Figures 2 and 4). This offset is much larger, and its color much bluer, than those for the five binary MSPs discussed above. We estimate the probability that this source is a spurious match by considering that blue ($U_{300} - B_{390} \lesssim -0.65$) objects are found in the error circles of two (47 Tuc D and N) of the seven isolated MSPs in the UVIS field. Due to their intrinsic faintness in the NUV/optical, no counterparts are expected for the isolated MSPs. The blue objects close to 47 Tuc D (at 0.′14 or 1.8σ, and at (−1.44, 11.50) in the CMD of Figure 2 and 47 Tuc N (at 0.′16 or 2.1σ, and at (−0.65, 9.68) in the CMD)—are therefore almost certainly chance alignments. The probability to find a blue star in the 3σ error circle by chance in a single trial is therefore, approximately, $2/7 \approx 0.29$. This results in a (binomial) probability to find a blue random match for exactly one of ten binary MSPs in our field of $\sim 14\%$. While we consider the NUV identification of 47 Tuc I not very likely, we give more details on this object in Section 4.6, and provide a finding chart in Figure 4.

For 47 Tuc E, H, J (binaries), and L (isolated) not a single NUV object was detected inside their 3σ match circles. For 47 Tuc O, R, and W (binaries) and C, F, G, and M (isolated) the objects in the match circles have colors that place them on the main sequence or sub-giant branch of 47 Tuc and lie at least 0.′11 (1.4σ) away from the radio positions. Without any additional information we cannot conclusively say if any of these are likely counterparts, and we do not discuss them further in this paper. We note that the true, non-degenerate, counterpart to 47 Tuc W (Edmonds et al. 2002) is not detected in the NUV images. This is not unexpected as it is relatively faint (mean $V = 22.3$) and red (compared to QUV, SUV, TUV, UUV, and YUV).

11 For 47 Tuc U and W excellent counterparts have already been identified.
limits on companion masses \( M_c \) for an assumed neutron star mass of \( 1.35 \, M_\odot \) as derived from the mass function (Freire et al. in preparation). Masses \( (M_{WD}) \), cooling ages, effective temperatures \( (T_{eff}) \), surface gravities \( (\log g) \) and luminosities \( (L) \) for the MSP companions studied, as derived from our NUV photometry and our \( Z = 0.003 \) He WD cooling models. In column 8, the inclination angle \( i \) as inferred from the mass function and the estimated masses \( M_{WD} \). The last column gives \( \Delta t_{\text{proto}} \), which is the lapse of time from the Roche-lobe detachment until the proto-He WD reaches the WD cooling track, calculated using the relation derived by Istrate et al. (2014).

1 Ages represent the time between the point of highest \( T_{eff} \) on the cooling track until the observed point along the track.
2 An upper mass limit of \( 0.17 \, M_\odot \) was found by E01, for which they estimated an age of \( \sim 0.6 \) Gyr, \( T_{eff} = 11000 \) K and \( \log g = 5.6 \).

### 4.1 47 Tuc Q

In the CMD of Figure 2, the counterpart of 47 Tuc Q is located between the main sequence of the Small Magellanic Cloud (SMC) and the CO WD cooling sequence, at a similar \( U_{390} - B_{390} \) color as \( Q_{UV} \), but about 2.4 mag fainter in \( B_{390} \). E03a reported the presence of a variable main-sequence turnoff star very close (at \( 0''12 \)) to the position of 47 Tuc Q. This star, which they labeled ’nQ’, is the bright object to the south-west of Q. This star, which they labelled ‘nQ’, is the faintest MSP companion studied, as derived from our NUV photometry and our \( Z = 0.003 \) He WD cooling models. In column 8, the inclination angle \( i \) as inferred from the mass function and the estimated masses \( M_{WD} \). The last column gives \( \Delta t_{\text{proto}} \), which is the lapse of time from the Roche-lobe detachment until the proto-He WD reaches the WD cooling track, calculated using the relation derived by Istrate et al. (2014).

In our \( R_{625} \) versus \( B_{435} - R_{625} \) CMD, \( Q_{UV} \) also lies faint in the region where He WDs are expected. But unlike the counterparts to 47 Tuc U and T that lie to the red side (Hα faint side) of the main sequence in the \( R_{625} \) versus Hα – \( R_{625} \) CMD (see Sect. 3.8 and 3.8 and Figure B), there is no indication for the presence of a broad Hα absorption line in \( Q_{UV} \); its Hα – \( R_{625} \) color is consistent with the color of most other stars in the field with similar \( R_{625} \) magnitude. If \( Q_{UV} \) actually is a He WD, the Hα – \( R_{625} \) color could be explained if there is some residual Hα emission in the system that effectively fills in the Hα absorption line of the H-rich outer layer of the WD. From the location of \( Q_{UV} \) in a \( B_{625} - R_{625} \) vs. Hα – \( R_{625} \) color-color diagram and synthetic colors of simulated spectra, we estimate that the equivalent width of such an emission line is about \( -70 \) Å. However, the inclination inferred from the mass function (Table 1) and our estimate for \( M_{WD} \) (Table 3) is high (\( 63^\circ \) to \( 90^\circ \)), so eclipses are expected if a large cloud of ionized material would be present. This explains the relatively large offset between \( S_{UV} \) and \( W77 \) in Table 2.

### 4.2 47 Tuc S

\( S_{UV} \), together with \( T_{UV} \), is the faintest MSP companion that we found. This object is clearly visible in our F435W images, but in the F625W and Hα images a reliable detection cannot be made. This is partly the result of a relatively bright diffraction spike of a brighter star that passes within a few pixels of the center of the PSF of \( S_{UV} \). From comparison with the He WD cooling tracks, we derive a mass of about \( 0.2 - 0.25 \, M_\odot \) and an age of about \( 0.4 - 0.1 \) Gyr. Taking into account its time spent as a "proto-WD" (up to 0.4 Gyr), this age range is roughly consistent with the lower limit of the companion mass derived from the pulsar mass function (0.18 \( M_\odot \) for an assumed neutron star mass of \( 1.35 \, M_\odot \)). The derived cooling age is very uncertain, as \( Q_{UV} \) lies in between the tracks for the slowly cooling \( 0.175 \, M_\odot \) models and the rapidly cooling \( 0.20 \, M_\odot \) He WDs; these respective masses predict an age range of \( 5.2 - 0.3 \) Gyr. In addition, the proto-WD phase can add up to 1 Gyr to obtain the time that passed since Roche lobe detachment. However, a comparison of the WD age with the characteristic pulsar spin-down age \( \tau_c \) is difficult. The observed period derivatives for the 47 Tuc MSPs are dominated by the effect of the acceleration of the pulsars along the line of sight in the gravitational potential of the cluster. As a result, the intrinsic period derivatives, and therefore the pulsar characteristic ages, are poorly constrained. However, better estimations of the intrinsic period derivatives, for stable MSP-WD systems, can be made by using the time derivative of the observed orbital periods, which essentially measures the acceleration of each binary MSP along the line of sight. Details about this technique will be given in Freire et al. (in preparation). By using this method we obtain \( \tau_c > 1.43 \) Gyr for \( Q_{UV} \).
4.3 47 Tuc T

We derive a mass for T_{UV} of 0.2–0.3 M_⊙, in agreement with the lower limit of the companion mass (Table 1). The approximate total WD age is about 0.8–0.1 Gyr. This value is roughly consistent with the lower limit on τ_c of this MSP.

T_{UV} lies in between the CO WD cooling sequence and the SMC main sequence in our NUV CMD. The blue color of T_{UV} is apparent from the finding charts in Figure 1. In the F390W image T_{UV} has a close neighbor at a separation of only 0′′.07. In the F300X image the neighbor, as well as stars of similar F390W magnitude, are much fainter. T_{UV} is clearly detected in our F435W images. While also detected in F625W and F658N, it is very faint at these redder wavelengths; the close neighbor and the contamination of its PSF by a weak diffraction spike of another neighboring star, leads to relatively large errors in its optical colors (Figure 4). Nevertheless, the optical counterpart is also clearly blue, and its location on the red side of the Hα – R_{g25} main sequence points at the presence of a strong Hα absorption line. T_{UV} was already identified as the likely counterpart to 47 Tuc T by E03a. They detected T_{UV} in their U images but not in V and I, and could therefore only derive an upper limit to the color.

4.4 47 Tuc Y

Our photometry confirms the blue color of Y_{UV} reported by E03a. We estimate that the mass of Y_{UV} is between 0.16–0.175 M_⊙, in agreement with the lower limit from the radio mass function (Table 1). The total age estimate, about 2 Gyr for the cooling time plus 1.3–1.9 Gyr for the proto-WD phase, makes Y_{UV}, possibly together with Q_{UV}, the oldest of the five WD companions discussed in this paper.

Y_{UV} is clearly detected in our F435W image. The PSF of the neighboring bright object, which can be seen a little offset from the center in the finding charts of Figure 1 reduces the sensitivity for very faint objects. As a result, Y_{UV} is not detected in the R_{g25} and Hα images.

4.5 47 Tuc U

E01 found that U_{UV} is a variable blue object, with a semi-amplitude variation of 0.004 mag and with a period that is consistent with the orbital period derived from radio timing (about 0.43 days). Based on a comparison between the U, V, and I photometry for this star and the [Serenelli et al. (2001)] models for He WD evolution, its mass and age were estimated to be ~0.17 M_⊙ and ~0.6 Gyr, respectively. E01 also identified this object as the counterpart of the X-ray source W11. E01 indeed found that the He WD companion is well inside its Roche lobe, which also indicates there is no ongoing accretion that contributes to the X-rays.

U_{UV} is the brightest of the five counterparts discussed in this work. It is an isolated object, so its UVIS and WFC photometry is robust. U_{UV} is located above and to the left of the SMC main sequence in the NUV and optical CMDs, in agreement with the results of E01 and E03a. The location of U_{UV} to the red side of the main sequence in the R_{g25} versus Hα – R_{g25} CMD points at the presence of a strong Hα absorption line, and is indeed in agreement with the He WD cooling tracks.

Figure 4. Finding chart of 47 Tuc I in the NUV. The solid red circles are the 3σ match circles for the radio position of the pulsar. They are centered on 47 Tuc I. The dashed cyan circles are the 3σ match circles of the Chandra source. The dashed white circles indicate the blue object that lies at 0′′.12 from the pulsar. The images are 170′′ × 170′′ in size.

The He WD atmosphere models used in this paper are computed for a lower metallicity and make use of updated atmosphere models [Bohrmann et al. (2011)] with respect to the ones used in E01. From the updated models and our UVIS photometry, we constrain the mass for U_{UV} to be 0.16 – 0.175 M_⊙, T_{eff} ≈ 11,000 K, and log g ≈ 5.6. This is consistent with the results from our WFC photometry and with the parameters derived by E01. Our cooling age estimate (0.2–0.3 Gyr) is somewhat lower than found in the latter study (~0.6 Gyr). If we take into account Δ_{proto}, the total age becomes 2.1–1.6 Gyr; this is still consistent with the lower limit to τ_c from Table 1.

4.6 47 Tuc I

The blue star in the 3σ error circle of 47 Tuc I is very faint. The errors in the photometry are considerable, and we plot the results from both DAOPHOT and KS2 in Figure 2 (denoted as oL and oLKS2, respectively); it is too faint to be detected in any of our optical images. This object is too blue to be a He WD. While the colors are more consistent with a CO WD than a He WD, the former option is not likely if the star is truly associated with 47 Tuc I. MSPs with CO WD companions typically have longer spin periods compared to systems with He WD companions [Tauris et al. (2012)]. The spin period of 47 Tuc I, on the other hand, is very short (P_s = 3.2 ms; Freire et al. 2003). We also point out that the mass function suggests that the companion is a very low-mass object, with M_c > 0.013 M_⊙. If the blue object is the ~ 0.5 M_⊙ CO WD companion to 47 Tuc I, this would imply an inclination of i ≈ 1.8°. None of the aforementioned arguments are conclusive grounds for rejecting or confirming the association.

5 DISCUSSION

The five binary MSPs in 47 Tuc that we discuss in this work are characterized by spin periods below 8 ms, orbital periods P_o between 0.43 and 1.2 d, and companions more massive than ~0.09 M_⊙ (Table 1). Based on a compilation of available data for binary pulsars in the Galactic disk, the nature of the companion for such binary pulsars is most likely a He
WD (see Tauris et al. 2012). We find that our NUV/optical photometry for the five MSP counterparts is indeed consistent with the magnitudes and colors predicted by the low-metallicity He WD cooling models by Serenelli et al. (2002). In particular, the derived mass constraints lie in the range 0.16 – 0.30 \( M_\odot \). Our results for the companion of 47 Tuc U are consistent with those derived by E01, who compared \( U, V, \) and \( I \) photometry for this star with the solar-metallicity He WD models by Serenelli et al. (2002).

The standard formation scenario for an MSP accompanied by a He WD involves a long period of stable mass transfer. In the models by Serenelli et al. (2002), the He WDs emerge from this phase with a thick H envelope. Calculations for the subsequent evolution of white dwarfs predict a dichotomy in cooling behavior \( ^{12} \) e.g. Alberts et al. 1999; Althaus et al. 2001; Serenelli et al. 2001; Panei et al. 2007; Althaus et al. 2013). He WDs with masses \( > 0.2 \ M_\odot \) (or equivalently \( P_\text{b} \gtrsim 1.55 \text{ d} \); see van Kerkwijk et al. 2003) experience thermonuclear H-shell flashes before they reach the cooling track. These flashes leave the WD with a thin H envelope, as a result of additional diffusion-induced H-shell flashes. After these short-lived episodes, the WD remnant cools down on a relatively short timescale. In He WDs less massive than \( \sim 0.2 \ M_\odot \) H-shell flashes do not occur, and therefore a thick H envelope is retained. Residual H burning can keep up a high temperature over long timescales, resulting in much longer cooling times. Figure 2 implies that \( S_{\text{UV}} \) and \( T_{\text{UV}} \) cool fast, \( U_{\text{UV}} \) and \( Y_{\text{UV}} \) cool slowly, while for \( Q_{\text{UV}} \) the time scale is ambiguous. Unfortunately, the spin-down ages of the pulsars in 47 Tuc are too uncertain to give an independent constraint on the WD age, and hence, mass.

There are only two binary MSPs in our field whose mass functions suggest He WD-like companions but for which we have not found a plausible counterpart, viz. 47 Tuc E and H. Their orbital periods are the longest of the binary MSPs in 47 Tuc included in our field (\( \sim 2.3 \text{ d} \)). The relation between orbital period and companion mass (see for example Tauris & Savonije 1999) then suggests that the companions in these systems are more massive than those in the other MSPs. Since a higher mass implies a shorter cooling time, the non-detection of the companions to 47 Tuc E and H can be understood if they were formed more than \( \sim 0.7 \text{ Gyr} \) ago so that they have dimmed below the detection limit.

In Figure 3 we show the relation between the mass of the He WD and the orbital period based on binary-evolution calculations by Tauris & Savonije (1999) valid for He WDs masses between 0.18 and 0.45 \( M_\odot \) and De Vito & Benvenuto (2010), valid for \( P_\text{b} > 0.25 \text{ d} \). We find that the orbital periods and mass estimates for \( S_{\text{UV}} \) and \( T_{\text{UV}} \) are more consistent with the relation derived by Tauris & Savonije (1999). In contrast, \( Y_{\text{UV}} \) and \( U_{\text{UV}} \) are offset from that relation, but their estimated masses lie below the mass range to which the relation applies. However, we observe that \( Y_{\text{UV}} \) and \( U_{\text{UV}} \) are in good agreement with the relation by De Vito & Benvenuto (2010). \( Q_{\text{UV}} \) is consistent with both relations. De Vito & Benvenuto (2010) made different assumptions on the mass transfer process and they obtain, for the same orbital periods, lower masses for the WD companions than Tauris & Savonije (1999). They also find that their mass – orbital period relation is not sensitive to the initial mass of the accreting neutron star. Studies about the assumption on how conservative the mass transfer is, have found that the dispersion around the relation decreases as the He WD mass increases De Vito & Benvenuto (2012).

The five binary MSPs discussed here have X-ray luminosities \( L_X = 2.9 – 8.9 \times 10^{30} \text{ erg s}^{-1} \) (Bogdanov et al. 2006). Like for the majority of the 47 Tuc MSPs, it was found that their X-ray emission can be described by a thermal (blackbody or neutron-star hydrogen atmosphere) spectrum as expected for emission from the heated magnetic polar caps of the neutron stars. Using the \( L, T_{\text{eff}} \) and mass estimates from Table 3 and the orbital periods from Table 1 we have calculated the WD radii (\( R_{\text{WD}} \)) and (assuming a neutron-star mass of 1.35 \( M_\odot \)) the corresponding radii of the Roche Lobe (\( R_{L,WD} \)) using the formula of Paczyński (1971). We indeed find that all five WD companions fit well within their

---

12 The evolutionary models by Istrate et al. (2014) do not show this dichotomy in cooling behavior depending on the occurrence of H shell flashes or not, but rather indicate that the cooling timescale mainly depends on the mass of the proto-WD.
Roche lobe ($R_{L,WD}/R_{WD} \geq 5$) as already found for 47 Tuc U by E01, so we indeed expect that accretion does not contribute to the X-ray luminosity.

For the five systems we studied, we calculate the contribution of the MSP radiation to the observed NUV luminosity of the WD. We used the values of the spin-down luminosity ($\dot{E}$) for each MSP given by Bogdanov et al. (2006). Assuming isotropic emission from the neutron star we calculate the energy flux intercepted by the WD ($\dot{E}_i$) using our estimates of $R_{WD}$ and the separation between the stars. For $Q_{UV}, S_{UV}$ and $T_{UV}$ we obtain $\log \dot{E}_i / (L_\odot) < -4$ which is well below their NUV luminosities. This result indicates that irradiation is not driving the luminosities of these systems. On the other hand, for $Y_{UV}$ and $U_{UV}$ we obtain $-4.2 < \log \dot{E}_i / (L_\odot) < -2.3$ which is a closer value to their respective $L$, implying that heating might be present, though not dominating the NUV luminosity. This result can be understood if we take into account that these two companions have larger $R_{WD}$ and are closer to their MSPs than the other three WDs.

We note that all the companions have cooling ages $\lesssim 6$ Gyr (including age uncertainties), which are considerably less than the age of the cluster (9.9 $\pm$ 0.7 Gyr). Hansen et al. (2013) proposed that the formation of recycled MSP systems happened mostly during the early life of the cluster. However, our results may suggest that dynamical interactions during the later evolution of the cluster have a more important role in the formation of these systems (for an evolutionary scenario in this context see for example Fregeau (2008).

The orbital periods of the five binary MSPs studied in this paper are all longer than the time span of the NUV observations ($\sim 9$ h); light curves constructed from these data alone give incomplete phase coverage. We defer a variability study, based on these and other HST data sets, to a future paper.
