BMJ Open  Glycaemic control and antidiabetic treatment trends in primary care centres in patients with type 2 diabetes mellitus during 2007–2013 in Catalonia: a population-based study

Manel Mata-Cases,1,2,3 Josep Franch-Nadal,1,2,4 Jordi Real,1,5 Didac Mauricio1,2,6

ABSTRACT

Objectives: To assess trends in prescribing practices of antidiabetic agents and glycaemic control in patients with type 2 diabetes mellitus (T2DM).

Design: Cross-sectional analysis using yearly clinical data and antidiabetic treatments prescribed obtained from an electronic population database.

Setting: Primary healthcare centres, including the entire population attended by the Institut Català de la Salut in Catalonia, Spain, from 2007 to 2013.

Participants: Patients aged 31–90 years with a diagnosis of T2DM.

Results: The number of registered patients with T2DM in the database was 257 072 in 2007, increasing up to 343 969 in 2013. The proportion of patients not pharmacologically treated decreased by 9.7% (95% CI −9.48% to −9.92%), while there was an increase in the percentage of patients on monotherapy (4.4% increase; 95% CI 4.16% to 4.64%), combination therapy (2.8% increase; 95% CI 2.58% to 3.02%), and insulin alone or in combination (increasing up to 3.02% increase; 95% CI 2.7% to 3.3%). The use of metformin and dipeptidyl peptidase-IV inhibitors increased gradually, while sulfonylureas, glitazones and α-glucosidase inhibitors decreased. The use of glinides remained stable, and the use of glucagon-like peptide-1 receptor agonists was still marginal. Regarding glycaemic control, there were no relevant differences across years: mean glycated haemoglobin (HbA1c) value was around 7.2%; the percentage of patients reaching an HbA1c≤7% target ranged between 52.2% and 55.6%, and those attaining their individualised target from 72.8% to 75.7%.

Conclusions: Although the proportion of patients under pharmacological treatment increased substantially over time and there was an increase in the use of combination therapies, there have not been relevant changes in glycaemic control during the 2007–2013 period in Catalonia.

INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a highly prevalent chronic disease at risk of chronic microvascular and macrovascular complications when glycaemic control is suboptimal.1 Although diet and lifestyle changes are initially effective, most patients will need an oral glucose-lowering agent to better control blood glucose levels, and most will eventually need multiple therapies as the disease progresses.2 The pharmacological armamentarium to treat hyperglycaemia in T2DM has changed substantially over the past 20 years with the development of new therapeutic agents, such as insulin secretagogues (glinides), thiazolidinediones, incretins (glucagon-like peptide-1 receptor agonists (GLP-1ra) and dipeptidyl peptidase-IV inhibitors (DPP4i)), sodium-glucose transporter-2 inhibitors, fixed-dose combinations, and also with the advent of...
insulin analogues. This, together with changing treatment recommendations advocating for an intense glycaemic control in early stages of the disease, makes drug choice increasingly challenging, and it has driven substantial changes in current prescribing practices with wide variations between countries depending on each therapeutic class.

General practice databases are a reliable and rich source of information from the general population, and therefore a valuable tool to study medical practice in the community. In Catalonia, Spain, such an electronic general practice database is available for researchers (Information System for the Development of Research in Primary Care (SIDIAP)), and it has been previously used to conduct several observational studies to assess different aspects of the natural history and treatment of T2DM in our autonomous region.

In the present study, we aimed to examine prescribing patterns for antidiabetic treatment in primary care in Catalonia between 2007 and 2013 using SIDIAP data, and how changes impacted the degree of attained glycaemic control over time.

MATERIALS AND METHODS

Design

This was a cross-sectional, retrospective study using the SIDIAP database, which started in 2006 and stores data from electronic medical records. The database contains anonymised longitudinal patient information obtained from the electronic clinical records using specific software (Electronic Clinical station in Primary Care, eCAP) developed by the institution and used since 2001 by all of the 274 primary care centres pertaining to the Catalan Health Institute (ICS), which attends 80% of the total population (about 5.835 million patients) in Catalonia.

Data extraction

Data from patients aged 31 to 90 years with a diagnosis of T2DM (by means of the International Classification of Diseases, 10th Revision (ICD-10) codes E11 or E14) were obtained from the SIDIAP database for the years 2007–2013. Data were extracted for patients for each particular year. As a dynamic database, new patients enter when a death occurs or the patient moves to another healthcare region not served by the Catalan Health Institute. Registered variables included: age; gender; time since diagnosis; the presence of comorbidities (ICD-10 codes); and the most recent value for each year of body mass index (BMI) and mean glycated haemoglobin (HbA1c). Before 1 January 2010, between 50% and 70% of laboratories in Spain expressed HbA1c values using the Japanese Diabetes Society/Japanese Society for Clinical Chemistry criteria (JDS/JCC; normal range 3.9–5.7%), and these values were not converted to the internationally defined Diabetes Control and Complications Trial/National Glycohemoglobin Standardization Program (DCCT/NGSP) calibration criteria (normal range 4–6%). All values from 1 January 2010 onwards were expressed using DCCT/NGSP criteria.

The prescribed antidiabetic treatments for each patient and year were extracted from prescription-invoicing and pharmacy-invoicing data provided by the Catalan Health Service (CatSalut), which are incorporated yearly into the SIDIAP database. Glucose-lowering agents included the use of insulin and non-insulin antidiabetic drugs (NIADs) marketed in Spain during the study period, namely metformin, sulfonylureas, glinides, glitazones, DPP4i, GLP-1ra and α-glucosidase inhibitors (AGI). The first DPP4i marketed in Spain was sitagliptin (2007) followed by vildagliptin (2007), saxagliptin (2010) and linagliptin (2012). For GLP-1ra, daily exenatide appeared in 2007, and liraglutide in 2011. Treatment steps were categorised as non-pharmacological treatment, an NIAD in monotherapy, NIADs in combination (2 or more without insulin), insulin alone or insulin in combination with NIADs.

Statistical analysis

Descriptive analyses by year are presented as mean and SD for continuous variables, and percentages for categorical variables. Changes across the study period were evaluated through the absolute overall increase and the 95% CIs using the normal approximation. We used three different criteria for adequate glycaemic control: mean HbA1c ≤7%, as widely recommended and accepted; HbA1c ≤8%, as recommended by our institution during the study period (ICS); and individualised goals based on age, duration of the disease, and presence of serious complications or comorbidities, as proposed by the Red de Grupos de Estudio de la Diabetes en Atención Primaria de la Salud 2014 (Red-GDPS). All statistical calculations were performed using StataCorp 2009 (Stata Statistical Software: Release 11. College Station, Texas, USA: StataCorp, LP).

RESULTS

Patients’ characteristics

The total number of registered patients with T2DM in our database was 257,072 in 2007, increasing up to 345,969 in 2013 (a total increase of 86,897 cases) (table 1). The patients’ mean age did not vary substantially over the years (overall increase 1.20 years; 95% CI 1.14 to 1.26 years), and nor did the mean BMI or the number of obese patients (overall decrease 0.08 kg/m²; 95% CI −0.11 to −0.05 kg/m²; overall 0.043% decrease in obese patients; 95% CI −0.12 to −0.074%), but we observed a small progressive increase in the proportion of male patients (overall increase 2.15%; 95% CI 1.90% to 2.40%), and also a gradual increase in the mean duration of the disease (overall increase 2.40 years; 95% CI 2.37 to 2.43 years).

Prescribing pattern of antidiabetic drugs

The proportion of patients not receiving antidiabetic drugs decreased by 9.7% (95% CI −9.48% to −9.92%)...
from 2007 to 2013, while the percentage of patients receiving pharmacological antidiabetic treatment was 71.9% in 2007, and this proportion increased annually and was 81.6% in the last year of the study, showing an overall 9.7% increase over the study period. The proportion of patients receiving each type of therapy across the time period 2007–2013 is shown in figure 1. The most frequent prescription was an NIAD in monotherapy, the use of which increased 4.4% (95% CI 4.16% to 4.64%) from 2007 to 2013, followed by NIADs in combination (increasing 2.8%; 95% CI 2.58% to 3.02%), and insulin alone or in combination (increasing 2.5%; 95% CI 2.2% to 2.8%). Among NIADs, the most frequently used drugs were metformin and sulfonylureas, although the prescription rate of metformin increased notably across time (19.5%; 95% CI 19.25% to 19.75%), whereas it decreased gradually in the case of sulfonylureas (8.20%; 95% CI −7.97% to −8.43%) (figure 2). As for the use of the rest of the available options, only the prescription of DPP4i increased substantially up to 13.2% in 2013 (95% CI 13.09% to 13.31%), while the use of glitazones, gli- nides, AGI and GLP-1ra remained low. Glitazones and AGI prescriptions even decreased with time: glitazones an overall 2.9% (95% CI −2.82% to −2.98%) and AGI 2.70% (95% CI −2.62% to −2.78%). Finally, glinides and GLP-1ra only increased slightly over time: 0.8% in the case of glinides (95% CI 0.69% to 0.91%) and 0.9% in the case of GLP-1ra (95% CI 0.87% to 0.93%).

Evolution of the degree of glycaemic control

The mean standardised HbA1c value was around 7.2%, with no clinically relevant differences across years (table 1). Moreover, the proportion of patients attaining a glycaemic target of HbA1c ≤7% ranged from 52.2% to 55.6% (overall change 0.29%; 95% CI −0.02% to 0.60%), and the ICS target ≤8% ranged from 77.8% to 79.6% (overall change 0.64%; 95% CI 0.39% to 21.42%), with no clinically relevant changes across years (table 1). Moreover, the percentage of patients attaining their individualised HbA1c target ranged increased by only 1.15% (95% CI 0.88% to 1.42%) (table 1). Finally, the analysis of the evolution of the attained glycaemic control according to different HbA1c intervals also showed that there were no remarkable changes among years in any case (figure 3). Of note, the group of patients who were less likely to achieve the corresponding glycaemic target included those younger than 65 years, without comorbidities, and duration of T2DM ≤15 years (range 50.8–55.1%) (see online supplementary table S1).

The evolution of the mean Hb1Ac levels according to each step of treatment and duration of T2DM is shown in figure 4 and online supplementary table S2. Considering all antidiabetic treatments, there was a progressive worsening of HbA1c levels as the disease duration increased, but this worsening was in fact only observed among patients treated with insulin alone or in combination with NIADs. Conversely, glycaemic values

---

**Table 1**

| Year | N | Demographic, clinical characteristics and degree of glycaemic control of patients with T2DM |
|------|---|---------------------------------------------------------------|
| 2007 | 257,072 | Age, mean (SD), years: 67.7 (11.7) |
| 2008 | 271,690 | HbA1c*, mean (SD), %: 7.16 (1.46) |
| 2009 | 286,019 | Obesity (BMI>30 kg/m2), %: 45.6 |
| 2010 | 301,144 | HbA1c ≤7%, %: 54.9 |
| 2011 | 317,215 | HbA1c ≤8%, %: 75.4 |
| 2012 | 331,317 | Individualised HbA1c target, %: 75.4 |
| 2013 | 343,969 | BMI, mean (SD), kg/m²: 30.1 (5.0) |

*Cut-off stated by the ICS. †The CI contains the null change (0), and therefore it is not statistically significant. ‡On the basis of the 2014 algorithm of the Red-GDPS.

DISCUSSION

This cross-sectional descriptive study is, to the best of our knowledge, the first to assess trends in the prescribing practices of antidiabetic drugs in relation to the level of attained glycaemic control between 2007 and 2013 in a primary healthcare setting in Spain.

A gradual increase in the prescription of antidiabetic agents has been previously reported in Spain and in studies conducted worldwide throughout the same or overlapping years as in our study. An increase in the use of combinations of oral antidiabetic drugs (OADs) has been consistently observed in several studies from different countries, but the trends in its use as monotherapy vary among reports, with some describing an overall increase over time, and others a progressive decrease. Moreover, while the number of prescriptions of insulin in combination with an OAD has been shown to increase with time, the use of insulin alone has been reported to remain stable, to decrease even to increase. Differences between drug schemes and studies may be attributable to health policy variations across countries, local professional expertise, physician’s personal choice, study setting, or inclusion of both patients with T1DM and T2DM in some cases.

Both an increase in the use of metformin and a decrease in the use of sulfonylureas have been consistently reported by other groups. This decline could be related to the recent recommendation of cautionary use in the elderly, their worse safety profile, associated weight gain, unclear role in reducing long-term complications and/or to the availability of safer new therapeutic options. Although a decrease in glinides and AGIs use has been reported in Spain, Japan...

Figure 2  Percentage of patients having non-insulin antidiabetic drug prescriptions (alone or in combination). AGI, a-glucosidase inhibitors; DPP4i, dipeptidyl peptidase-IV inhibitors; GLP-1ra, glucagon-like peptide-1 receptor agonists; T2DM, type 2 diabetes mellitus.
and in the UK, in our study the number of gli-
nides prescriptions remained stable, which could be
explained by the fact that in spite of their risk of hypo-
glycaemia, they are the most used therapeutic class in
patients with chronic kidney disease. The decrease in
AGIs might be explained by the high frequency of
gastrointestinal side effects that led to the recommenda-
tion to only use them in people unable to use other oral
glucose-lowering medications. The decrease in the use
of glitazones has been consistently documented in
several studies that included data after 2007, when the
first regulatory warnings and the results of a meta-analysis alerted clinicians to cardiovas-
cular risk associated with rosiglitazone, and to a risk of bladder cancer with pioglitazone in 2011. Both side
effects have been recently ruled out, but the influ-
ence of these alarms, together with weight gain, the risk of heart failure and the increased risk of bone fractures
in women observed with this class of drugs, has limited
its use. The marginal use of GLP-1ra in our study is
similar to that of a recent study conducted in the UK, but in contrast with a substantial increase documented
in another region of Spain, Ireland and the USA. The administrative restrictions and negative economic
incentives of our institution (ICS) for the prescription of
GLP-1ra may have contributed to the limited use of this
therapeutic class. Finally, DPP-4i the class of newly devel-
oped NIDAs with the greatest increase in use, which is
in agreement with other reports conducted worldwide.

The rapid adoption, mainly as an alternative to sulfonylureas, may respond to the lower risk of hypoglycaemia, its neutral effects on body weight and also the greater convenience of an oral treatment instead of the need of injections for GLP-1ra or insulin. In summary, although a plethora of hypoglycaemic agents are currently available with a substantially comparable effect in terms of glycaemic control, the physician’s choice should be personalised based on patient’s characteristics such as age, risk factors and comorbidities.

When we assessed the attained glycaemic control based on the treatment step, we found that patients on NIDAs in combination or on insulin with or without an NID were the ones with the highest HbA1c levels. This is in line with the results of several studies showing a delay in treatment intensification in patients already on combina-
tion therapies whose control of blood glucose remained
or became inadequate. Moreover, we found that about half of the patients had HbA1c levels ≤7% as
recommended by clinical guidelines, about 80% below the 8% recommended by our institution (ICS), and about 75% below the individualised goal recommended by the Red-GDPS. Our figures are slightly worse than the ones reported by a study conducted in the Basque country in Spain for patients achieving HbA1c levels ≤7% (about 64.1% of them), but similar to their 85.5% of patients achieving a ≤8% target. Finally, and con-
fiming previous analyses, the subgroup with the highest proportion of patients attaining appropriate individualised glycaemic control was the one of patients older than 75 years, while patients younger than 65 years without comorbidities or serious complications and T2DM duration ≤15 years were less likely to achieve the corresponding individualised glycaemic control target. This could be explained by a higher proportion of obesity among younger patients, a longer survival among adequately controlled older patients, or by an easier to reach glycaemic goal in the elderly (≤8% vs ≤7%). More important, our results confirm that an individualised therapeutic approach considerably increases the chances of attaining adequate glycaemic control and provides effective T2DM care. However, one of the most striking
findings of our study was that there were no relevant changes across years, meaning that in spite of the overall observed gradual increase in pharmacological treatments along the study there was no obvious trend towards an increase in the proportion of patients with an adequate HbA1c target whatever the used cut-off, and the mean HbA1c values did not significantly change over time regardless of the treatment step. There are few reports on how the evolution in the prescription pattern of antidiabetic drugs affects the level of attained glycaemic control, but our results are in contrast with a study conducted in Japan showing that the rate of patients achieving the ≤7% goal significantly improved together with the progressive increase in the proportion of pharmacological treatments.11 However, a very recent study conducted in Canada reported that the mean HbA1c values in older patients even increased slightly over a 5-year period in spite of the overall increase in the use of antidiabetic treatment.14 Our results seriously question the ICS threshold to maintain HbA1c levels ≤8% for all patients, giving general practitioners financial incentives if this goal is attained, without taking into account age, diabetes duration or the presence of comorbidities. This threshold was established to avoid overtreatment—especially in the elderly—but can be counterproductive in younger patients. Certainly, about 25% of patients had HbA1c between 7.1% and 8%, and were therefore at potential risk of suboptimal management or undertreatment until they reached this value, especially in people aged under 65 years. Thus, this institutional policy potentially contributes to therapeutic inertia, defined as a delay in treatment intensification among patients with poor glycaemic control. Clinical inertia has been documented in primary care settings,44 45 and a study conducted in Catalonia in 2007 in a sample of 2783 patients with T2DM reported that therapeutic inertia was present in 33.2% of cases, and treatment intensification was implemented in patients with a mean HbA1c of 8.4%,41 which is far above the 8% threshold established by the institution. On the other hand, most family physicians find that patients treated with an NIAD combination but needing intensification with insulin or GLP-1r, and those already on insulin needing optimisation with multiple insulin doses or the addition of a GLP-1r, are difficult to manage or they have reasonable safety concerns. In these cases, clinical inertia is a major factor that contributes to inadequate glycaemic control in the long term.

Figure 4  Evolution of mean HbA1c according to the different steps of antidiabetic treatment and T2DM duration. HbA1c, glycated haemoglobin; NIAD, non-insulin antidiabetic drug; T2DM, type 2 diabetes mellitus.
Our results show a global negative effect of T2DM duration on glycaemic control that did not change substantially across the study period. A progressive worsening of mean HbA1c values within each sequential evaluation might be expected because the proportion of patients with a disease duration >10 years increased, but this could have been counteracted by an intensified management in all treatment steps, eventually leading to steady mean HbA1c levels along the study. This is a possible explanation if we take into account that patients in the lowest treatment steps (ie, no drugs, and NIADs in monotherapy or combined) and with a disease duration >10 years had lower HbA1c values than those with a disease duration lower than <2 years, as those on poor glycaemic control were probably switched to the next superior treatment step. In contrast, glycaemic control among patients on insulin (alone or in combination) worsened as the duration of disease increased, probably because they are at the last treatment step and only intensive management with multiple insulin doses under endocrinologist supervision may improve control.

This study has strengths and limitations worth mentioning. The main strength is that we used a large outpatient database that, although not completely representative of other areas of Spain, is indicative of the trends of general practitioners’ practices in a real-life clinical setting. However, this was a retrospective study subject to errors in data recording. For instance, the percentage of missing values for HbA1c was 35% in 2007 and decreased to 25% in 2013, although this would apply equally to all study periods, therefore not affecting the conclusions of the study. Moreover, we were not able to assess whether the change in prescribed treatments over time was driven by patients’ needs and characteristics (eg, prior low tolerability or effectiveness), and we cannot therefore claim a causal effect. Finally, we could not assess whether doses were appropriately chosen, and we did not consider data on prescriptions within the same therapeutic class.

CONCLUSIONS

Although the intensity of pharmacological antidiabetic treatment of T2DM increased substantially during 2007–2013 in Catalonia, there was no evidence that this was accompanied by a positive change in the degree of glycaemic control. This reveals shortcomings in the primary healthcare system that could be tackled through more intensive educational programmes for physicians oriented to the individualisation of glycaemic goals and prioritising more intensive treatments in younger patients.
