We propose a lattice model for RNA based on a self-interacting two-tolerant trail. Self-avoidance and elements of tertiary structure are taken into account. We investigate a simple version of the model in which the native state of RNA consists of just one hairpin. Using exact arguments and Monte Carlo simulations we determine the phase diagram for this case. We show that the denaturation transition is first order and can either occur directly or through an intermediate molten phase.

I. INTRODUCTION

In recent years, the diversity of roles played by RNA in cellular processes has become increasingly clear [1]. RNA is a heteropolymer which is build from four types of monomers (nucleotides) [2] and as for proteins, a major issue is the prediction of the tertiary (folded) structure for a given sequence of nucleotides [3]. In some respects, this question is easier to answer for RNA than for proteins. Firstly, the four nucleotides are chemically more similar than the twenty amino acids that form proteins. Secondly, it has been argued [3] that folding in RNA is hierarchical in the sense that the energy scales involved in secondary structure elements are larger than those of tertiary structure. Therefore much attention, also in the physics literature [4, 5, 6, 7, 8, 9, 10, 11], has been devoted to predicting the secondary structure of RNA.

In most of the existing models, self-avoidance has not been fully taken into account. If one also neglects certain type of monomer-monomer interactions such as those occurring in pseudoknots and kissing hairpins [2], it becomes possible to calculate secondary structures with a recursive algorithm whose complexity only grows as the third power of the number of monomers [12]. Despite its success, this approach has several drawbacks. Firstly, the neglect of self-avoidance leads to unphysical properties for the radius of gyration [4], especially at low temperatures. Secondly, the neglect of part of the physically relevant interactions is often justified a posteriori from the observation that (for example) pseudoknots are not very common in real RNA. However, it would be more attractive to have a model which allows to predict the rate of occurence of these structural elements. A first attempt along these lines, but neglecting self-avoidance, was made in [12].

In this paper, we propose a lattice model for RNA which can take into account both self-avoidance and most of the physically relevant interactions. To get a first insight into the properties of the model, we study here in detail a simplified version, which is a lattice variant of the model studied in [8]. By using rigorous and numerical techniques well-known from the study of other lattice models of polymers [13], we find that RNA can exist in three phases. In the present work we study the properties of these phases and of the transitions between them. In a forthcoming publication, we will investigate questions such as the probability of formation of pseudoknots.

This paper is organised as follows. In section II we present our lattice model and show how one can include several aspects of real RNA in a natural way. We also introduce the simplified version of the model. In section III we present a number of semi-exact results from which the phase diagram for this case can be obtained. In section IV we give the results of an extensive Monte Carlo study of this phase diagram in two dimensions. Finally, in section V, we present our conclusions.

II. AN INTERACTING TWO-TOLERANT TRAIL MODEL OF RNA

RNA is a heteropolymer whose primary structure consists of a sequence of ribonucleotide bases. Of these there are four types, which are denoted by the symbols C, G, U and A. The particular sequence of these bases determines the three dimensional structure through base-base interactions, of which pairing and stacking are the most important.

We make a lattice model for RNA starting from a two-tolerant trail [14]. This is a lattice random walk that can visit each edge of the lattice at most twice. The walk has $L$ steps, each of which corresponds to a monomer of RNA. Doubly visited edges correspond to bonded base pairs. The restriction to allow only doubly visited edges thus takes into account the saturation of the base-base interactions. In Fig. 1 we show a typical two-tolerant trail of 500 steps. When step $i$ and $j$ are on the same edge, we say that they are bonded. The two-tolerant trail consists of sets of connected bonded steps (corresponding to helices in real RNA) alternating with sets of singly visited edges (corresponding to loops and bulges) [2]. With each $L$-step two-tolerant trail $T$ we associate a set $S_T$ whose elements are the bonded steps of the trail: $S_T = \{(i,j) : i,j$ are bonded$\}$. In most of the existing theoretical work on RNA the following restriction is put on the bonded steps: when both $(i,j)$
and \((i', j')\) are bonded, one only allows the combinations \(i < j < i' < j'\) and \(i < i' < j' < j\). The situation in which \(i < i' < j < j'\) will be referred to as a pseudoknot, even though in the biological literature this class of structures is further divided into several types \([2]\). In our model, pseudoknots are treated on the same footing as the other types of bonds.

Next, we associate to each doubly visited edge a pairing energy \(\varepsilon_{i,j}\), which depends on the nature of the bases \(i\) and \(j\) present on the edge. Below we will propose a simple form for \(\varepsilon_{i,j}\) inspired by the work of \([6]\) and investigate the phase diagram of the resulting model.

Before doing that we comment here on how other physically relevant interactions can be introduced in a natural way in our model. The most important of these is the stacking energy. This is an interaction between neighboring bonded base pairs and it can be modelled by associating an energy \(\sigma_{i,i+1,j-1,j}\) with each element of \(S_T\). The value of this stacking energy depends on the four nucleotides forming the stack. When the pair \((i+1, j-1)\) is not bonded we put \(\sigma_{i,i+1,j-1,j} = 0\).

Because of the semiflexible nature of nucleic acids, it is also necessary to add a bending rigidity for which we assume the form \(\kappa(\vec{n}_i - \vec{n}_{i+1})^2\) with \(\kappa \geq 0\). Here \(\vec{n}_i\) is the unit vector in the direction of the \(i\)-th step. The total energy associated with the two-tolerant trail \(T\) thus becomes

\[
E_T = \kappa \sum_{i=1}^{L-1} (\vec{n}_i - \vec{n}_{i+1})^2 + \sum_{(i,j) \in S_T} (\varepsilon_{i,j} + \sigma_{i,i+1,j-1,j}) \quad (1)
\]

The thermodynamic properties of the RNA-model can then be determined from the partition sum

\[
Z_L = \sum_T \exp (-\beta E_T) \quad (2)
\]

where the sum is over all \(L\)-step two-tolerant trails and \(\beta\) is the inverse temperature \(\beta = 1/k_B T\). Moreover, if \(A\) is a particular set of bonded monomer pairs we can determine the probability \(p_{A,L}\) that this set occurs by calculating the ratio

\[
p_{A,L} = \frac{Z_{A,L}}{Z_L} \quad (3)
\]

where \(Z_{A,L}\) is given by an expression similar to \((2)\) with the sum restricted to trails \(T\) for which \(A \subset S_T\). In this way, it is possible to calculate, for example, the probability that a pseudoknot appears as a function of temperature.

Within this model we can calculate the thermodynamic properties of an RNA molecule with a given sequence of bases by taking from the literature the estimated values of the relevant pairing and stacking energies. Clearly, such a calculation can only be performed numerically. Here, we follow another route with the main purpose of gaining a more detailed insight into a simplified version of our model. Such an approach can give useful information against which the results of a full numerical calculation can be understood. In the simplified model we neglect the stacking energies and the bending rigidity. Moreover, we modify the nucleotide dependence of the pairing energies. A common approach in the physics literature is to take it as random \([8, 9, 10, 11]\). In this way, the study of RNA can be linked to that of random systems such as spin glasses. However, clear differences between random and real RNA have been pointed out \([12]\). The latter has an evolutionary evolved, correlated sequence of bases, which is such that most often the ground state secondary structure is less degenerated than that of random RNA. An expression for the pairing energy which has this feature and which lends itself to detailed analysis was introduced in \([\overline{2}]\). Following that work, we take

\[
\varepsilon_{i,j} = \varepsilon_0 + \tilde{\varepsilon} \delta_{i,j,L+1} \quad (4)
\]

(where \(\delta\) is the Kronecker-delta and from now on we take \(L\) even). In the physical region of interest \(\varepsilon_0 < 0\) and \(\tilde{\varepsilon} < 0\). The second term in \((\overline{4})\) favors the formation of just one hairpin. This structure thus corresponds to the native state of our model. With all these simplifications, \((\overline{2})\) becomes

\[
E_T = \varepsilon_0 I + \tilde{\varepsilon} N \quad (5)
\]

where \(I\) is the total number of bonded base pairs and \(N\) the total number of native interactions (i.e. those pairs \(i,j\) for which \(\delta_{i,j,L+1} = 1\)). Finally, we introduce \(q = \exp (-\beta \varepsilon_0)\) and \(\tilde{q} = \exp (-\beta \tilde{\varepsilon})\), so that the partition sum \((\overline{4})\) becomes

\[
Z_L(q, \tilde{q}) = \sum_T q^I \tilde{q}^N \quad (6)
\]

In the rest of this paper we study the phase diagram of the model defined by \((\overline{6})\).
III. THE PHASE DIAGRAM

The two-tolerant trail was originally introduced as a simple model for the coil-globule transition of homopolymers \(^{16}\). The authors of that work studied the two-tolerant trails with attractive self-interactions, which corresponds to our model for \( \tilde{q} = 1 \). A closer investigation \(^{17}\) revealed however that in the low temperature phase, the universal properties of the trail are not those of a collapsed globular polymer, but coincide with those of branched polymers (BP). In the high temperature phase it was found \(^{15}\) that the universality class of two-tolerant trails is that of the self-avoiding walk (SAW) \(^{13}\). These results were based on exact enumerations in two dimensions and on a study of the model on fractal lattices. More recently, we investigated the non-interacting two-tolerant trail (i.e. \( q = \tilde{q} = 1 \)) with a Monte Carlo method that will be discussed in the next section. We also found clear evidence that, at least in two dimensions, the non-interacting trail has the critical properties of the SAW. Let us therefore assume for the moment that along the line \( \tilde{q} = 1 \), our model has a phase transition at some \( q_c(1) > 1 \) between a SAW-phase and a branched polymer phase. A more quantitative investigation of this transition will be presented in the next section. We now show how this assumption, together with a number of other, semi-exact results, leads to a qualitative determination of the form of the phase diagram.

For this purpose, we introduce the free energy \( f(q, \tilde{q}) \) which is defined as

\[
f(q, \tilde{q}) = \lim_{L \to \infty} \frac{1}{L} \ln Z_L(q, \tilde{q})
\]

Besides this free energy it is convenient to introduce the connective constant \( \mu_2(q, \tilde{q}) = \exp(f(q, \tilde{q})) \). The existence of the limit in \( \ref{eq:free_energy} \) can only be proven rigorously for \( q \leq 1 \), \( \tilde{q} \leq 1 \) \(^{15}\). The proof is based on concatenation arguments and is a straightforward extension of that for the SAW \(^{10}\). On the basis of an exact enumeration we recently determined the estimate \(^{15}\)

\[
\mu_2(1, 1) = 3.486 \pm 0.003
\]

on the square lattice. Moreover, it can also be proved that in the non-interacting case the connective constant for two-tolerant rings (i.e. two-tolerant trails whose last step ends at the starting point) equals that of all two-tolerant trails. Again, this result can be shown by extension of the proof of a similar result for self-avoiding walks \(^{14}\). For more details, we refer to \(^{15}\). In the following, we will assume that \( \ref{eq:connective_constant} \) exists.

Firstly, we investigate the behaviour of the free energy at fixed \( q \) and as a function of \( \tilde{q} \). Consider therefore the limit \( \tilde{q} = 0 \) where the only contribution to the free energy \( f(q, 0) \) comes from trails without native contacts. A special subset of these are the trails in which the first \( L/2 \) steps and the last \( L/2 \) steps are in different halfspaces. It is known that for quite general type of walks, the free energy of walks limited to a halfspace is the same as that of unrestricted walks (i.e. \( f(q, 1) \)) in our case) up to surface corrections \(^{20}\). These however vanish in the limit \( L \to \infty \). Thus, the free energy of the trails without native contacts is bounded from below by that of trails living in a half-space, which equals that of trails without spatial restrictions. Therefore, \( f(q, 1) \leq f(q, 0) \), \( \forall q \). However, since the free energy is a non-decreasing function of \( \tilde{q} \) we must conclude

\[
f(q, \tilde{q}) = f(q, 1) = \ln \mu_2(q, 1) \quad 0 \leq \tilde{q} \leq 1
\]

Secondly, it is possible to obtain a lower bound to the partition sum \(^{3}\) by considering only the contribution from two-tolerant trails with a maximum number of native contacts, i.e. those for which \( N = L/2 \). Each of these is a walk whose first \( L/2 \) steps is a one-tolerant trail (i.e. a walk that can visit each edge of the lattice at most once), and which then retraces these same steps in reverse order during its last \( L/2 \) steps. For this type of walk \( I = L/2 \) and therefore

\[
f(q, \tilde{q}) \geq \frac{1}{2} [\ln \mu_1 + \ln q + \ln \tilde{q}]
\]

Here \( \mu_1 \) is the connective constant for non-interacting one-tolerant trails. For example, on the square lattice one has \( \mu_1 = 2.72058 \pm 0.00020 \) \(^{21}\).

Together \( \ref{eq:free_energy} \) and \( \ref{eq:lower_bound} \) imply the existence of a phase transition at some \( \tilde{q}_c(q) \). Moreover, one trivially arrives at the bounds

\[
0 \leq \tilde{q}_c(q) \leq 2 \ln \mu_2(q, 1) - \ln q - \ln \mu_1
\]

It also follows that for each \( q \) fixed, the free energy equals the value given by \( \ref{eq:free_energy} \) as long as \( \tilde{q} \leq \tilde{q}_c(q) \).

Further information on the upper bound in \( \ref{eq:free_energy} \) can be obtained from the following reasoning. For \( \tilde{q} = 1 \) and for \( q \to \infty \), the partition sum is dominated by trails in which each edge is visited twice. Each such trail of \( L \) steps has the appearance of a weakly embedded bond lattice animal \(^{13}\) whose \( L/2 \) bonds correspond with the doubly visited edges as we show for an example in Fig. 2. But in the same figure we show that the mapping is not one-to-one. If we suppose that the number of trails that are mapped onto the same lattice animal is not extensive in \( L \) we can conclude that for \( q \gg 1 \)

\[
\ln \mu_2(q, 1) \approx \frac{1}{2} [\ln \mu_{BP} + \ln q]
\]

Here, \( \mu_{BP} \) is the connective constant for weakly embedded bond lattice animals. Its value on the square lattice is estimated as \( \mu_{BP} = 5.21 \pm 0.006 \) \(^{22}\). Hence, we can make the upper bound \(^{14}\) more precise for \( q \sim \infty \). We obtain

\[
\ln \tilde{q}_c(q) \leq \ln \mu_{BP} - \ln \mu_1 \quad q \to \infty
\]
FIG. 2: Two two-tolerant trails with $I = L/2$ that can be mapped onto the same bond lattice animal.

What is the physical nature of the phase transition whose existence we have just proven? To answer this question, consider the density of native contacts $n(q, \tilde{q})$.

$$n(q, \tilde{q}) = 2 \lim_{L \to \infty} \frac{\langle N \rangle}{L} = 2 \lim_{L \to \infty} \sum_{T} N q^{L} \tilde{q}^{N}$$ (14)

The factor 2 ensures that $n(q, \tilde{q}) = 1$ when the two-tolerant trail consists of one single hairpin. In terms of the free energy this density equals

$$n(q, \tilde{q}) = 2 \frac{\partial f(q, \tilde{q})}{\partial \tilde{q}}$$ (15)

Thus, from our earlier results on the free energy we find that $n(q, \tilde{q}) = 0$ for $q < \tilde{q}_c(q)$ while this density becomes strictly positive above $\tilde{q}_c(q)$. We therefore interpret the phase transition at $\tilde{q}_c(q)$ as a denaturation transition, i.e. a transition into (or out of) the native state. Also notice that this transition exist for every value of $q$.

As discussed in the beginning of this section, numerical evidence shows that there is also a transition between a self-avoiding walk regime and a branched polymer (BP) one along the line $\tilde{q} = 1$, at some critical value $q_c(1)$. Clearly, since the free energy does not depend on $\tilde{q}$ for $\tilde{q} < \tilde{q}_c(q)$, the SAW-BP transition has to be also present for some range of $\tilde{q}$-values, and moreover neither the location of the transition point nor its critical properties can depend on $\tilde{q}$.

We therefore arrive at the phase diagram shown in Fig. 3: Schematic phase diagram of our model. The thick full line is a line of second order transitions, whereas along the broken line the transition is first order. The thin full lines indicate the three paths along which we investigated the model numerically.

Arguments we have given are quite general and we therefore believe that this phase diagram is correct, independently of dimension. While the denaturation transition is always present, it is possible that the SAW-BP transition disappears above some critical dimension. As an example of this we mention that in the model of reference 6 where pseudoknots and self-avoidance are neglected, and which thus can be seen as a mean-field model, no evidence for the coil phase is found, and only the transition between the native and molten phase is present. It is interesting to remark that in that work it was also found that in the molten phase, RNA has the properties of (mean-field) branched polymers, as is the case here.

IV. NUMERICAL RESULTS

In order to get a more quantitative insight into the phase diagram, we have investigated our model in the $(q, \tilde{q})$-plane with extensive Monte Carlo simulations. Further numerical insight was obtained from an exact enumeration of our model for $L \leq 18$. In these numerical approaches, we worked on a square lattice.

For the simulations, we used the pivot algorithm 22, a well-known technique that generates a Markov chain in the set of all allowed walks of a certain type. The pivot algorithm was originally introduced for self-avoiding walks. In 24 we investigate the extension of this method to non-interacting two-tolerant trails, discussing such aspects as ergodicity of the algorithm, acceptance ratio, autocorrelation times, and so on.
Here we have to take into account interactions and do this by adding a standard Metropolis step to the algorithm. Moreover, we implement the program within a Multiple Markov Chain approach (MMC) \cite{25}. In this method several Markov chains at different temperatures are run in parallel and at regular intervals an attempt is made to switch two trails between Markov chains at different temperature. Such an attempt is accepted with a probability that is a trivial extension of that of the Metropolis algorithm. The MMC approach has the advantage that it allows better sampling at lower temperatures, where a standard algorithm may easily get stuck near a metastable state. Besides the pivot moves, we also found it useful to add some local moves to enhance the performance of the algorithm. Typically, at each temperature we performed $10^9$ Monte Carlo steps resulting in $(.5 \sim 1.) \times 10^6$ independent configurations over which averages are calculated.

With this approach, we investigated our model on the square lattice along three lines. For these, we chose $q = 1$, $\tilde{q} = 1$ and $q = \tilde{q}^2$. We now discuss the results.

The line $q = 1$.

On the basis of the phase diagram obtained in the previous section, we expect that along this line there is only the denaturation transition. Evidence for this transition can most easily be found by looking at the density of native contacts. In Fig. 4, we show our results for $n(1,\tilde{q})$ for two-tolerant trails of different $L$ as obtained from the exact enumeration data. We clearly recognise the behaviour predicted in section III, dressed with finite size roundings. From the intersections of the curves for different $L$-values a first estimate for the location of the critical point can be made. Moreover, since the transition into the native state shares some properties with the adsorption transition of a polymer onto a surface, we expect that right at the critical point the density of contacts scales as $n \sim L^{\phi_n-1}$, where $\phi_n$ is a crossover exponent. From the exact enumeration data shown in Fig. 4, we estimate $\phi_n \approx .88$. However, a study of the same quantity with the Monte Carlo approach shows that this estimate is still strongly affected by finite size effects. For example, the value for $\phi_n$ tends to increase to a value close to 1. This suggests that the actual value of $\phi_n$ is one, which would be the case for a first order transition. To verify this idea we made histograms for our data for $n$ at different $\tilde{q}$-values. These are indeed consistent with a first order transition. As an example, we show in Fig. 5 such an histogram at the transition point. There is clear evidence for two peaks, one near $n = 0$, the other around $n \approx .65$. In fact, it turns out that from these histograms, a rather sharp estimate for $\hat{q}_c$ can be obtained, with the result $\hat{q}_c = 4.20 \pm .02$.

The fact that the denaturation transition is first order can also be understood with hindsight from a comparison with known results from DNA-models. Indeed, in recent years there has been quite some interest in understanding the nature of the denaturation transition for that biopolymer. Almost all existing evidence now shows that this transition is first order, both in $d = 2$ and $d = 3$ \cite{26, 27, 28}. When within our model, we divide the two-tolerant trail into two halves, we can see them as the two strands of a DNA-molecule whose starting point is halfway on the two-tolerant trail. The native interactions, which are the only ones appearing along the line $q = 1$, can thus be interpreted as interactions between homologous bases on the two strands of the DNA. In this way, our model with $q = 1$ becomes in a sense the dual of a recently studied lattice model of DNA \cite{24, 28}, and we can therefore expect both models to have a similar critical behaviour.

FIG. 4: The number of native contacts as a function of $\tilde{q}$ along the line $q = 1$ for different $L$-values, as obtained from exact enumerations.

FIG. 5: Histogram for the density of native contacts at the denaturation transition for $L = 300$ ($q = 1$).
The line $\tilde{q} = 1$.

The phase transition between the coil and branched polymer regime along the line $q = 1$ is more difficult to analyse. There is no obvious order parameter characterising this transition, since the average number of bonded base pairs, $\langle I \rangle$, is extensive on both sides of the transition.

We therefore investigated two other quantities. Firstly, we looked at the specific heat, which for $\tilde{q} = 1$ equals

$$C_L(q) = \frac{1}{L} \left[ \frac{\sum_T I^2 q^I}{\sum_T q^I} - \left( \frac{\sum_T I q^I}{\sum_T q^I} \right)^2 \right].$$

While both the exact enumerations and the Monte Carlo simulations show that the specific heat has a peak that slowly grows with $L$, it is difficult to obtain reliable estimates for the location of the critical point and for the crossover exponent from these data.

Secondly, it is possible to get information on the SAW-BP transition from the ratio $Y(q, 1)$ of the average squared end-to-end distance over the average squared radius of gyration. It is well known that this is a universal quantity so we expect its behaviour to be stepwise as a function of $q$, at least for $L \to \infty$. In fact, we expect that for large $q$ where the two-tolerant trail visits each edge twice (see Fig. 2), the end-to-end distance approaches zero and hence $Y(q, 1)$ goes to zero for large $L$. On the other hand, we verified recently that for non-interacting two-tolerant trails $Y(1, 1) = 7.1235 \pm .001$ [24], fully consistent with the value for the SAW. Hence along the line $\tilde{q} = 1$, $Y(q, 1)$ should assume this value below $q_c(1)$, and then drop to zero. In Fig. 5 we present our data for $Y(q, 1)$, which have the expected behaviour, dressed with finite size rounding. From these results we are able to obtain the most accurate estimate for $q_c(1)$ which equals $2.91 \pm .08$.

In Fig. 4 we show data for the squared radius of gyration $R_G^2(L)$ as a function of $L$ in the BP-phase. From this we can obtain the geometric exponent $\nu$ since

$$R_G^2(L) \sim L^{2\nu}$$

From a fit of the exact enumeration and Monte Carlo data in the BP-phase we find $\nu \approx .55$. This is still far from the best known value for two-dimensional branched polymers which is $\nu = .64075 \pm .00015$ [20]. This difference is probably due to strong corrections to scaling. Indeed, this also happens for the non-interacting situation where very long trails can be simulated, up to $L = 7500$. From them we obtain $\nu = .749 \pm .001$, as should be expected for a walk in the SAW universality class. However, this exponent is only recovered for $L > 200$. We expect that the $\nu$-exponent for branched polymers will show up if one studies longer trails at temperatures sufficiently below the transition. But that regime is difficult to probe with our Monte Carlo technique.

The line $q = \tilde{q}^2$.

From the phase diagram shown in Fig. 3 from the available estimates for $q_c(1)$, and from [13] we expect that along this line two phase transitions will be encountered. The first one is the SAW-BP transition, which can be analysed most suitably from an investigation of the ratio $Y(q, \tilde{q})$. The BP-native transition on the other hand, should show itself through a study of the density of native contacts.

In Fig. 5 we show our results for $Y(q, \sqrt{q})$. As was the case before, the data for different $L$-values intersect, yielding the estimate $q_c = 3.00 \pm .06$. This result is within the numerical accuracy the same as that for $\tilde{q} = 1$, as was predicted in section III.

From a study of the density of native contacts, we conclude that the transition between the branched polymer and the native phase is also first order. Since in this case
it is a transition between two rather dense phases, it is more difficult to obtain a reliable estimate for $\tilde{q}_c$. We find $\tilde{q}_c = 2.17 \pm .15$. Fig. 9 shows a histogram for the number of native contacts at this point.

V. CONCLUSIONS

In this paper, we have introduced a lattice model, based on a two-tolerant trail that seems well suited to investigate thermodynamic properties of RNA. We have found that for a simple version of the interaction energies, there are three phases and we have investigated in detail the transitions between these phases with a Monte Carlo method.

We believe that the structure of the phase diagram that we found here is not particular for the choice of the interaction energy but would be similar also for other choices of $\varepsilon_{i,j}$ that break the homogeneity of the interaction energies. Indeed, it is known that, at least in mean-field theory, the inclusion of a random part in the interaction energy gives rise to the appearance at low temperature of a spin-glass like phase. This phase then plays the role of the native one. It therefore seems quite possible that taking into account self-avoidance and for rather general choices of non-homogeneous interaction energies, one recovers the three phases found here.

Upon lowering the temperature at fixed values of the interaction energies $\varepsilon_{i,j}$ there are thus two possible scenario’s. Either one goes directly into the native regime, or one goes through an intermediate molten phase. We believe that the first order transition line approaches the line $\bar{q} = 1$ when $q \to \infty$, although we could not prove this and simulations in this regime are difficult with the pivot algorithm. If this belief is correct it seems that the molten phase, where a description in terms of homogeneous interactions is correct, can never be the stable one at very low temperatures.

Our results can be used as a starting point for studies which are of more interest from the point of view of molecular biophysics. Firstly, still within the context of the simplified model we are investigating the probability of occurrence of pseudoknots. It is intuitively obvious that in the hairpin-phase the occurrence of pseudoknots will be severely suppressed. But one would be interested to obtain a more quantitative insight into this issue.

Another application for which we think that our model can be useful is an investigation of the elastic properties of RNA. These have been measured recently using micromanipulation techniques. The theoretical study of elastic properties of biomolecules is usually performed within simple continuum models such as the worm like chain (WLC). This is certainly a very good approach when effects of self-avoidance can be neglected. For non-interacting models of polymers, it is known that as soon as an infinitesimal force is applied, the polymer becomes stretched and in such a regime it can be expected that it can be described by the WLC or in terms of directed polymers. However, for homopolymers below the theta-point it has been established that they undergo a transition to a stretched phase only for forces greater then a critical force $F_c > 0$. Then, in the whole region where the forces are below this threshold, effects of self-avoidance are of importance. We expect that a similar scenario might hold within the low-temperature phases (BP and native) of RNA.

Finally, the scenario which we have found here for the denaturation transition could be quite general and also be of relevance for proteins. Also in that case it is possible that depending on the ratios of relevant interactions, the denaturation transition takes place immediately, or through an intermediate molten phase.

Acknowledgement We would like to thank R. Kawai for the use of his computer cluster.
