Key Words: composition, discrete Morse function, Möbius function, permutation pattern, subword order

AMS classifications: 06A07, 05E25, 68R15

Abstract

We determine the Möbius function of the poset of compositions of an integer. In fact we give two proofs of this formula, one using an involution and one involving discrete Morse theory. The composition poset turns out to be intimately connected with subword order, whose Möbius function was determined by Björner. We show that using a generalization of subword order, we can obtain both Björner’s results and our own as special cases.

If $A$ is any set then the corresponding Kleene closure or free monoid, $A^*$ is the set of words with letters from $A$, i.e.,

$$A^* = \{w = w(1)w(2)\ldots w(n) \mid n \geq 0 \text{ and } w(i) \in A \text{ for all } i\}.$$ 

We denote the length (number of elements) of $w$ by $|w|$.

Letting $\mathbb{P}$ denote the positive integers, we see that $\mathbb{P}^*$ is the set of integer compositions (ordered partitions). We can turn $\mathbb{P}^*$ into a partially ordered set by letting $u \leq w$ if there

∗This work was partially done while the author was on leave at DIMACS

is a subword $w(i_1)w(i_2)\ldots w(i_l)$ of $w$ having length $l = |u|$ such that $u(j) \leq w(i_j)$ for $1 \leq j \leq l$. For example, $433 \leq 16243$ because of the subword 643. Bergeron, Bousquet-Mélou and Dulucq [2] were the first to study $P^*$, enumerating saturated chains that begin at its minimal element. Snellman has also studied saturated chains in this poset as well as two other partial orders on $P^*$ [20, 21]. One of the main results of this paper is a formula for the Möbius function of $P^*$.

This order on $P^*$ is closely related to subword order. If $A$ is any set then the subword order on $A^*$ is defined by letting $u \leq w$ if $w$ contains a subsequence $w(i_1), w(i_2), \ldots, w(i_l)$ such that $u(j) = w(i_j)$ for $1 \leq j \leq l = |u|$. By way of illustration, if $A = \{a, b\}$ then $abba \leq aabbbaba$ because $w(1)w(3)w(5)w(8) = abba$. Note that we use the notation $A^*$ when referring to subword order as opposed to the partial order on $P^*$, even though we use $\leq$ for both. We will always give enough context to make it clear which poset we are dealing with. Björner [4] was the first to completely determine the Möbius function of subword order, although some special cases had been obtained previously by Farmer [12] and Viennot [23]. In fact, Björner gave two proofs of his formula, one using an involution [5] and one using shellability [4]. He also gave a demonstration with Reutenauer [6] via generating functions on monoids. Another proof was given by Warnke [25] using induction while Wang and Ma [24] used Cohen-Macaulayness to investigate $\mu$. We derive the Möbius function formula for $P^*$ using first combinatorial and then topological techniques.

The rest of this paper is structured as follows. In the next section we review Björner’s result for subword order as well as the related definitions which will be useful for $P^*$. It contains a statement of our formula for the Möbius function of $P^*$ in Theorem 1.2. Section 2 is devoted to giving a proof of this theorem using a sign-reversing involution.

Although intervals in $A^*$ are shellable, those in $P^*$ need not even be connected as evident from the example in Figure 2, so we need a more powerful tool to study the topology of the composition poset. For this we turn to discrete Morse theory, which was developed by Forman [13, 14] and can be used to compute the homology of any CW-complex. A method for applying this theory to the order complex of a poset was given by Babson and Hersh [1] and further studied by Hersh herself [15]. Since this is a relatively recent addition to the combinatorial toolbox, we provide an exposition of the basic ideas of the theory in Section 3. The subsequent section gives a Morse theoretic proof of Theorem 1.2.

The similarity between the formulas for the Möbius functions of $A^*$ and $P^*$ leads one to ask if there is a common generalization. In fact, if $P$ is any poset then there is a partial order on $P^*$ which we call generalized subword order. It has been used in the context of well-quasi-ordering; see Kruskal’s article [17] for a survey of the early literature. When $P$ is a chain or an antichain in the present context, one recovers our results or Björner’s, respectively. This construction is studied in Section 5. Finally, we end with a section of comments and open problems.

1 Subword and composition order

We now review Björner’s formula for the Möbius function of subword order, reformulating it slightly so as to emphasize the connection to the composition order which is our main objective. We assume the reader is familiar with Möbius functions, but all the necessary
definitions and theorems we use here can be found in Stanley’s text [22, §3.6–3.7].

We first need to restate the definition of the partial order in $A^*$ in a way that, although slightly more complicated, has a direct connection with the Möbius function. Suppose we have a distinguished symbol, 0, and suppose that $0 \not\in A$. Then a word $\eta = \eta(1)\eta(2)\ldots\eta(n) \in (A \cup 0)^*$ has support

$$\text{Supp} \eta = \{i \mid \eta(i) \neq 0\}.$$ 

An expansion of $u \in (A \cup 0)^*$ is a word $\eta_u \in (A \cup 0)^*$ such that the restrictions of $u$ and $\eta_u$ to their supports are equal. For example, if $u = abba$ then one expansion of $u$ is $\eta_u = a0b0b00a$.

An embedding of $u$ into $w$ is an expansion $\eta_{uw}$ of $u$ which has length $|w|$ and satisfies

$$\eta_{uw}(i) = w(i) \text{ for all } i \in \text{Supp} \eta_{uw}.$$ 

Note that $u \leq w$ in $A^*$ if and only if there is an embedding of $u$ into $w$. The example expansion $\eta_{uw}$ given above is exactly the embedding which corresponds to the subword of $w = aabbbaba$ given at the beginning of the third paragraph of this paper. If $w$ is clear from context we simply write $\eta_u$ for $\eta_{uw}$.

The Möbius function of $A^*$ counts certain types of embeddings. If $a \in A$ then a run of $a$’s in $w$ is a maximal interval of indices $[r, t]$ such that

$$w(r) = w(r + 1) = \ldots = w(t) = a.$$ 

Continuing our example, the runs in $w = aabbbaba$ are $[1, 2]$, $[3, 5]$, $[6, 6]$, $[7, 7]$, and $[8, 8]$. Call an embedding $\eta_u$ into $w$ normal if, for every $a \in A$ and every run $[r, t]$ of $a$’s, we have

$$(r, t] \subseteq \text{Supp} \eta_u$$ 

where $(r, t]$ denotes the half-open interval. In our running example, this means that the second $a$ and the fourth and fifth $b$’s must be in any normal embedding. (If $r = t$ then $(r, t] = \emptyset$, so there is no restriction on runs of one element.) Thus in this case there are precisely two normal embeddings of $u$ into $w$, namely

$$\eta_u = 0a0bba00 \text{ and } 0a0bb00a.$$ 

Define $\binom{w}{u}_n$ to be the number of normal embeddings of $u$ into $w$.

We now have everything in place to state Björner’s result.

**Theorem 1.1 (Björner [4]).** If $u, w \in A^*$ then

$$\mu(u, w) = (-1)^{|w|-|u|} \binom{w}{u}_n.$$ 

Finishing our example, we see that

$$\mu(abba, aabbbaba) = (-1)^{8-4} \cdot 2 = 2.$$ 

We now turn to $P^*$. The definitions of support and expansion are exactly as before, but the notion of embedding must be updated to reflect the different partial order. To this end we define an embedding of $u$ into $w$ as an expansion $\eta_u$ of $u$ having length $|w|$ such that

$$\eta_u(i) \leq w(i) \text{ for } 1 \leq i \leq |w|.$$
Again, \( u \leq w \) in \( \mathbb{P}^* \) is equivalent to the existence of an embedding of \( u \) into \( w \). An interval in \( \mathbb{P}^* \) is displayed in Figure 2.

If \( u \leq w \) and \( \eta_w \) is an expansion of \( w \) then there is a unique last or rightmost embedding \( \rho_{uw} \) of \( u \) into \( \eta_w \) which has the property that for any other embedding \( \eta_{uw} \) of \( u \) into \( \eta_w \) one has \( \text{Supp}(\eta_{uw}) \leq \text{Supp}(\rho_{uw}) \). (If \( S = \{i_1, \ldots, i_m\} \) and \( S' = \{i'_1, \ldots, i'_m\} \) then we write \( S \leq S' \) to mean that \( i_j \leq i'_j \) for \( 1 \leq j \leq m \).) Note that \( \rho_{uw} \) depends on \( \eta_w \), not just on \( w \), but the expansion of \( w \) used will always be clear from context.

Like subword order, we define normal embeddings for \( \mathbb{P}^* \) in terms of runs (defined in the same way in this context). We say that an embedding \( \eta_u \) into \( w \) is normal if the following conditions hold.

1. For \( 1 \leq i \leq |w| \) we have \( \eta_u(i) = w(i), w(i) - 1, \) or 0.

2. For all \( k \geq 1 \) and every run \([r, t]\) of \( k \)'s in \( w \), we have
   
   \[
   \text{(a) } (r, t] \subseteq \text{Supp} \eta_u \text{ if } k = 1, \\
   \text{(b) } r \in \text{Supp} \eta_u \text{ if } k \geq 2.
   \]

Comparing this with Björner’s definition, we see that in \( \mathbb{P}^* \) a normal embedding can have three possible values at each position instead of two. Also, the run condition for ones is the same as in \( A^* \), while that condition for integers greater than one is complementary. As an example, if \( w = 2211133 \) and \( u = 21113 \), then there are two normal embeddings, namely \( \eta_u = 2101130 \) and 2011130. Note that 2001113 and 0211130 are not normal since they violate conditions (1) and (2), respectively.

The sign of a normal embedding depends on the embedding itself and not just the length of the compositions. Given a normal embedding \( \eta_u \) into \( w \) we define its defect to be

\[
d(\eta_u) = \#\{i \mid \eta_u(i) = w(i) - 1\}.
\]

We can now state our main theorem about \( \mathbb{P}^* \).

**Theorem 1.2.** If \( u, w \in \mathbb{P}^* \) then

\[
\mu(u, w) = \sum_{\eta_u} (-1)^{d(\eta_u)}
\]

where the sum is over all normal embeddings \( \eta_u \) into \( w \).

In the example of the previous paragraph, this gives

\[
\mu(21113, 2211133) = (-1)^2 + (-1)^0 = 2.
\]

Although this example does not show it, it is possible to have cancellation among the terms in the sum for \( \mu \).
2 Proof by sign-reversing involution

We now prove Theorem 1.2 using a sign-reversing involution. The proof is similar in nature to Björner’s proof in [5], but is significantly more complicated.

Proof (of Theorem 1.2). If \( u = w \) then there is exactly one normal embedding \( \eta_{uw} \) and it has defect 0. This gives \((-1)^0 = 1 = \mu(w, w)\), as desired.

Now assume that \( u < w = w(1) \cdots w(n) \). Since the Möbius recurrence uniquely defines \( \mu \), it suffices to show that

\[
\sum_{v \in [u, w]} \sum_{\eta_{uw}} (-1)^{\eta_{uw}} = 0,
\]

where the inner sum is over all normal embeddings of \( v \) into \( w \). We prove this by constructing a sign-reversing involution on the set of normal embeddings \( \eta_{uw} \) for \( v \in [u, w] \).

Let \( \rho_{uw} \) denote the rightmost embedding of \( u \) into \( \eta_{uw} \), so for all \( i \in [1, n] \),

\[
\rho_{uw}(i) \leq \eta_{uw}(i) \leq w(i). \tag{1}
\]

Also let \( s \) denote the left-most index where \( \rho_{uw} \) and \( w \) differ, i.e., \( s = \min\{i : \rho_{uw}(i) \neq w(i)\} \). Since \( u < w \), \( s \) must exist, and by the definition of \( s \) we have

\[
\rho_{uw}(i) = \eta_{uw}(i) = w(i) \text{ for all } i \in [1, s). \tag{2}
\]

Set \( k = w(s) \), so \( \eta_{uw}(s) \) is \( k \), \( k - 1 \), or 0 by normality and \( \rho_{uw}(s) \leq k - 1 \). Finally, let \([r, t]\) denote the indices of the run of \( k \)’s in \( w \) that contains the index \( s \).

Our involution maps \( \eta_{uw} \) to the embedding \( \eta_{uw} = \eta_{uw}(1) \cdots \eta_{uw}(n) \) where \( \eta_{uw}(i) = \eta_{uw}(i) \) for all \( i \neq s \) and \( \eta_{uw}(s) \) is determined by the following rules. If \( k = 1 \) then

\[
\eta_{uw}(s) = \begin{cases} 
0 & \text{if } \eta_{uw}(s) = 1, \\
1 & \text{if } \eta_{uw}(s) = 0.
\end{cases} \tag{3}
\]

If \( k \geq 2 \), \( s > r \), and \( \rho_{uw}(s) = 0 \) then

\[
\eta_{uw}(s) = \begin{cases} 
0 & \text{if } \eta_{uw}(s) = k - 1, \\
k - 1 & \text{if } \eta_{uw}(s) = 0.
\end{cases} \tag{4}
\]

Finally, if \( k \geq 2 \) and either \( s = r \) or \( \rho_{uw}(s) \neq 0 \) then

\[
\eta_{uw}(s) = \begin{cases} 
k - 1 & \text{if } \eta_{uw}(s) = k, \\
k & \text{if } \eta_{uw}(s) = k - 1.
\end{cases} \tag{5}
\]

It is not obvious that this map is defined for all normal embeddings \( \eta_{uw} \) when \( k \geq 2 \). For example, if \( s > r \) and \( \rho_{uw}(s) = 0 \), then we should apply (4), but it is a priori possible that \( \eta_{uw}(s) = k \), in which case (4) is not defined. However, since \( s > r \), \( \rho_{uw}(s - 1) = w(s - 1) = k \) by (2), and this contradicts our choice of \( \rho_{uw} \) as the rightmost embedding of \( u \) into \( \eta_{uw} \). Similar issues arise when \( s = r \) or \( \rho_{uw}(s) \neq 0 \): if \( s = r \) then \( \eta_{uw}(s) \neq 0 \) by normality, and if \( \rho_{uw}(s) \neq 0 \) then \( \eta_{uw}(s) \neq 0 \) by (1).

Having established that this map is indeed defined on all normal embeddings, we have several properties to prove. First, it is evident from (3), (4), and (5) that the number
of elements equal to \( k - 1 \) changes by exactly one in passing from \( \eta_{uw} \) to \( \eta_{vw} \), and thus \((-1)^{\eta_{vw}} = -(-1)^{\eta_{uw}}\). We must now prove that \( \eta_{vw} \) is a normal embedding of \( \overline{v} \) into \( w \) for some \( \overline{v} \in [u, w] \) and that this map is an involution.

We begin by showing that \( \eta_{vw} \) is an embedding of some \( \overline{v} \in [u, w] \) into \( w \). It follows from the fact that \( \eta_{uw} \) is an embedding into \( w \) and the definition of our map that \( \eta_{vw} \) is an embedding of some word \( \overline{v} \) into \( w \), so we only need to show that \( \overline{v} \geq u \). We prove this by showing that

\[
\eta_{vw}(i) \geq \rho_{uv}(i)
\]

for all \( i \in [1, n] \). This is clear for all \( i \neq s \) because for these indices \( \eta_{vw}(i) = \eta_{uw}(i) \geq \rho_{uv}(i) \).

Furthermore, \( \rho_{uv}(s) \leq k - 1 \) by the definition of \( s \), so the only case in which (6) is not immediate is when \( k \geq 2 \) and \( \eta_{uw}(s) = 0 \). However, this can only occur from using (4), which requires that \( \rho_{uw}(s) = 0 \), completing the demonstration that \( \overline{v} \in [u, w] \).

We now aim to show that \( \eta_{vw} \) is a normal embedding. If \( \eta_{vw}(s) > 0 \) then \( \text{Supp}(\eta_{vw}) \supseteq \text{Supp}(\eta_{uw}) \), so the normality of \( \eta_{uw} \) follows from the normality of \( \eta_{vw} \) and the fact that \( \eta_{uw}(s) \) is either \( k - 1 \) or \( k \). If \( \eta_{uw}(s) = 0 \) then there are two cases depending on whether (3) or (4) was applied. Suppose first that (3) was applied, so \( k = 1 \). Comparing (3) with the definition of normality, we see that it suffices to show \( s = r \). Suppose to the contrary that \( s \in (r, t] \). Since \( s \) is the left-most position at which \( \rho_{uv} \) and \( w \) differ, we have \( \rho_{uw}(s) = 0 \) and \( \rho_{uw}(s - 1) = 1 \). However, this contradicts our choice of \( \rho_{uw} \) as the rightmost embedding of \( u \) in \( \eta_{uw} \). Now suppose that (4) was applied, so \( s > r \) and \( \rho_{uw}(s) = 0 \). Then (2) implies that \( \eta_{uw}(r) = \eta_{uw}(r) = k \), and normality is preserved.

It only remains to show that this map is an involution. Consider applying the map to \( \eta_{vw} \). In this process we define \( \rho_{vw} \) to be the rightmost embedding of \( u \) into \( \eta_{vw} \), \( \overline{s} = \min\{i : \rho_{vw}(i) \neq w(i)\} \), and \( \overline{k} = w(\overline{s}) \). We then follow the rules (3), (4), and (5) to construct an embedding \( \eta_{vw} \), which we would like to show is equal to \( \eta_{uw} \).

First we claim that \( \rho_{vw} = \rho_{uw} \). Suppose to the contrary that \( \rho_{vw} \neq \rho_{uw} \). By (6), \( \eta_{vw}(i) \geq \rho_{uw}(i) \) for all \( i \), so \( \rho_{uw} \) also gives an embedding of \( u \) into \( \overline{v} \), and thus the only way we can have \( \rho_{uw} \neq \rho_{vw} \) is if \( \rho_{uw} \) is further to the right than \( \rho_{uw} \). This requires that

\[
0 = \rho_{uw}(s) < \rho_{vw}(s) \leq k
\]

and that

\[
\eta_{uw}(s) < \eta_{vw}(s).
\]

Because we are assuming that \( \rho_{vw} \) is further to the right than \( \rho_{uw} \), there is some position to the left of \( s \) at which \( \rho_{uw} \) is nonzero. In fact, (2) shows that we must have \( \rho_{uw}(s - 1) \neq 0 \) and also implies that

\[
\eta_{uw}(s) < \rho_{uw}(s) = \rho_{uw}(s - 1) = w(s - 1).
\]

We now consider the three cases arising from each of the rules (3), (4), and (5) in turn.

Suppose (3) was applied so \( k = 1 \). It follows from (8) and the definition of our map that \( \eta_{uw}(s) = 0 \). Also (7) and (9) give \( w(s - 1) = \rho_{vw}(s) = 1 \). But then \( \eta_{uw} \) zeroed out a 1 which was not the first in its run, contradicting normality.

Now suppose (4) was applied. Then by (8) we have \( \eta_{vw}(s) = k - 1 \). We also have \( s > r \) which in conjunction with (9) gives \( \rho_{vw}(s) = w(s - 1) = k \). This implies that \( \eta_{vw}(s) < \rho_{uw}(s) \), but that contradicts the \( \overline{v} \) version of (1).
Finally suppose that (5) was used. By (7) it must be the case that $s = r$. Also, equation (8) gives $\eta_{vw}(s) = k - 1$ and $\eta_{vw}(s) = k$. Now applying (7) and (9) we have $k - 1 < w(s - 1) = \rho_{uv}(s) \leq k$, so $w(s - 1) = k$ which contradicts that fact that $s = r$.

Now that we have established the equality of $\rho_{uv}$ and $\rho_{wu}$, the fact that this map is an involution can be readily observed. We must have $\overline{s} = s$, so $\overline{k} = k$, and thus we apply the same rule to go from $\eta_{vw}$ to $\eta_{uw}$ as we applied to get $\eta_{uw}$ from $\eta_{vw}$, and each of these rules is clearly an involution. \hfill \square

3 Introduction to discrete Morse theory

In this section we review the basic ideas behind Forman’s discrete Morse theory [13, 14] as well as Babson and Hersh’s method for applying the theory to the order complex of a poset [1].

Let $X$ be a CW-complex. Since we will be working in reduced homology, we assume that $X$ has an empty cell $\emptyset$ of dimension $-1$ which is contained in every cell of $X$. If $\sigma$ is a $d$-cell (cell of dimension $d$) in $X$ then let $\sigma^0$ be the set of $(d - 1)$-cells $\tau$ which are contained in the closure $\overline{\sigma}$. Dually, let $\sigma^d$ denote the set of $(d + 1)$-cells $\tau$ such that $\sigma \subset \overline{\tau}$.

A real-valued function $f$ on the cells of $X$ is a Morse function if it satisfies the following two conditions.

1. For every cell $\sigma$ of $X$ we have
   
   (a) $\# \{ \tau \in \sigma^0 \mid f(\tau) \geq f(\sigma) \} \leq 1$, and
   
   (b) $\# \{ \tau \in \sigma^d \mid f(\tau) \leq f(\sigma) \} \leq 1$.

2. If $\tau \in \sigma^d$ and $f(\tau) \leq f(\sigma)$ then $\sigma$ is a regular face of $\tau$.

Intuitively the first condition says that, with only certain exceptions, $f$ increases with dimension. In fact, $f(\sigma) = \dim \sigma$ is a perfectly good Morse function on $X$, although we will see shortly that it is not very interesting. A simple example of a Morse function on a CW-complex is given in Figure 1 where the value of $f$ is given next to each cell $\sigma$ and we also set $f(\emptyset) = -1$. 

Figure 1: A Morse function on a CW-complex
The fact that condition (1) holds for every cell implies that, in fact, at most one of the two sets under consideration has cardinality equal to 1. Thus the function $f$ induces a Morse matching between pairs of cells $\sigma, \tau$ with $\sigma \in \tau^d$ and $f(\sigma) \geq f(\tau)$. The regularity condition ensures that for each such pair there is an elementary collapse of $\overline{\tau}$ onto $\overline{\tau} - (\tau \cup \sigma)$. The cells which are not matched by $f$ are called critical. Since each collapse is a homotopy equivalence, $X$ can be collapsed onto a homotopic complex $X^f$ built from the critical cells. The cells which are not matched by $f$ are called critical.

Let $\tilde{m}_d$ be the number of critical $d$-cells of $X$ and let $\tilde{b}_d$ be the $d$-th reduced Betti number over the integers. We also use $\tilde{\chi}(X)$ for the reduced Euler characteristic. From the considerations in the previous paragraph, we have the following Morse inequalities which are analogous to those in traditional Morse theory.

**Theorem 3.1 (Forman [14]).** For any Morse function on a cell complex $X$ we have

1. $\tilde{b}_d \leq \tilde{m}_d$ for $d \geq -1$, and
2. $\tilde{\chi}(X) = \sum_{d \geq -1} (-1)^d \tilde{m}_d$.

(One can get further inequalities relating various partial alternating sums of the $\tilde{b}_d$ and $\tilde{m}_d$.) Continuing our example, we see that $\tilde{m}_{-1} = \tilde{m}_0 = \tilde{m}_1 = 1$ which bound $\tilde{b}_{-1} = \tilde{b}_0 = 0$ and $\tilde{b}_1 = 1$, as well as $\tilde{\chi}(X) = -1 + 1 - 1 = -1$, as expected.

We now turn to the special case of order complexes. Let $P$ be a poset and consider an open interval $(u, w)$ in $P$. The corresponding order complex $\Delta(u, w)$ is the abstract simplicial complex whose simplices (faces) are the chains in $(u, w)$. We are interested in the order complex because of the fundamental fact [19] that

$$\mu(u, w) = \tilde{\chi}(\Delta(u, w)).$$

(10)

Therefore finding a Morse function for $\Delta(u, w)$ could permit us to derive the corresponding Möbius value as well as give extra information about its Betti numbers. Suppose we have an ordering of the maximal chains of $(u, w)$ (facets of $\Delta(u, w)$), say $C_1, C_2, \ldots, C_l$. Call a face (subchain) $\sigma$ of $C_k$ new if it is not contained in any $C_j$ for $j < k$. We would like to construct a Morse matching inductively, where at the $k$th stage we extend the matching on the faces in $C_j$ for $j < k$ by matching up as many of the new faces $\sigma$ in $C_k$ as possible. It turns out that under fairly mild conditions on the facet ordering, one can construct such a matching so that all the new faces in $C_k$ are matched if there are an even number of them, and only one is left unmatched if the number is odd. Thus adding each facet contributes at most one critical cell. A maximal chain contributing a critical cell is called a critical chain. In reading the details of this construction, the reader may find it useful to refer to the example of the interval $[322, 3322] \subset \mathbb{P}^*$ given in Figure 2. Note that by abuse of notation we include $u$ and $w$ when writing out a maximal chain $C$, even though $C$ is really a subset of the open interval $(u, w)$. Also, because of the way our chain order is constructed, we start...
with the top element \( w \) and work down to \( u \) which is dual to what is done normally. Thus in a chain \( C \), terms like “first” and “last” refer to this ordering of \( C \)’s elements. Finally, we list the elements of a chain as embeddings into \( w \) for reasons which will become apparent when we also describe the labels given to the edges (covers) of a chain.

To define the types of chain orderings we consider, suppose we have two chains \( C : w = v_0 \ldots v_j \ldots u \) and \( C' : w = v'_0 \ldots v'_j \ldots u \) where \( x \) covers \( y \). Then we say that \( C \) and \( C' \) agree to index \( j \) if \( v_i = v'_i \) for \( i \leq j \). In addition, \( C \) and \( C' \) diverge from index \( j \) if they agree to index \( j \) and \( v_{j+1} \neq v'_{j+1} \). In addition, we use the notation \( C' < C \) to mean that \( C' \) comes before \( C \) in the order under consideration. An ordering of the maximal chains of \([u, w]\) is a poset lexicographic order, or PL-order for short, if it satisfies the following condition. Suppose \( C' \) and \( C \) diverge from index \( j \) with \( C' < C \). Then for any maximal chains \( D' \) and \( D \) which agree to index \( j + 1 \) with \( C' \) and \( C \), respectively, we must have \( D' < D \). Note that orderings coming from the EL-labelings introduced by Björner [3] or from the more general CL-labelings of Björner and Wachs [8] are PL-orders as long as one breaks ties among labels consistently.

The PL-order we use in \( \mathbb{P}^* \) is as follows. If \( x \) covers \( y \) then \( y \) is obtained from \( x \) by reducing a single part of \( x \) by 1. Thus there is a unique normal embedding of \( y \) into \( x \), since if a 1 is reduced to 0 then it must be the first element in the run of ones to which it belongs. Similarly, for any expansion \( \eta_x \) there is a unique normal embedding of \( y \) into \( \eta_x \). Now given any chain \( C : w = v_0 \ldots v_j \ldots u \) we inductively associate with each \( v_j \) an embedding \( \eta_{v_j} \) into \( w \) where \( \eta_{v_0} = w \) and, for \( j \geq 0 \), \( \eta_{v_{j+1}} \) is the unique normal embedding

Figure 2: The interval \([322, 3322]\) and its maximal chains
of $v_{j+1}$ into $\eta_{v_j}$. We label the edge $v_j \rightarrow v_{j+1}$ of $C$ with the index $i$ of the position which was decreased in passing from $\eta_{v_j}$ to $\eta_{v_{j+1}}$. Furthermore, we often write $\eta_{v_j}$ in place of $v_j$ when listing the elements of $C$. Figure 2 illustrates this labeling. It is important to note that although $\eta_{v_{j+1}}$ is normal in $\eta_{v_j}$, it need not be normal in $w$. We should also remark that this labeling is similar to the one used by Björner [4] in his CL-shelling of the intervals in subword order. Finally, if one orders the chains of $[u, w]$ using ordinary lexicographic order on their label sequences, then the result is a PL-order. This is due to the fact that if two chains agree to index $j$ then their first $j$ labels are the same. The chains in Figure 2 are listed in PL-order.

We no return to the general exposition. To construct our matching, when we come to a chain $C : w = v_0 \rightarrow v_1 \rightarrow \ldots \rightarrow v_{j-1} u$ in a given order we must be able to determine which faces of $C$ are new. Denote the open interval $I$ from $v_i$ to $v_j$ in $C$ by

$$I = C(v_i, v_j) = v_{i+1} \rightarrow v_{i+2} \rightarrow \ldots \rightarrow v_{j-1}.$$ 

(Do not to confuse this with an open interval in the poset.) Then $I$ is a skipped interval if $C - I \subset C'$ for some $C' < C$. It is a minimal skipped interval or MSI if it does not strictly contain another skipped interval. In Figure 2, the MSI’s are circled. One can find the MSI’s by taking the maximal intervals in $C - (C' \cap C')$ for each $C' < C$ and then throwing out any that are not containment minimal in $C$. Let $\mathcal{I} = \mathcal{I}(C)$ be the set of MSI’s in $C$. Then it is easy to check that a face $\sigma$ is new in $C$ if and only if $\sigma$ has a nonempty intersection with every $I \in \mathcal{I}(C)$.

The set $\mathcal{I}$ in not quite sufficient to construct the matching because the MSI’s can overlap and we will need disjoint intervals. However, there are no containments among the intervals in $\mathcal{I}$, so they can be ordered $I_1, I_2, I_3, \ldots$ according to when they are first encountered on $C$. We now inductively construct a set $\mathcal{J} = \mathcal{J}(C)$ of $J$-intervals as follows. Let $J_1 = I_1$. Then consider the intervals $I_2' = I_2 - J_1, I_3' = I_3 - J_1, \ldots$; throw out any which are not minimal; and pick the first one which remains to be $J_2$. Continue this process until there are no nonempty modified MSI’s left. It happens that in all the critical chains for $\mathbb{P}^*$, the intervals in $\mathcal{I}$ will already be disjoint and so we will not need this step.

We are finally in a position to describe the matching. List the maximal chains of $[u, w]$ using a PL-order. A family $\mathcal{K}$ of intervals of a maximal chain $C$ covers the chain if $C = \cup \mathcal{K}$. There are three cases depending on whether $\mathcal{I}(C)$ or $\mathcal{J}(C)$ covers $C$ or not. First suppose that $\mathcal{I}(C)$ does not cover $C$, so neither does $\mathcal{J}(C)$, and pick $x_0$ to be the first vertex in $C - \cup \mathcal{I}$. Consider the map $\sigma \rightarrow \sigma \Delta \{x_0\}$ where $\Delta$ is symmetric difference (not the order complex). One can show that this map is a fixed-point free involution on the new faces $\sigma$ in $C$ which extends the Morse matching already constructed from the previous chains. Now suppose that $\mathcal{J} = \{J_1, J_2, \ldots, J_r\}$ does cover $C$ and consider the new face $\sigma_C = \{x_1, x_2, \ldots, x_r\}$ where $x_i$ is the first element of $J_i$ for $1 \leq i \leq r$. Given any other new face $\sigma \neq \sigma_C$, we find the interval $J_i$ of smallest index where $\sigma \cap J_i \neq \{x_i\}$ and map $\sigma \rightarrow \sigma \Delta \{x_i\}$. This involution pairs up all new faces in $C$ except $\sigma_C$, which is critical. Finally, suppose that $\mathcal{I}$ covers $C$ but $\mathcal{J}$ does not. Then we use the mapping of the second case to pair up all new faces whose restriction to $\cup \mathcal{J}$ is different from $\sigma_C$. We also pair up the remaining new faces (including $\sigma_C$) by using the mapping of the first case where we take $x_0$ to be the first vertex in $C - \cup \mathcal{J}$. Thus we have outlined the proof of the following theorem, remembering that the dimension of a simplex is one less than its number of vertices.
Theorem 3.2 ([1]). Let \( P \) be a poset and \([u, w]\) be a finite interval in \( P \). For any PL-order on the maximal chains of \([u, w]\), the above construction produces a Morse matching in \( \Delta(u, w) \) with the following properties.

1. The maximal chain \( C \) is critical if and only if \( J \) covers \( C \).

2. If \( C \) is critical then its unique critical cell has dimension \( \#J(C) - 1 \).

4 A Morse theory derivation of \( \mu \)

We are now ready to find the critical cells for the PL-order in \( P^* \) defined previously. We first need three lemmas which will prove useful in a number of cases. Unless otherwise specified, we always use the notation

\[
C : w = v_0 \stackrel{l_1}{\longrightarrow} v_1 \stackrel{l_2}{\longrightarrow} v_2 \cdots \stackrel{l_d}{\longrightarrow} v_d = u
\]

for labeled maximal chains, or

\[
C : w = \eta_{v_0} \stackrel{l_1}{\longrightarrow} \eta_{v_1} \stackrel{l_2}{\longrightarrow} \eta_{v_2} \cdots \stackrel{l_d}{\longrightarrow} \eta_u
\]

if we wish to be specific about the embeddings determined by \( C \). We also use \( l(C) = (l_1, l_2, \ldots, l_d) \) for its label sequence.

Take an interval \([u, w] \subset P^*\) with \(|u| = |w|\) and let \( m_i = w(i) - u(i) \). Now consider the multiset \( M_{uw} = \{\{1^{m_1}, 2^{m_2}, \ldots\}\} \) where \( i^{m_i} \) means that \( i \) is repeated \( m_i \) times. Then every permutation of \( M \) is the label sequence for a unique maximal chain in \([u, w]\) and this accounts for all the chains. (In fact, \([u, v]\) is isomorphic to the poset of submultisets of \( M_{uw} \).) We record this simple observation for later reference.

Lemma 4.1 (Same Length Lemma). If \(|u| = |w|\) then the label function \( l \) gives a bijection between the maximal chains in \([u, w]\) and the permutations of \( M_{uw} \). In particular, if \( M_{uw} \) contains only one distinct element (possibly with multiplicity) then \([u, w]\) contains a unique maximal chain. \( \square \)

If \(|u| < |w|\) then we no longer have the nice bijection of the previous paragraph, but we can still say something. Let \( C \) be a maximal chain as in (11) and let \( l' = (l'_1, \ldots, l'_d) \) be any permutation of the label sequence \( l(C) \). Then \( l' \) defines a sequence of expansions \( \eta_{v_0}', \eta_{v_1}', \ldots, \eta_{v_d}' \) where \( \eta_{v_0}' = w \) and for \( j \geq 1 \) we get \( \eta_{v_j}' \) from \( \eta_{v_{j-1}}' \) by subtracting one from position \( l'_{j} \) in \( \eta_{v_{j-1}}' \). It is still true that \( C' : w = v'_0 \stackrel{l'_1}{\longrightarrow} v'_1 \cdots \stackrel{l'_d}{\longrightarrow} v'_d = u \) is a maximal chain in \([u, w]\). We call \( C' \) the chain specified by \( l' \). Since \( \eta_{v_j}' \) may not be a normal embedding in \( \eta_{v_{j-1}}' \), we may not have \( l(C') = l' \). Still, at the first place where \( l(C') \) and \( l' \) differ, that difference must have been caused because using the label in \( l' \) would have resulted in changing a 1 to a 0 where that 1 was not the first in its run. Thus the corresponding normal embedding in \( l(C') \) uses the first 1 in that run which is to the left. Hence \( l(C') \leq l' \) in lexicographic order. We summarize this discussion in the following lemma.
Lemma 4.2 (Chain Specification Lemma). If $C$ is a maximal chain in $[u, w]$ and $l'$ is any permutation of $l(C)$ then $l(C') \leq l'$ where $C'$ is the chain specified by $l'$.

As our first application of the Chain Specification Lemma, we can determine what happens at descents. A descent of $C$ is $v_j \in C$ such that $l_j > l_{j+1}$. An ascent is defined by reversing the inequality.

Lemma 4.3 (Descent Lemma). If $v_j$ is a descent of $C$ then it is an MSI.

Proof. Let $l'$ be the permutation of $l(C)$ gotten by interchanging $l_j$ and $l_{j+1}$ and let $C'$ be the chain specified by $l'$. Then by Lemma 4.2 we have $l(C') \leq l' < l(C)$, so $C'$ comes before $C$ in PL-order and it is easy to check that $C'$ diverges from $C$ at $v_{j-1}$ and rejoins $C$ at $v_{j+1}$. Thus $\{v_j\}$ is a skipped interval; and since the interval contains only one element it must also be minimal.

We only need a few more definitions to state our result characterizing the critical chains. A chain $C$ will be said to have a certain property, e.g., weakly decreasing, if $l(C)$ has that property. Also, if $\eta_u$ is a normal embedding into $w$ then we need to keep track of the zero positions which did not come from decreasing a 1 in $w$ by letting

$$D(\eta_u) = \# \{ i \mid \eta_u(i) = 0, \ w(i) \geq 2 \}.$$ 

Theorem 4.4. Consider the maximal chains in $[u, w] \subset \mathbb{P}^*$ in the given PL-order.

1. There is a bijection between critical chains $C$ and normal embeddings $\eta_u$ into $w$ where the chain corresponding to $\eta_u$ is the unique weakly decreasing chain ending at $\eta_u$.

2. If $C$ is critical and ends at $\eta_u$ then $\mathcal{I}(C) = \mathcal{J}(C)$ and

$$\# \mathcal{I}(C) = d(\eta_u) + 2D(\eta_u) - 1.$$ 

We shall prove this theorem by considering 3 cases: when $C$ is weakly decreasing and ends at a normal embedding, when $C$ is weakly decreasing and does not end at a normal embedding, and when $C$ is not weakly decreasing. Note that for any embedding $\eta_u$ into $w$, there is at most one decreasing chain ending at $\eta_u$, and that if $\eta_u$ is normal then such a chain will exist because it will be possible to make each cover normal. Thus there is a bijection between normal embeddings and weakly decreasing chains ending at them, but we need to show such chains are critical. To do so, we define a plateau of $C$ to be an interval $C(v_i, v_j)$ such that $(l_{i+1}, l_{i+2}, \ldots, l_j)$ is a run of length at least 2 in $l(C)$.

Proposition 4.5. If $C$ is weakly decreasing and ends at a normal embedding $\eta_u$ then $C$ is critical, $\mathcal{I}(C) = \mathcal{J}(C)$, and $\# \mathcal{I}(C) = d(\eta_u) + 2D(\eta_u) - 1$.

Proof. Every descent is an MSI of $C$ by the Descent Lemma, so any other MSI must be contained in a plateau by minimality. In fact, we claim that any plateau $C(v_i, v_j)$ is an MSI. Without loss of generality we can assume $v_i = w$ (since otherwise $v_i$ is a descent and so no MSI can contain it) and $v_j = u$.

To show $C = C(w, u)$ is a skipped interval, first note that by construction $l(C)$ consists of $c$ repeated $k = j - i \geq 2$ times, so $w(c) = \eta_u(c) + k$. Thus by normality and the fact that
\[ k \geq 2 \text{ we get } \eta_u(c) = 0 \text{ and } w(c) = k. \text{ Using normality again implies that } c \text{ cannot be the first element in its run of } k\text{'s in } w, \text{ and thus } w(c - 1) = k. \text{ Because of this, there is a chain } C' \text{ from } w \text{ to } u \text{ all of whose labels are } c - 1. \text{ By construction } C' < C \text{ and } C \cap C' = \emptyset, \text{ so } C \text{ is a MSI as desired.}

To show the plateau is minimal suppose, to the contrary, that there is a skipped interval \( I \subset C \) and let \( w = v_0, u = v_j \). Note that because \( |v_0| = |v_1| = \ldots = |v_{j-1}| \), the Same Length Lemma applies to show that there is only one chain (namely an interval of \( C \)) between any two of these compositions. Thus the chain \( C' \) giving rise to \( I \) must rejoin \( C \) at an embedding \( \eta'_u \) of \( u \) into \( w \), and hence also contain \( v_1 \) in order to cut out a proper subinterval. From this and normality of \( \eta_u \) we have

\[ \eta'_u(c) < k = w(c - 1) = \eta_u(c - 1). \tag{13} \]

Also, \( |u| = |w| - 1 \) implies that \( C' \) must zero out exactly one element of \( w \). Since \( C' < C \), that element must be in a position strictly to the left of position \( c \). But then because \( \eta_u \) and \( \eta'_u \) are both expansions of \( u \) we are forced to have \( \eta_u(c - 1) = \eta'_u(c) \), contradicting (13).

Now we know that \( J(C) \) consists of the descents and plateaus of \( C \) which are disjoint and cover \( C \) by their definition, so \( J(C) = I(C) \) and \( C \) is critical by Theorem 3.2. To count the number of MSI’s, note that if \( c \) is a position counted by \( d(\eta_u) \) then the vertex just before the edge labeled \( c \) in \( C \) will be a descent, unless that edge is the very first one. On the other hand, if \( c \) is counted by \( D(\eta_u) \) then the run of \( c \)'s in \( l(C) \) contribute both a plateau and a descent just before the plateau to \( I \) (unless the run is at the beginning of \( C \) when only the plateau will be an interval). In this manner we count each MSI exactly once for a total of \( d(\eta_u) + 2D(\eta_u) - 1 \) intervals. \hfill \Box

**Proposition 4.6.** If \( C \) is weakly decreasing and ends at an embedding \( \eta_u \) which is not normal then \( C \) is not critical.

**Proof.** As in the proof of the previous proposition, it suffices to consider the case where \( l(C) \) consists of a label \( c \) repeated \( k \geq 2 \) times so that \( w(c) = \eta_u(c) + k \). If \( \eta_u(c) > 0 \) then \( |w| = |u| \) and so the Same Length Lemma applies to show that \( C \) is the only chain from \( w \) to \( c \). In particular, it is the lexicographically first chain and thus not critical.

If \( \eta_u(c) = 0 \) then \( w(c) = k \) and, since \( \eta_u \) is not normal, it must be that \( c \) is the first index in this run of \( k \)'s in \( w \). Let

\[ \eta_u(c - 1) = w(c - 1) = h \neq k. \tag{14} \]

To demonstrate that \( C \) is not critical, it suffices to show that there is no MSI \( I \) containing the element \( v_1 \) in \( C \). Suppose, to the contrary that such an interval \( I \) exists and let \( C' \) be a chain giving rise to \( I \). Using the Same Length Lemma as in the proof of Proposition 4.5 (third paragraph) we see that \( C' \) must rejoin \( C \) at \( u \) and this forces \( I = C(w, u) \).

To finish the proof, it suffices to find a skipped interval \( I'' \subset I \) since that will contradict the minimality of \( I \). Let \( b \) be the smallest label in \( l(C') \). Then \( b < c \) since \( l(C') < l(C) = (c^k) \). Now using the same argument as at the end of the third paragraph of the previous proposition as well as equation (14) gives

\[ \eta'_u(c) = \eta_u(c - 1) = h \neq k = w(c). \]
Since the parts of a composition can only (weakly) decrease along a chain, we must have \( \eta_u'(c) < w(c) \). It follows that \( c \) is a label on \( C' \). Now consider any permutation of \( l(C') \) which starts \( l'' = (c, b, \ldots) \) and let \( C'' \) be the chain specified by \( l'' \). Then by construction and the Chain Specification Lemma \( l(C'') \leq l'' < l(C) \). This implies that \( C'' < C \) in PL-order and, by construction again, \( C'' \) contains \( v_1 \). Thus no MSI of \( C \) can contain \( v_1 \), a contradiction. \( \square \)

Our third and final proposition completes the proof of Theorem 4.4

**Proposition 4.7.** If \( C \) is not weakly decreasing then \( C \) is not critical.

**Proof.** If \( C \) is not weakly decreasing then it has an ascent \( v \). It suffices to show that \( v \) is in no MSI. Suppose, to the contrary, that \( v \) is in an MSI \( I = C(v_i, v_j) \). Then by the Descent Lemma, \( I \) contains no descents and so \( C \) is weakly increasing from \( v_i \) to \( v_j \). But as in the previous two proofs, it is no loss of generality to assume \( v_i = w \) and \( v_j = u \) so that \( C \) is itself an MSI.

Since \( C \) is an MSI, it is not the first chain in \([u, w]\). That first chain is the unique weakly increasing chain which ends at the rightmost embedding \( \rho_u \) of \( u \) into \( w \). Thus if \( \eta_u \) is the embedding defined by \( C \) then we must have \( \eta_u \neq \rho_u \).

For \( \eta_u \) define

\[
z_\eta(j) = \#\{i \leq j \mid \eta_u(i) = 0\}
\]

and similarly define \( z_\rho(j) \) for \( \rho_u \). Because \( \rho_u \) is rightmost we always have \( z_\rho(j) \geq z_\eta(j) \) with equality when \( j = |w| \). But \( \rho_u \) is not equal to \( \eta_u \), so there is an index \( a \) such that \( z_\rho(a) > z_\eta(a) \). Thus there is a first index \( c > a \) such that \( z_\rho(c) = z_\eta(c) \). This definition of \( c \) forces \( \eta_u(c) = 0 \) and \( \rho_u(c) = k \) for some \( k > 0 \). But \( \eta_u \) and \( \rho_u \) are embeddings of the same composition, so there must be some index \( b \) with \( a \leq b < c \) such that \( \eta_u(b) = \rho_u(c) = k \) and \( \eta_u(i) = 0 \) for \( b < i \leq c \).

We can now derive a contradiction by constructing a smaller skipped interval in \( C \) as follows. We have \( w(c) \geq \rho_u(c) = k \) and \( \eta_u(c) = 0 \). Since \( C \) is weakly increasing, the labels equal to \( c \) must occur as a plateau. Therefore there must be vertices \( w', u' \in C \) such that \( I' = C(w', u') \) satisfies \( \eta_{w'}(c) = k \), \( \eta_{w'}(c) = 0 \), and \( l(I') = (c^k) \). But

\[
\eta_{w'}(i) = \eta_{w'}(i) = \eta_u(i) = \begin{cases} k & \text{if } i = b, \\ 0 & \text{if } b < i < c, \end{cases}
\]

so there is a chain \( C' \) from \( w' \) to \( u' \) with \( l(C') = (b^k) \). Since \( b < c \), \( I' \) is a skipped interval and we have obtained the desired contradiction. \( \square \)

We can now rederive the formula for \( \mu(u, w) \) in \( \mathbb{P}^* \). Combining equation (10) with Theorems 3.1, 3.2, and 4.4 we obtain

\[
\mu(u, w) = \tilde{\chi}(u, w) = \sum_C (-1)^{\dim \sigma_C} = \sum_{\eta_u} (-1)^{d(\eta_u) + 2D(\eta_u) - 2} = \sum_{\eta_u} (-1)^{d(\eta_u)}
\]

where the first sum is over all critical chains \( C \) in \((u, w)\) and the other two are over all normal embeddings \( \eta_u \) into \( w \).

We end this section by remarking that the Morse method can be used as a powerful tool not just for proving theorems but for discovering the correct statement to be proved. The
reader may have found our definition of a normal embedding somewhat ad hoc. However, by
starting with the very natural chain labeling used above and looking at the critical chains,
one is quickly led to this definition in order to characterize the embeddings at which such
chains end. Similarly, the defect may seem to have come out of nowhere, but in order to
determine the dimension of the critical cells one is forced to define this quantity as well as
its big brother $D(\eta_u)$.

5 Generalized subword order

We can now generalize both our result and Björner’s as follows. Let $(P, \leq_P)$ be any poset.

**Generalized subword order** is the partial order on $P^*$ obtained by saying that $u \leq_P^* w$ if $w$
contains a subsequence $w(i_1), w(i_2), \ldots, w(i_l)$ such that $u(j) \leq_P w(i_j)$ for $1 \leq j \leq l = |u|$. We
get ordinary subword order when $P = A$ is an antichain and we get the composition
poset when $P = \mathbb{P}$.

It is a simple matter to recast this generalized order in terms of embeddings. Let $\hat{0}$ be
a special element which is not in $P$ and let $\hat{P}$ be the poset obtained by adjoining $\hat{0}$ as a
minimum element, i.e., $\hat{0} <_P x$ for all $x \in P$. Then the definitions of support and expansion
are as usual, just replacing 0 with $\hat{0}$. An embedding of $u$ into $w$ is a length $|w|$ expansion $\eta_u$
of $u$ with

$$\eta_u(i) \leq_P^* w(i) \text{ for } 1 \leq i \leq |w|.$$ 

As expected, $u \leq_P^* w$ if and only if there is an embedding of $u$ into $w$.

Finding an analogue of normality in this context is more delicate. So far, we have only
been able to do it for a special class of posets. But there is evidence that more general
results are possible; the next section contains a discussion of this issue. First note that the
definition of a run carries over verbatim to any $P^*$. Now call $P$ a **rooted tree** if its Hasse
diagram is a tree with a minimum element. A **rooted forest** is a poset where each connected
component of its Hasse diagram is a rooted tree. Note that both antichains and chains are
rooted forests. Note also that if $P$ is a rooted forest then $\hat{P}$ is a rooted tree so the following
definition makes sense. If $x \in P$ where $P$ is a rooted forest then let $x^-$ be the element
adjacent to $x$ on the unique path from $x$ to $\hat{0}$ in the Hasse diagram for $\hat{P}$. For a rooted
forest, a **normal embedding** of $u$ into $w$ is an embedding $\eta_u$ into $w$ satisfying two conditions.

1. For $1 \leq i \leq |w|$ we have $\eta_u(i) = w(i), w(i)^-, \text{ or } \hat{0}$.

2. For all $x \in P$ and every run $[r, t]$ of $x$’s in $w$, we have

   (a) $[r, t] \subseteq \text{Supp} \eta_u$ if $x$ is minimal in $P$,

   (b) $r \in \text{Supp} \eta_u$ otherwise.

   Finally, we need the definition of **defect** in this situation, which is as expected:

$$d(\eta_u) = \# \{i \mid \eta_u(i) = w(i)^-\}$$

for a normal embedding $\eta_u$ into $w$. The following theorem is the promised generalization of
Theorems 1.1 and 1.2. Both of the two proofs we have given of the special case where $P = \mathbb{P}$
generalize easily, with the minimal elements playing the rôle of 1 and the rest functioning like the integers \( k \geq 2 \).

**Theorem 5.1.** Let \( P \) be a rooted forest. Then the Möbius function of \( P^* \) is given by

\[
\mu(u, w) = \sum_{\eta_u} (-1)^{\eta_u},
\]

where the sum is over all normal embeddings \( \eta_u \) of \( u \) into \( w \). \( \square \)

### 6 Comments and open problems

There are several possible avenues for future research. We discuss some of them here.

#### 6.1 Generating Functions

As mentioned in the introduction, Björner and Reutenauer [6] gave another proof of the formula for \( \mu \) in \( A^* \) using generating functions on monoids. Let \( \mathbb{Z}\langle\langle A \rangle\rangle \) denote the algebra of formal series using the elements in \( A \) as noncommutative variables and the integers as coefficients. Such a series can be written

\[
f = \sum_{w \in A^*} c_w w
\]

for certain \( c_w \in \mathbb{Z} \). For example, given \( u \in A^* \) one can consider the series

\[
m(u) = \sum_{w \geq u} \binom{w}{u} w.
\]

(15)

Björner and Reutenauer showed that (15) is rational for any \( u \) and obtained, upon specialization of the variables, nice expressions for various ordinary generating functions associated with the Möbius function of \( A^* \). They also derived results for the zeta function of \( A^* \). The map \( m : A^* \to \mathbb{Z}\langle\langle A \rangle\rangle \) can be extended to a continuous linear endomorphism of \( \mathbb{Z}\langle\langle A \rangle\rangle \). In fact, the full incidence algebra of \( A^* \) is isomorphic to a subalgebra of this endomorphism algebra. Björner and Reutenauer give another proof of Theorem 1.1 using this fact.

It is natural to try and apply these ideas to \( \mathbb{P}^* \), and more generally to rooted forests. This has been done by Björner and Sagan [7].

#### 6.2 The poset of permutations

Our original interest in \( \mathbb{P}^* \) came from the rapidly growing subject of permutation patterns. For an overview of permutation patterns the reader is referred to Bóna’s text [9]. Let \( S_n \) denote the \( n \)th symmetric group and let \( \pi \in S_n \) and \( \sigma \in S_l \). We say that \( \pi \) contains a \( \sigma \)-pattern, and write \( \pi \geq \sigma \), if there are indices \( i_1 < i_2 < \cdots < i_l \) such that the subsequence \( \pi(i_1)\pi(i_2)\cdots\pi(i_l) \) has the same pairwise comparisons as \( \sigma(1)\sigma(2)\cdots\sigma(l) \). This subsequence is called a copy of \( \sigma \) in \( \pi \). For example, \( 312 \leq 24153 \) because of the copy 413. This is a
Figure 3: The Hasse diagram for the interval \([1, 31524]\) in the pattern containment ordering on permutations

partial order on the set of all finite permutations. Wilf was the first to ask the following question.

« To-do #1: It seems to me that our definition of pattern doesn’t need a one-line notation warning, although our example \(312 \leq \ldots\) might. »

**Question 6.1 (Wilf [26]).** What can be said about the Möbius function of permutations under the pattern-containment ordering?

Given two permutations \(\pi \in S_m\) and \(\sigma \in S_n\), their direct sum is the permutation of length \(m + n\) whose first \(m\) elements form \(\sigma\) and whose last \(n\) elements are the copy of \(\pi\) gotten by adding \(m\) to each element of \(\pi\). For example, \(132 \oplus 32145 = 13265478\). A permutation is said to be layered if it can expressed as the direct sum of some number of decreasing permutations. (An equivalent characterization of layered permutations is that they are the permutations that contain neither a 231-pattern nor a 312-pattern.) Our previous example is layered because \(13254378 = 1 \oplus 21 \oplus 321 \oplus 1 \oplus 1\). Clearly the set of layered permutation of length \(n\) is in bijection with the set of compositions of \(n\). Almost as clearly, this bijection sends the pattern-containment order to the composition order we have considered, so Theorem 1.2 answers Wilf’s question for the set of layered permutations.

Any normal embedding approach to describing the Möbius function for permutations in general must incorporate non-unitary weights, as witnessed by the fact that \(\mu(1, 31524) = 6\).

### 6.3 Factor order

Subword order is not the only partial order on the set of words. We say that the word \(u\) is a factor of the word \(w\) if there exist (possibly empty) words \(v_1\) and \(v_2\) so that \(w = v_1uv_2\), or in other words, if \(u\) occurs as a contiguous subword in \(w\). Björner [5] showed that the Möbius function for factor order only takes on values in \(\{0, \pm 1\}\) and gave a recursive rule that allows the computation of \(\mu(u, w)\) in \(O(|w|^2)\) steps.
The factor order can be defined on $P^*$ for any poset $P$: we say that $u$ is a factor of $w$ if there are words $v_1, v_2, v_3$ such that:

1. $w = v_1v_2v_3$,
2. $|v_2| = |u|$,
3. $u(i) \leq v_2(i)$ for all $1 \leq i \leq |u|$.

Indeed, this is one of the orders on $P^*$ studied by Snellman [20, 21]. The Möbius function of $P^*$ under factor order remains unknown.

### 6.4 Subwords over $\Lambda$

The smallest poset to which Theorem 5.1 is inapplicable is the poset $\Lambda$ depicted in Figure 4. Still, the Möbius function of $\Lambda^*$ seems to be quite interesting. In fact, numerical evidence points to a surprising connection with the Tchebyshev polynomials of the first kind, $T_n(x)$, which can be defined as the unique polynomials such that

$$T_n(\cos \theta) = \cos(n\theta).$$

**Conjecture 6.2.** For all $i \leq j$, $\mu(a^i, c^j)$ is the coefficient of $x^{j-i}$ in $T_{i+j}(x)$.

As with the poset of permutations, a normal embedding interpretation of $\mu(a^i, c^j)$ would need to use weights because, for example, $\mu(a, cc) = -3$.

One possible way to attack this conjecture is to use the three-term recurrence for $T_n(x)$. Translating this in terms of the conjecture, it would suffice to show that

$$\mu(a^i, c^j) = 2\mu(a^i, c^{j-1}) - \mu(a^{i-1}, c^{j-1})$$

for $j \geq i \geq 1$. However, we have not been able to see any relationship between the intervals $[a^i, c^j]$, $[a^i, c^{j-1}]$, and $[a^{i-1}, c^{j-1}]$ which would permit us to derive this relation for their Möbius functions.

There are two closely related areas where the Tchebyshev polynomials have appeared. A permutation $\pi$ avoids a permutation $\sigma$ if it doesn’t contain a $\sigma$-pattern. Chow and West [10] showed that the generating function for the number of elements in $S_n$ avoiding both 132 and 12...k for fixed $k$ can be expressed in terms of Tchebyshev polynomials of the second kind. Mansour and Vainshtein [18] extended this result to count permutations avoiding 132 and containing exactly $r$ copies of 12...k.
More recently, Hetyei [16] defined poset maps $T$ and $U$ which he called Tchebyshev transformations of the first and second kind. This is because when applied to the ladder poset $L_n$, the cd-index of the images can be expressed in terms of $T_n(x)$ and $U_n(x)$. Since the cd-index is related to the Möbius function, it is conceivable that Hetyei’s map could be used to prove our conjecture. But the posets $T(L_n)$ are not isomorphic to any of our intervals $[a',c']$ in general, so it is not clear how to proceed. However, these maps are very interesting in their own right and have been further studied by Ehrenborg and Readdy [11].

Acknowledgment. We are indebted to Patricia Hersh for useful discussions and references.
