No spin-singlet $b\bar{b}$ quarkonium state has yet been observed. In this paper we discuss the production of the singlet P-wave $b\bar{b}$ and $c\bar{c}$ $^{1}P_{1}$ states $h_b$ and $h_c$. We consider two possibilities. In the first the $^{1}P_{1}$ states are produced via the electromagnetic cascades $\Upsilon(3S) \rightarrow \eta_b(2S) + \gamma \rightarrow h_b + \gamma \gamma \rightarrow \eta_b + \gamma \gamma \gamma$ and $\psi' \rightarrow \eta'_c + \gamma \rightarrow h_c + \gamma \gamma \rightarrow \eta_c + \gamma \gamma \gamma$. A more promising process consists of single pion transition to the $^{1}P_{1}$ state followed by the radiative transition to the $^{1}S_{0}$ state: $\Upsilon(3S) \rightarrow h_b + \pi^0 \rightarrow \eta_b + \pi^0 + \gamma$ and $\psi' \rightarrow h_c + \pi^0 \rightarrow \eta_c + \pi^0 + \gamma$. For a million $\Upsilon(3S)$ or $\psi'$'s produced we expect these processes to produce several hundred events.

The study of bound states of heavy quarks has provided important tests of quantum chromodynamics (QCD) [1]. The heavy quarkonium $c\bar{c}$ and $b\bar{b}$ resonances have a rich spectroscopy with numerous narrow $S$, $P$, and $D$-wave levels below the production threshold of open charm and beauty mesons. The spin-triplet $S$-wave states, $\psi(nS)$ and $\Upsilon(nS)$ with $J^{PC} = 1^{--}$, are readily produced by virtual photons in $e^+e^-$ or hadronic interactions, and then undergo electric dipole (E1) transition to the spin-triplet $P$-wave levels. Previous studies have discussed the production of the spin-triplet $D$-wave $b\bar{b}$ states [2, 3] and there has been some discussion of how one might produce the $^{1}P_{1}$ $c\bar{c}$ state [1, 4, 5, 6, 7, 8, 9]. Up to now, the only observed heavy quarkonium spin-singlet state has been the $\eta_c(1S_0)$, but the Belle Collaboration [10] has just announced the discovery of the $\eta'_c(2S_0)$ in $B$ decays at a mass of $(3654 \pm 6 \pm 8)$ MeV/$c^2$. There have also been a few measurements suggesting the $^{1}P_{1}(c\bar{c})$ state in $\bar{p}p$ annihilation experiments [11, 12, 13] but these results have yet to be confirmed. No $b\bar{b}$ spin-singlet states have yet been seen.

The mass predictions for the singlet states are an important test of QCD motivated potential models [14, 15, 16, 17, 18, 19, 20, 21, 22, 23] and the applicability of perturbative quantum chromodynamics to the heavy quarkonia $c\bar{c}$ and $b\bar{b}$ systems

[24, 23, 20, 27], as well as the more recent NRQCD [28] approach. For QCD-motivated
potential models the triplet-singlet splittings test the Lorentz nature of the confining
potential with different combinations of Lorentz scalar, vector, etc., giving rise to different
orderings of the triplet-singlet splittings in the heavy quarkonium P-wave mesons.
Furthermore, the observation of $c\bar{c}$ and $b\bar{b}$ states and the measurement of their masses
is an important validation of lattice QCD calculations [29, 31, 32, 33, 34], which
will lead to greater confidence in their application in extracting electroweak quantities
from hadronic processes. Under the assumption of a Fermi-Breit Hamiltonian and only
vector-like and scalar-like components in the central potential, Stubbe and Martin [35]
predicted that the $n^1P_1$ mass lies no lower than the spin-averaged $^3P_J$ masses (weighted
with the factors $2J + 1$), denoted by $n^3P_cog$. Violation of these bounds would indicate
a significant underestimate by [35] of relativistic effects.

In Table 1 we summarize some predictions for hyperfine mass splittings for P-wave $c\bar{c}$ and $b\bar{b}$ levels. The wide variation in the predicted splittings demonstrates the need
for experimental tests of the various calculational approaches.

There are two possibilities for producing spin-singlet states. In the first, the system
undergoes a magnetic dipole (M1) transition from a spin-triplet state to a spin-singlet
state. The predictions for M1 transitions from the $\Upsilon(n^3S_1)$ levels to the $\eta_c(n^1S_0)$
states, for both favored M1 transitions and hindered M1 transitions with changes of
the principal quantum number, have been reviewed in Ref. [30]. The second route
begins with a hadronic transition, from a $n^3S_1$ state to a $^1P_1$ state, emitting one or
more pions, followed by the electromagnetic decay of the $^1P_1$ state.

In this paper we examine the production of the spin-singlet P-wave $c\bar{c}$ and $b\bar{b}$ states.
We examined the decay chains that start with the $M1$ transition from the $\psi'$ to the
$\eta_c$ in the $c\bar{c}$ system and from the $\Upsilon(3S)$ to either the $\eta_b(3S)$ or $\eta_b(2S)$ state in the
$b\bar{b}$ system. In both cases the $M1$ transition is followed by an $E1$ transition to the
spin-singlet $2P$ or $1P$ state. This is in turn followed by a second $E1$ transition to a
$n^1S_0$ state. In addition, the $2^1P_1$ $b\bar{b}$ state can undergo an $E1$ transition to the $1^1D_2$
state. However, with the current CLEO data set, the only decay chain which has any
hope of being seen in the $b\bar{b}$ system is $\Upsilon(3S) \rightarrow \eta_b(2S)\gamma \rightarrow h_b(1P)\gamma\gamma$. We therefore
only present results relevant to this set of decays.

The decay chains originating with the hadronic transitions are more promising. We
therefore include estimates of branching ratios for chains originating with the direct
hadronic transition $\Upsilon(3S) \rightarrow h_b(1P_1) + \pi^0$ discussed by Voloshin [37] followed by the
radiative decay $h_b(1P_1) \rightarrow \eta_b(1S) + \gamma$ and the analogous transitions in the charmonium
system $\psi'(2S) \rightarrow h_c(1P_1) + \pi^0 \rightarrow \eta_c(1S)\gamma\pi^0$. Kuang and Yan [38]
have also considered the related spin-flip transition $\Upsilon(3S) \rightarrow h_b(1P_1) + \pi\pi$ which may provide an additional
path to the $h_b$.

Searches for the $^1P_1$ states have taken on renewed interest because of the current
data-taking runs of the CLEO Collaboration at the Cornell Electron Storage Ring
(CESR), which are expected to significantly increase their sample of data at the $\Upsilon(3S)$
resonance, and the proposed CLEO-c project which will study physics in the charmonium
system.

We begin with the $b\bar{b}$ mesons and decay chains involving only radiative transitions.

To estimate the number of events expected from these decay chains we need to estimate the radiative partial decay widths between states and the hadronic partial widths of the appropriate $1^1S_0$ and $1^1P_1$ states.

The $M1$ transitions from the $\Upsilon(3S)$ to the $\eta_b(3S)$ and $\eta_b(2S)$ were studied in detail in Ref. [36], which we will use in what follows. The $E1$ transitions are straightforward to work out [2] and in the nonrelativistic limit are given by

\begin{align*}
\Gamma(1^1S_0 \rightarrow 1^1P_1 + \gamma) &= \frac{4}{3} \alpha e_Q^2 \omega^3 |\langle 1^1P_1 | r | 1^1S_0 \rangle|^2 \\
\Gamma(1^1P_1 \rightarrow 1^1S_0 + \gamma) &= \frac{4}{9} \alpha e_Q^2 \omega^3 |\langle 1^1S_0 | r | 1^1P_1 \rangle|^2 \\
\Gamma(1^1P_1 \rightarrow 1^1D_2 + \gamma) &= \frac{8}{9} \alpha e_Q^2 \omega^3 |\langle 1^1D_2 | r | 1^1P_1 \rangle|^2
\end{align*}

where $\alpha = 1/137.036$ is the fine-structure constant, $e_Q$ is the quark charge in units of $|e| (-1/3$ for $Q = b)$, and $\omega$ is the photon’s energy. The photon energies, overlap integrals, and partial widths for the $E1$ transitions between $1^1P_1$ and $1^1S_0$ levels are given in Table II and summarized in Fig. 1, along with the relevant $M1$ transitions. The $n^1S_0$ masses were obtained by subtracting the predictions of Ref. [14] for the $n^3S_1 - n^1S_0$ splittings from the measured $n^3S_1$ masses, while the $n^1P_1$ masses were obtained by subtracting the predictions for the $n^3P_{cog} - n^1P_1$ splittings of Ref. [14] from measured $n^3P_{cog}$ values. The overlap integrals, $\langle r \rangle \equiv \langle 1^1L_L | r | 1^1L_L \rangle$, were evaluated using the wavefunctions of Ref. [14]. We found that the relativistic effects considered in Ref. [14] reduce the partial widths by a few percent at most. Somewhat larger matrix elements were obtained in an inverse-scattering approach [2], except for the highly suppressed $3S \rightarrow 1P$ transition, whose matrix element is very sensitive to details of wave functions [39].

To estimate the number of events in a particular decay chain requires branching fractions which depend on knowing all important partial decay widths. Inclusive strong decays to gluon and quark final states generally make large contributions to the total
Figure 1: Radiative transitions in the $b\bar{b}$ system. The dashed lines represent $M1$ transitions, the solid lines $E1$ transitions and the dotted lines single $\pi^0$ emission. The transitions are labelled with their partial widths given in keV.
width and have been studied extensively [10, 11, 12, 13, 14, 15]. The relevant theoretical
expressions, including leading-order QCD corrections [11], are summarized in Ref. [14]:
\[
\Gamma(1S_0 \to gg) = \frac{8\pi\alpha_s^2}{3m_Q^2} |\psi(0)|^2
\]
(4)
with a multiplicative correction factor of \((1 + 4.4\frac{\alpha_s}{\pi})\) for \(b\bar{b}\) and \((1 + 4.8\frac{\alpha_s}{\pi})\) for \(c\bar{c}\),
\[
\Gamma(1P_1 \to ggg) = \frac{20\alpha_s^3}{9\pi m_Q^4} |R_{P'}(0)|^2 \ln(m_Q \langle r \rangle)
\]
(5)
and
\[
\Gamma(1P_1 \to gg + \gamma) = \frac{36}{5} e_\alpha^2 \Gamma(1P_1 \to ggg)
\]
(6)
where we also include the decay \(^1P_1 \to gg + \gamma\).

Considerable uncertainties arise in these expressions from the model-dependence of
the wavefunctions and possible relativistic contributions [14]. In addition, the loga-
rithm in the decay \(\Gamma(1P_1 \to ggg)\) is a measure of the virtuality of the quark emitting
the gluon. Different choices have been proposed for its argument, introducing further
uncertainty. Rather than evaluating these expressions in a specific potential model,
we can obtain less model-dependent estimates of strong decays by relating ratios of
theoretical predictions, in which much of the theoretical uncertainties factor out, to
experimentally measured widths. Although we expect the wavefunction at the origin
to be slightly larger for the singlet state than the triplet state, we expect this difference
to be much smaller than the uncertainties mentioned above.

To make our estimates, we will need in addition to Eqs. (3)–(5), the following
expressions [14]:
\[
\Gamma(3S_1 \to ggg) = \frac{40(\pi^2 - 9)\alpha_s^3}{81m_Q^2} |\psi(0)|^2
\]
(7)
with a multiplicative correction factor of \((1 - 4.9\frac{\alpha_s}{\pi})\) for \(b\bar{b}\) and \((1 - 3.7\frac{\alpha_s}{\pi})\) for \(c\bar{c}\),
\[
\Gamma(3S_1 \to \gamma + gg) = \frac{32(\pi^2 - 9)e_\alpha^2 \alpha_s^2}{9m_Q^2} |\psi(0)|^2
\]
(8)
with a multiplicative correction factor of \((1 - 7.4\frac{\alpha_s}{\pi})\) for \(b\bar{b}\) and \((1 - 6.7\frac{\alpha_s}{\pi})\) for \(c\bar{c}\), and
\[
\Gamma(3P_1 \to q\bar{q} + g) = \frac{8\alpha_s^3 n_f}{9\pi m_Q^2} |R_{P'}(0)|^2 \ln(m_Q \langle r \rangle),
\]
(9)
where the QCD correction factor for the last expression is not known. Taking account
of decays of the \(2^3S_1\) and \(3^3S_1\) states to \(\pi\pi\Upsilon(nS)\), lepton pairs, and \(\chi_b(nP)\gamma\), as quoted
in Ref. [16], we find total branching ratios to non-glue final states, and assume glue
to constitute the remainder. Using branching ratios and total widths quoted in Ref.
[16], we then arrive at the estimates summarized in Table I for \(\Gamma[\Upsilon(nS) \to \text{glue}] \equiv \Gamma[\Upsilon(nS) \to \text{hadrons}] + \Gamma[\Upsilon(nS) \to \gamma + \text{hadrons}]\).
Using Eqs. (7) and (8), $\alpha_s(\Upsilon(2S)) = 0.181$, and $\alpha_s(\Upsilon(3S)) = 0.180$ we find $\Gamma[\Upsilon(2S) \to \text{hadrons}] = 21.8 \pm 3.5$ keV and $\Gamma[\Upsilon(3S) \to \text{hadrons}] = 14.1 \pm 2.0$ keV. The ratio of the widths from Eqs. (4) and (7):

$$
\Gamma(^1S_0 \to gg) = \frac{27\pi}{5(\pi^2 - 9)} \frac{1}{\alpha_s} \frac{1 + 4.4\alpha_s}{\pi} \times \Gamma(^3S_1 \to gg) \tag{10}
$$

results in $\Gamma[\eta_b(2S) \to \text{hadrons}] = 4.1 \pm 0.7$ MeV and $\Gamma[\eta_b(3S) \to \text{hadrons}] = 2.7 \pm 0.4$ MeV.

We follow the same procedure to estimate the hadronic width for the $^1P_1$ states, although in this case we need to make use of a theoretical estimate for the partial width $^3P_1 \to ^3S_1\gamma$. Here we have

$$
\Gamma(^1P_1 \to \text{hadrons}) = \frac{5}{2n_f} \times \Gamma(^3P_1 \to \text{hadrons}) \tag{11}
$$

where $n_f$ is the number of light quark flavours in the final state which we will take to be 3, ignoring the kinematically suppressed charm-anticharm channel. This results in a conservative upper limit for $\Gamma(^1P_1 \to \text{hadrons})$ and hence a lower limit for the branching ratio of this state to $\gamma + \eta_b$. As mentioned, the QCD corrections to these widths are not known. The large uncertainties arising from the wavefunction and logarithms in Eqs. (5) and (9) cancel out.

The only branching ratios quoted in Ref. [46] for the $^3P_1$ states are for decays to $n^3S_1\gamma$. Using quark model predictions for the radiative transitions and assuming that hadronic decays dominate the remainder of the total widths, we can estimate the hadronic partial widths of these states. The results are summarized in Table IV.

The branching ratios obtained by combining the partial widths given in Tables II and IV are summarized in Table V.

To study the singlet $P$-wave $b\bar{b}$ states we considered the two-photon inclusive transitions $^3S_1 \to 3^1S_0 \to 2^1P_1$ or $^3S_1 \to 1^1P_1$ and $3^3S_1 \to 2^1S_0 \to 1^1P_1$. In all cases the $^1P_1$ states can undergo further $E1$ radiative transitions to $^1S_0$ states. It may be that this last photon provides a useful tag to distinguish the cascade of interest from other possible decays involving triplet $P$ and $D$-wave $b\bar{b}$ states. We use the branching ratios predicted in Ref. [36] for the initial $M1$ transitions, $B(\Upsilon(3S) \to \eta_b(3S) + \gamma) = 0.10 \times 10^{-4}$ and $B(\Upsilon(3S) \to \eta_b(2S) + \gamma) = 4.7 \times 10^{-4}$, which correspond to the GI mass-splittings and wavefunctions [14] and where the latter result takes into account relativistic corrections. Combined with the branching ratios for the subsequent $E1$ transitions given
Table IV: Partial widths of $^3P_1$ and $^1P_1$ states. The details of the calculation are given in the text.

Table V: Partial widths and branching ratios for spin-singlet $b\bar{b}$ states. The details of the calculation are given in the text.

| Initial state | Final state | Width (keV) | $B$ (%) |
|---------------|-------------|-------------|---------|
| $^3S_0$       | $^2P_1\gamma$ | 3.2         | 0.12    |
|               | $^1P_1\gamma$ | 1.4         | 0.05    |
|               | $gg$         | 2700        | 99.8    |
| $^2P_1$       | $^2S_0\gamma$ | 15.4        | 19.3    |
|               | $^1S_0\gamma$ | 10.0        | 12.5    |
|               | $^1D_2\gamma$ | 2.7         | 3.4     |
|               | $ggg$        | 50.2$^a$    | 62.8    |
|               | $\gamma gg$  | 1.6         | 2.0     |
| $^2S_0$       | $^1P_1\gamma$ | 2.3         | 0.057   |
|               | $gg$         | 4100        | 99.9    |
| $^1P_1$       | $^1S_0\gamma$ | 37.0        | 41.4    |
|               | $ggg$        | 50.8$^a$    | 56.8    |
|               | $\gamma gg$  | 1.6         | 1.8     |

$^a$ Based on the partial width for $^3P_1 \to ^3S_1\gamma$ of Ref. [2] in Table IV.
in Table V the only decay chain that might yield enough events to be observed is \(3^3S_1 \rightarrow 2^1S_0 \rightarrow 1^1P_1\) which yields roughly 0.3 events per million \(\Upsilon(3S)\) states produced.

A more promising approach is the decay chain \(\Upsilon(3S) \rightarrow 1^1P_1\pi^0\) followed by the \(E1\) radiative transition \(1^1P_1 \rightarrow 1^1S_0\). Voloshin estimates \(\mathcal{B}(\Upsilon(3S) \rightarrow 1^1P_1 + \pi^0) = 0.10 \times 10^{-2}\) [37]. Thus, \(\mathcal{B}[\Upsilon(3S) \rightarrow 1^1P_1 + \pi^0 + 1^1S_0\gamma] \approx 4 \times 10^{-4}\), which would yield \(\approx 400\) events per million \(\Upsilon(3S)\) produced. This signature should be easily seen by the CLEO detector, which has excellent photon detection capabilities. Since the recoil of the \(1^1P_1\) state is relatively small, the 488 MeV photon from the \(1^1P_1 \rightarrow 1^1S_0\) decay (suitably Doppler-shifted by up to \(\pm 20\) MeV) should provide a useful tag. Kuang and Yan predict [38] the partial width for the hadronic transition \(\Upsilon(3S) \rightarrow h_b(1^1P_1) + \pi\pi\) to be \(0.1–0.2\) keV, giving a branching ratio of \(\sim (3.8–7.6) \times 10^{-3}\). This is substantially higher than the value for \(\mathcal{B}(\Upsilon(3S) \rightarrow 1^1P_1 + \pi^0)\) quoted above so it could provide an alternative path to the \(h_b\). However, Voloshin [37] does not obtain such a favorable branching ratio for this process, finding instead \(< 10^{-4}\).

We now turn to the charmonium system. The search for the \(h_c\) was discussed recently by Kuang [3] so we will be brief in our analysis, emphasizing aspects that are different from Kuang [3]. As in the case of \(b\bar{b}\) there are two routes to the \(h_c\). The first is the decay chain \(\psi' \rightarrow \eta_c'\gamma \rightarrow h_c\gamma\) and the second is through the hadronic transition \(\psi' \rightarrow h_c\pi^0\).

For the first case we need the various radiative widths. The expression for the \(E1\) width is given by Eq. (1), while the rates for magnetic dipole transitions are given in the nonrelativistic approximation by

\[
\Gamma(3^3S_1 \rightarrow 1^1S_0 + \gamma) = \frac{4\alpha Q}{3m^3_Q} \omega^3 |\langle f | j_0(kr/2) | i \rangle|^2
\]

\[
\Gamma(1^1S_0 \rightarrow 3^1S_1 + \gamma) = \frac{4\alpha Q}{m^3_Q} \omega^3 |\langle f | j_0(kr/2) | i \rangle|^2
\]

where we take \(m_c = 1.628\) GeV. The results, using the wavefunctions and \(1^1P_1\) mass of Ref. [4], are summarized in Table VI. To calculate \(\Gamma(\psi' \rightarrow \eta_c'\gamma)\), we took \(M(\eta_c') = 3654\) MeV, the central value quoted in Ref. [10]. Note that the widths for the hindered \(M1\) transitions are very sensitive to the wave functions. The hadronic widths for the \(\eta_c'\) and \(h_c\) given in Table VI were obtained using the same procedure used for the \(b\bar{b}\) hadronic widths: We relate theoretical expressions for ratios of the widths to a known measured width and take \(\alpha_s(\psi') = 0.236\). (In contrast to the \(b\bar{b}\) system, the total width of the \(1^3P_1\) \(c\bar{c}\) meson is known [16]: \(\Gamma_{\text{tot}}(\chi_{c1}) = 0.88 \pm 0.14\) MeV.) The predicted results for \(h_c \rightarrow \) hadrons is consistent with the NRQCD result obtained by Bodwin, Braaten and Lepage [17]. Combining these results we find that \(\mathcal{B}(\psi' \rightarrow \eta_c'\gamma) \times \mathcal{B}(\eta_c' \rightarrow h_c\gamma) \sim 10^{-6}\), which would yield a modest number of \(h_c\) mesons at best.

As in the case of the \(h_b\), a more promising avenue is the single pion transition \(\psi' \rightarrow h_c\pi^0\) followed by the radiative transition \(h_c \rightarrow \eta_c\gamma\), where the photon is expected to have an energy very close to 496 MeV and can be used to tag the event. Using the branching ratio of \(\mathcal{B}(\psi' \rightarrow h_c\pi^0) = 0.1%\) predicted by Voloshin [37] (see also Ref. [7, 38]) and the branching ratio given for \(h_c \rightarrow \eta_c\gamma\) in Table VI, we obtain \(\mathcal{B}(\psi' \rightarrow h_c\pi^0) \times \ldots\)
Table VI: Partial widths and branching ratios for spin-singlet $c\bar{c}$ states. In column 5, $\mathcal{O}$ represents the operator relevant to the particular electromagnetic transition; $\mathcal{O} = r$ (GeV$^{-1}$) for $E1$ transitions and $\mathcal{O} = j_0(kr/2)$ for $M1$ transitions. The details of the calculation are given in the text.

| Initial state | Final state | $M_i$ (MeV) | $M_f$ (MeV) | $\omega$ (MeV) | $\langle f | \mathcal{O} | i \rangle$ | Width (keV) | $\mathcal{B}$ (%) |
|---------------|-------------|-------------|-------------|--------------|------------------|------------|--------------|
| $2^3S_1$      | $2^1S_0\gamma$ | 3686        | 3654        | 31.8         | 0.982            | 0.051      | 0.018        |
|               | $1^1S_0\gamma$ | 3686        | 2980        | 638          | 0.151            | 9.7        | 3.5          |
| $2^1S_0$      | $1^1P_1\gamma$ | 3654        | 3517        | 134.4        | $-2.21$          | 51.3       | 0.69         |
|               | $1^3S_1\gamma$ | 3654        | 3097        | 515          | $-0.0973$        | 6.3        | 0.084        |
|               | $gg$         |             |             |              |                  |            |              |
|               | $ggg$        |             |             |              |                  |            |              |
| $1^1P_1$      | $1^1S_0\gamma$ | 3517        | 2980        | 496          | 1.42             | 354        | 37.7         |
|               | $gg$         |             |             |              |                  |            |              |
|               | $\gamma gg$  |             |             |              |                  |            | 52           |

$\mathcal{B}(h_c \to \eta_c\gamma) = 3.8 \times 10^{-4}$, which is substantially larger than the decay chain proceeding only via radiative transitions. In his recent paper Kuang [5] finds $h_c$ production to be sensitive to $^3S_1 - ^3D_1$ mixing, so that a measurement of $\mathcal{B}(\psi' \to h_c\pi^0)$ would be a useful test of detailed mixing schemes between the $\psi'$ and the $\psi(3770) \equiv \psi''$, some of which are discussed in Ref. [48, 49].

Another promising approach for the detection of the $h_c$ has recently been proposed by Suzuki [4]. He suggests looking for the $h_c$ by measuring the final state $\gamma\eta_c$ of the cascade $B \to h_cK/K^* \to \gamma\eta_cK/K^*$. This channel is especially timely given the announcement by the Belle Collaboration of the discovery of the $\eta_c(2S)$ in $B$ decays [10] and, previously, the observation of the related decay, $B \to \chi_0K$ [50].

In the case of the S-wave ($^1S_0$) states, one should also bear in mind that $\gamma\gamma$ collisions have been used to observed the $\eta_c$ in several experiments (see [18]). One candidate for $\gamma\gamma \to \eta_b$ with mass $9.30 \pm 0.02 \pm 0.02$ GeV/$c^2$ (consistent, however, with background) has been reported by the ALEPH Collaboration [51].

To conclude, we have explored different means of looking for the $^1P_1$ states in heavy quarkonium. In both the $b\bar{b}$ and $c\bar{c}$ systems the $^1P_1$ state can be reached via the chain $^3S_1 \to ^1S_0 + \gamma \to ^1P_1 + \gamma$. However, in both systems one only expects of the order of a few events per million $\Upsilon(3S)$ or $\psi'$ produced. In both systems, a more promising avenue is the transition $^3S_1 \to ^1P_1 + \pi^0$ followed by the $E1$ radiative transition to the $^1S_0$ state which would yield several hundred events per million $\Upsilon(3S)$ or $\psi'$'s produced. The alternative suggestion [38] of searching for the transitions $^3S_1 \to ^1P_1 + \pi\pi$ also is worth pursuing.

One of us (J.L.R.) thanks Steve Olsen and San Fu Tuan for informative discussions. The authors thank Christine Davies for helpful communications.
