We report on the observation of jet-like azimuthal and pseudorapidity correlations between the highest $p_T$ photon (leading photon) and charged hadrons produced in both p-p and Au-Au collisions at $\sqrt{s_{NN}} = 200$ GeV.

1. Introduction

The behavior at high-$p_T$ in heavy ion collisions at RHIC is currently not well understood. Two interesting observations have been made so far. First, there is a significant suppression in the yield of high-$p_T$ particles relative to the expected yield from binary scaling \cite{1}. Second, high-$p_T$ particles have a strong $v_2$ correlation to the reaction plane which is constant with $p_T$ \cite{2}. There have been many proposed theoretical explanations for these observations, such as parton energy loss \cite{3,4}, gluon saturation \cite{5}, or correlations from minijets \cite{6}, but at this time there is no consensus on the explanation for the above observations.

To better study the origin of these high-$p_T$ particles, we study in detail the angular correlation of charged hadrons from a leading photon for those events with photons above 2.5 GeV/c in $p_T$. It has been well established by UA1 and UA2 at the $Sp\bar{p}S$ that high-$p_T$ behavior is dominated by hard parton-parton scattering in nucleon-nucleon collisions, confirming the previous discovery of this effect at the CERN ISR \cite{7,8}. We expect leading photons in the $p_T$ range of our measurement to come predominantly from the decay of $\pi^0$'s. At high-$p_T$ the decay photon lies very nearly along the $\pi^0$ direction, and since the $\pi^0$ comes from the fragmentation of a jet, the photon is strongly correlated with the jet axis. By examining the yield of charged hadrons as a function of $\Delta\phi$ and $\Delta\eta$ with respect to the leading photon in p-p, we can measure the correlation from the fragmentation of the jets in the near and back-to-back jet cones. Then, using the p-p analysis as a reference we can check whether similar correlations can be seen in Au-Au, which would provide evidence for hard scattering behavior in high energy heavy ion collisions.

2. Analysis

For this analysis, we use the two central arms of the PHENIX detector. Each arm covers 90° in $\phi$ and $\pm0.35$ in $\eta$. The arms consist of inner tracking (Drift Chambers, Pad Chambers) and particle ID (RICH) detectors for measuring charged particle type and momenta, followed by either Lead-Scintillator or Lead-Glass Electromagnetic Calorimeters

Figure 1. Per triggered event differential distribution in $\Delta \phi$ for associated charged hadrons with $p_T$ between 2 and 4 GeV/c relative to a trigger photon in p-p collisions at $\sqrt{s_{NN}} = 200$ GeV. The flat background from the fit has been subtracted, leaving only the jet-like excess.

(EMCal) for measuring photon and electron energies. In addition there are Beam-Beam Counters (BBC) and Zero-Degree Calorimeters (ZDC) at forward rapidities for global event characterization and triggering.

The p-p data presented here were obtained from 59,306 events triggered at Level-1 via either the BBC or the EMCal 2x2 and 4x4 tower sum triggers. The Level-1 triggers are described elsewhere in these proceedings [9]. Our Au-Au sample consists of 170,910 triggered events from scanning through the PHENIX minimum-bias trigger (BBC and ZDC) plus another 145,285 events from data obtained with our Level-2 EMCal Tile Trigger. We take only those triggered events which have an offline reconstructed photon at a $p_T$ above 2.5 GeV/c. Photons are identified in the EMCal using a combination of Time-of-Flight, shower shape, and charge veto cuts. The momenta of the charged particles are reconstructed using the Drift Chamber. Track quality is enforced by matching to hits in the outer Pad Chambers and the EMCal. We also apply a RICH veto to remove background electrons.

We correct for the acceptance of the leading-photon/charged-hadron pair by using mixed events to estimate the correction function in $\Delta \phi$ and $\Delta \eta$. We take the leading photon from the event and calculate $\Delta \phi$ (or $\Delta \eta$) to a charged hadron taken from another event. The mixed event distribution is proportional to the average pair acceptance $\text{Acc}(\Delta \phi)$ (or $\text{Acc}(\Delta \eta)$), leaving only an overall efficiency, $\langle \epsilon \rangle$, which can be computed via Monte Carlo.

3. Results

3.1. p-p

Fig. shows the acceptance-corrected $\Delta \phi$ distribution for the associated charged particles. The p-p $\Delta \phi$ distribution at RHIC includes many of the qualitative features expected from jets, including a large near angle peak and a smaller peak in the back-to-back region at 180 degrees. The back-to-back signal is lower in magnitude due to a limited $\eta$ acceptance, and is broadened from the effects of intrinsic $k_T$.

The p-p azimuthal correlation is well described by a fit to Eqn. 1, which consists of a
flat background distribution plus the correlation predicted by PYTHIA 6.131 (with the default settings) [10]:

\[
\frac{1}{N_{trig}} \frac{dN_{ch}}{d\Delta \phi} = Acc(\Delta \phi) \langle \varepsilon \rangle \left( a_{bkg} + \frac{1}{N_{pythia}} \frac{dN_{pythia}}{d\Delta \phi} \right)
\] (1)

In the fit we allow the background level and PYTHIA amplitude to vary. We checked that within the PYTHIA simulation events with a high-\(p_T\) photon are dominated by hard scattering and resonance contributions to \(\Delta \phi\) correlations are small.

3.2. Au-Au

Perhaps surprisingly, even in the high multiplicity environment of Au-Au collisions, the azimuthal correlations from jet fragmentation can be resolved above the background. In fig. 2a, we plot the raw distribution of charged hadrons into the PHENIX Central Arm acceptance, a flat background folded with the PHENIX acceptance, and the subtracted distribution. There is a clear and statistically significant excess above the flat background. We assume that the contributions to the shape of the excess come from a jet-like signal plus a \(\cos(2\Delta \phi)\) term from elliptic flow:

\[
\frac{1}{N_{trig}} \frac{dN_{ch}}{d\Delta \phi} = Acc(\Delta \phi) \langle \varepsilon \rangle \left( a_{bkg} + a_{flow} \cos(2\Delta \phi) + \frac{1}{N_{pythia}} \frac{dN_{pythia}}{d\Delta \phi} \right)
\] (2)

If the jet and elliptic flow are not coupled, then \(a_{flow} = a_{bkg} * 2v_{trig}^2v_{ch}^2\).

Fig. 2b shows the result of this fit. There is good agreement between the data and our functional fit. Further checks were made to test whether the correlations are consistent with those from jets. By studying the distributions in \(\Delta \phi\) for cuts in \(|\Delta \eta| > 0.35\) and
|Δη| < 0.35, we can check whether the particles are simultaneously correlated in Δη and Δφ. For cuts of |Δη| > 0.35, which should exclude many particles in a jet cone, we see a suppression of 5 in the jet-like amplitude relative to that from a cut of |Δη| < 0.35, consistent with the suppression obtained in the p-p analysis. We also studied the Δη distribution directly. For cuts of |Δη| > 0.35, which should exclude many particles in a jet cone, we see a suppression of 5 in the jet-like amplitude relative to that from a cut of |Δη| < 0.35, consistent with the suppression obtained in the p-p analysis. We also studied the Δη distribution directly. For the near side (|Δφ| < 0.5), there is a strong peak in Δη with a similar width to the Δφ correlation, while for the away side (|Δφ| > 2.5) we see no correlation with Δη. These studies show that the angular correlations are peaked in a cone at Δη and Δφ angles near to the lead photon, and also peaked around Δφ = 180° but flat in Δη on the away side. This behavior is consistent with results from an identical analysis of our p-p data.

In fig. 3, we plot the fit value for the jet-like amplitude at various centralities and for two pT bins. The fit values show no strong centrality dependence, though at this time systematic errors have not been computed and are under investigation.

4. Conclusions

We have studied the azimuthal correlations between leading photons with pT > 2.5 GeV/c and associated charged hadrons in √s = 200 GeV p-p collisions at RHIC, and find good agreement with hard scattering expectations as described by a QCD based Monte Carlo (PYTHIA). In addition, we find an excess above a constant background in Au-Au collisions at the same incident energy per nucleon and for different centrality classes, and find that this excess is described well by a fit to jet-like correlations predicted by PYTHIA plus an additional flow-like \( \cos(2\Delta\phi) \) modulation.
