ABSTRACT

Aims. Messier 8 (M8) is one of the brightest HII regions in the sky. We collected an extensive dataset comprising multiple submillimeter spectral lines from neutral and ionized carbon and from CO. Based on this dataset, we aim to understand the morphology of M8 and that of its associated photodissociation region (PDR) and to carry out a quantitative analysis of the physical conditions of these regions such as kinetic temperatures and volume densities.

Methods. We used the Stratospheric Observatory For Infrared Astronomy (SOFIA), the Atacama Pathfinder Experiment (APEX) 12 m, and the Institut de Radioastronomie Millimétrique (IRAM) 30 m telescopes to perform a comprehensive imaging survey of the emission from the fine structure lines of [C ii] and [C i] and multiple rotational transitions of carbon monoxide (CO) isotopologs within 1.3 × 1.3 pc around the dominant Herschel 36 (Her 36) system, which is composed of at least three massive stars. To further explore the morphology of the region, we compared archival infrared, optical, and radio images of the nebula with our newly obtained fine structure line and CO data, and in particular with the velocity information these data provide. We performed a quantitative analysis, using both LTE and non-LTE methods to determine the abundances of some of the observed species, kinetic temperatures, and volume densities.

Results. Bright CO, [C ii] and [C i] emission have been found toward the HII region and the PDR in M8. Our analysis places the bulk of the molecular material in the background of the nebulousity illuminated by the bright stellar systems Her 36 and 9 Sagitarii. Since the emission from all observed atomic and molecular tracers peaks at or close to the position of Her 36, we conclude that the star is still physically close to its natal dense cloud core and heats it. A veil of warm gas moves away from Her 36 toward the Sun and its associated dust contributes to the foreground extinction in the region. One of the most prominent star forming regions in M8, the Hourglass Nebula, is particularly bright due to cracks in this veil close to Her 36. We obtain H2 densities ranging from 10^5–10^6 cm−3 and kinetic temperatures of 100–150 K in the bright PDR caused by Her 36 using radiative transfer modeling of various transitions of CO isotopologs.

Key words. ISM: general – ISM: individual objects: M8 – submillimeter: ISM – HII regions – ISM: clouds

1. Introduction

The influence of bright stars on their surrounding interstellar medium (ISM) is immense. Their strong ultraviolet and far-ultraviolet (FUV) fields give rise to bright HII regions and photodissociation regions (PDRs). These are the best grounds to study the effect of UV and FUV photons on the heating and chemistry of ISM. The fine structure lines of C+ and O, observable at far-infrared (FIR) wavelengths, are mainly responsible for the cooling in these regions (Tielens & Hollenbach 1985b), which allow us to deduce the amount and sometimes the source of heating as well. The fine structure line of C+ at 158 μm is one of the brightest lines in PDRs and traces the transition from H+ to H and H2 as C has an ionization potential of 11.3 eV (e.g., Pabst et al. 2017). In PDRs, a C+ layer extends to a depth of Aν ~ 2–4, after which C+ recombines to C probing the interface to CO (Hollenbach & Tielens 1999). Deeper into the associated molecular clouds, cooling is dominated by the transitions of CO, observable at (sub)millimeter and FIR wavelengths. Modeling the relative intensity distributions of multiple lines from various molecular and atomic species allows us to derive the physical conditions in PDRs.

Messier 8 (M8) is located in the Sagittarius-Carina arm, near our line of sight toward the Galactic center. It is located at a distance ~ 1.25 kpc (1 pc corresponds to 3.086 × 1019 cm) from the Sun (Damiani et al. 2004; Arias et al. 2006) with an error of ~ 0.1 kpc (Tothill et al. 2008) and is about 34 × 12 pc in diameter. M8 is associated with the open young stellar cluster NGC 6530, the HII region NGC 6523/33, and large quantities of molecular gas (Tothill et al. 2008). The open cluster NGC 6530 (centered at RA 18h04m24s, Dec −24°21′12″(J2000)) is a relatively young cluster (formed about 2–4 Myrs ago, Chen et al. 2007) and contains several bright O-type stars. The brightest among them is Her 36 (Wolf 1961) at RA 18h03m40s, Dec −24°22′43″ (J2000). It is resolved into three main components: a close massive binary consisting of an O9 V and a B0.5 V star and a more distant companion O7.5 V star (Arias et al. 2010; Sanchez-Bermudez et al. 2014). Her 36 is responsible for ionizing the gas in...
the western half of the HII region of NGC 6523 including the bright Hourglass Nebula (Woolf 1961; Lada et al. 1976; Woodward et al. 1986). Lada et al. (1976) compared the optical and millimeter-wave observations of the M8 region and suggested the molecular cloud is located behind the HII region of the nebula, similar to the Orion-KL nebula. An ultracompact HII region, G5.97−1.17 is also very close to Her 36 at (RA 18h03m40.5s, Dec −24°22′44.3″ (J2000)) (Masqué et al. 2014).

A multiband near-IR image of Her 36 and its surroundings presented in Goto et al. (2006) shows the IR source Her 36 SE lying 0.25″ SE of Her 36 and it is completely obscured. It is inferred to be an early-type B star with a visual extinction A_V > 60 mag that is deeply embedded in dense, warm dust and is powering the ultracompact HII region G5.97−1.17. The morphology of H2 and CO J = 3 → 2 emission around Her 36 (White et al. 1997; Burton 2002) is in accordance with the Hubble Space Telescope (HST) jet-like feature detections extending 0.5″ southeast of Her 36 (Stecklum et al. 1995), which suggest there might be a molecular outflow in the core of M8 (Burton 2002). X-ray emission from Her 36 and diffuse X-ray emission from the Hourglass region, which is the brightest part of the optically visible nebula located ~15″ east from Her 36 (Rauw et al. 2002), suggest the presence of a bubble of hot gas of size 0.4 pc that is produced by the interaction of the stellar wind of Her 36 with the denser part of the molecular cloud in the background. Anomalously broad diffuse interstellar bands (DIBs) at 5780.5, 5797.1, 6196.0, and 6613.6 Å along with CH⁺ and CH are found in absorption along the line of sight to Her 36 (Dahlstrom et al. 2013). CH⁺ and CH are radiatively excited by strong FIR emission from the adjacent IR source Her 36 SE (Goto et al. 2006) and the broadening of DIBs is attributed to radiative pumping of closely spaced high-J rotational levels of small polar carbon molecules (Dahlstrom et al. 2013; Oka et al. 2014; York et al. 2014). We performed (sub)millimeter observations related to these species that will be discussed in a future paper.

The eastern half of the HII region is illuminated by the 9 Sgr stellar system, as shown in Fig. 1. 9 Sgr is a well-known binary with an orbit of ~9 yr duration, consisting of an O3.5 V primary and an O5-5.5 V secondary (Rauw et al. 2012). South-east of the cluster core (NGC 6530), another cluster, M8E, although optically invisible, is associated with two massive star forming regions (Tothill et al. 2008). A superposition of four HII regions seems to be responsible for the ionization of the gas in M8: the Hourglass Nebula illuminated by Her 36, the core of NGC 6523 illuminated by Her 36, the remaining parts of NGC 6523 and NGC 6533 illuminated by 9 Sgr (O4V) (Tothill et al. 2008), and M8E illuminated by HD 165052 (Lynds & Oneil 1982; Woodward et al. 1986).

Although M8 has been studied extensively in the X-ray, optical, and IR regimes (Stecklum et al. 1995; Damiani et al. 2004; Arias et al. 2006; Goto et al. 2006; Damiani et al. 2017), only few studies have been performed at millimeter and submillimeter wavelengths. White et al. (1997) reported the discovery of the second strongest source of millimeter and submillimeter wavelength CO line emission in our Galaxy toward Her 36 in M8 (White et al. 1997). Lada et al. (1976) compared optical and millimeter-wave observations to sketch the morphology of M8 where the core surrounding Her 36, the hourglass nebula with its structure and the eastern part of M8 are described. Tothill et al. (2002) presented submillimeter- and millimeter-wavelengths maps of the J = 2 → 1 and J = 3 → 2 transitions of 12CO tracing the molecular gas and dust around Her 36.

We report a comprehensive survey of the 1.5 × 1 pc (4′ × 4″) region around Her 36 (as shown by the blue square in Fig. 1) at FIR, millimeter- and submillimeter wavelengths to probe the physical conditions and image the morphology of this exceptional PDR. We present for the first time extended maps of this region in the 158 μm fine structure line of C⁺, high-J transitions of 12CO emission observed with the GREAT1 receiver

---

1 GREAT is a development by the MPI für Radioastronomie and KOSMA/Universität zu Köln, in cooperation with the MPI für Sonnensystemforschung and the DLR Institut für Planetenforschung.
Fig. 2. Color maps of the integrated intensity of the [C ii] 158 μm and $J = 11 \rightarrow 10$, $J = 13 \rightarrow 12$, and $J = 16 \rightarrow 15$ transitions of $^{12}$CO toward Her 36, which is the central position ($\Delta \alpha = 0$, $\Delta \delta = 0$) at RA(J2000) = 18$^h$03$^m$40.3$^s$ and Dec(J2000) = −24◦22′43″, denoted with an asterisk. The contour levels are 10% (>3×rms, given in Table 1) to 100% in steps of 10% of the corresponding peak emission given in Table 1. All maps are plotted using original beam sizes shown in the lower left of each map.

on board SOFIA observatory, the mid-$J$ transitions of $^{12}$CO and $^{13}$CO using the PI230, FLASH*, and CHAMP* receivers of the APEX$^2$ telescope, and low-$J$ transitions of $^{12}$CO and $^{13}$CO using the EMIR receiver of the IRAM$^3$ 30 m telescope.

2 This publication is based on data acquired with the Atacama Pathfinder EXperiment (APEX). APEX is a collaboration between the Max-Planck-Institut für Radioastronomie, the European Southern Observatory, and the Onsala Space Observatory.

3 Based on observations carried out with the IRAM 30 m telescope. IRAM is supported by INSU/CNRS (France), the MPG (Germany), and IGN (Spain).

2. Observations

2.1. SOFIA/GREAT data

The high-$J$ CO and [C ii] 158 μm observations summarized in Table 1 were conducted with the L1 channel of the German Receiver for Astronomy at Terahertz frequencies (GREAT; Heyminck et al. 2012) and the upGREAT LFA arrays (Risacher et al. 2016) on board the Stratospheric Observatory for Infrared Astronomy (SOFIA; Young et al. 2012). The data was acquired during observatory flight #297 on 2016 May 14 at 14.2 km altitude and under a median water vapor column.
of 11 μm. The upGREAT was employed with 14 pixels (seven pixels for each polarization, with a hexagonal layout). The spectral analysis was performed by means of fast Fourier transform spectrometers (Klein et al. 2012), in a mode providing 4.0 GHz bandwidth with 214 spectral channels.

In the first setup we simultaneously mapped the 12CO J = 11 → 10 transition at 1267.014.486 GHz and the [C n] 2P1/2 → 2P1/2 fine structure line at 1900.537 GHz. In a second setup the 12CO J = 13 → 12 and J = 16 → 15 transitions at 1496.923 GHz and 1841.345 GHz were mapped, respectively. Typical single-sideband system temperatures ranged between 1600 and 1800 K for the lower frequency L1 channel and between 2080 and 2260 K for the higher frequency upGREAT array with atmospheric transmissions of 0.90–0.94.

The resulting antenna temperatures (Guan et al. 2012), which is part of the KOSMA software package, was maintained. The originally chosen reference position at (30′, −30′) was chosen as reference, similar to the SOFIA observations. The pointing accuracy (<3″) was maintained by pointing at bright sources such as RAFGL5254 and R Dor every 1–1.5 h. A forward efficiency F缶 = 0.95 was used for all receivers, and the beam coupling efficiencies B缶 = 0.62, 0.69, 0.63, 0.43, and 0.32 were used for the PI230, FLASH+340, FLASH+460, CHAMP+660, and CHAMP+810 receivers, respectively.

2.3. IRAM 30 m data

Observations of low-J 12CO, 13CO, and hydrogen recombination line observations were performed with the IRAM 30 m telescope in August 2016. We observed the whole 3 mm range using the EMIR receivers (Carter et al. 2012). We simultaneously mapped a region of 240′ × 240′, which is similar to the size of most other maps previously observed with SOFIA and APEX in the 12CO and 13CO J = 1 → 0 transitions (Table 1) and the hydrogen recombination lines H40r to H43r at 99.023 GHz, 92.034 GHz, 85.688 GHz, and 79.912 GHz, respectively. Molecular high density tracers, which were also detected in our wide spectral band observation, will be analyzed in a subsequent paper.

All maps shown in Fig. 4 were observed in OTF total power mode centered on Her 36. Each subscan lasted 25 s and the integration time on the off-source reference position was 5 s. The offset position relative to the center at (30′, −30′) was similar to that used for the SOFIA and APEX mapping and the pointing accuracy (<3″) was maintained by pointing at the bright calibrator 1757-240 every 1–1.5 h. A forward efficiency F缶 = 0.95 and a beam coupling efficiency B缶 = 0.69 were adopted for the EMIR receivers. These values were taken from the latest (2015) commissioning report. All data reduction was performed using the CLASS and MIRA programs that are a part of the GILDAS software package and all the observations are summarized in Table 1.

3. Results

3.1. Peak intensities of the molecular line emission

The maxima of the distributions of the velocity integrated intensities of the emission in the [C II] and [C III] lines and different transitions of 12CO, 13CO, and 12CO are presented in Table 1. Figure 2 shows velocity integrated intensity maps of the 12CO J = 11 → 10, 13 → 12, and 16 → 15 transitions. The emission in all the lines has a similar spatial distribution and peaks are found at about the same offset position (Qα = 5.0′′, δ = 5.0′′) northwest of Her 36.

Figures 3 and 4 show velocity integrated intensity maps of low- and mid-J transitions of 12CO, 13CO, and 12CO, i.e., the J = 1 → 0, 2 → 1, 3 → 2, 6 → 5, 7 → 6 transitions of 12CO, the J = 1 → 0, 2 → 1, 3 → 2, 4 → 3, and 6 → 5 transitions of 13CO, and the J = 1 → 0 transition of 12CO. The intensities of the low-J transitions peak close to Her 36 (Qα = 0.0′′, δ = 0.0′′) for 12CO mid-J transitions; the peaks shift toward the northwest of Her 36 with offsets of (Qα = −13.0′′, δ = 8.0′′). It seems like there

5 www.iram.fr/IRAMFR/GILDAS/
Fig. 3. Colour maps of the integrated intensity of the $J = 2 \rightarrow 1$, $J = 3 \rightarrow 2$, $J = 6 \rightarrow 5$, and $J = 7 \rightarrow 6$ transitions of $^{12}$CO, the $J = 2 \rightarrow 1$, $J = 4 \rightarrow 3$, and $J = 6 \rightarrow 5$ transitions of $^{13}$CO, the $J = 2 \rightarrow 1$ line of $^{12}$CO and [C II] $1 \rightarrow 0$ toward Her 36. This corresponds to the central position ($\Delta \alpha = 0$, $\Delta \delta = 0$) at RA(J2000) = 18°03′40.3′′ and Dec(J2000) = −24°22′43.9′′, denoted with an asterisk. The contour levels of $^{12}$CO and [C II] are $3 \times \text{rms}$ in steps of $2 \times \text{rms}$, while those of other molecules are from 10% ($>3 \times \text{rms}$, given in Table 1) to 100% in steps of 10% of the corresponding peak emission given in Table 1. All maps are plotted using original beam sizes shown in the lower left of each map.

is a systematic shift in the peak emission of CO transitions with low-$J$ peaking near Her 36, mid-$J$ peaking toward the northwest, while high-$J$ lines peak again closer to Her 36. Nevertheless, all maps show at least a small offset toward the northwest and the emission from CO transitions becomes more and more compact with increasing $J$.

Figures 2 and 3 show velocity integrated intensity maps of the [C II] $^2P_{3/2} \rightarrow ^2P_{1/2}$ and [C I] $^2P_1 \rightarrow ^2P_0$ transitions. [C II] peaks at Her 36 and is very bright toward the northwest of Her 36. [C II] peaks at an offset of $(\Delta \alpha = 30.6''$, $\Delta \delta = -1.6''$), which is toward the east of Her 36 and the emission extends even further. This extended emission comes from the part of the HIII region that is illuminated by the stellar system 9 Sgr (Tothill et al. 2008).

Figure 4 shows a velocity integrated intensity map of an average of the H40α to H44α hydrogen recombination lines. We have taken the average to obtain a better signal-to-noise ratio. The distribution or the radio recombination line emission agrees well with the 5 GHz continuum Very Large Array (VLA) interferometric map in Fig. 4 of Woodward et al. (1986) and the peak of
all maps are plotted using original beam sizes shown in the lower left of each map.

| H$\alpha$   |                 |                               |                               |                   |                   |                   |
| H$\alpha$   |                 |                               |                               |                   |                   |                   |

the H$\alpha$ lines is at ($\Delta \alpha = 10.0''$, $\Delta \delta = 9.0''$), close to the center of the Hourglass Nebula, which indicates the presence of hot ionized gas in the east of Her 36.

### 3.2. Correlation between $^{12}$CO, $^{13}$CO, [C i], and [C ii]

As can be seen from the velocity integrated intensity maps, emission from [C ii] is spread out the most as compared to [C i], $^{12}$CO, and $^{13}$CO. In order to visualize the correlation between these species, scatter plots of [C ii] vs. [C i], [C ii] vs. $^{12}$CO $J = 6 \rightarrow 5$, and [C i] vs. $^{13}$CO $J = 2 \rightarrow 1$ are shown in Fig. 5. We chose CO $6 \rightarrow 5$ owing to its association with the warm PDR due to its higher upper level energy compared to low-$J$ CO transitions, while we chose $^{13}$CO $2 \rightarrow 1$ in particular, as its critical density is comparable to that of [C i]. [C ii] is correlated the least with $^{12}$CO $J = 6 \rightarrow 5$. The Pearson correlation coefficient is $r = 0.471$. Two branches appear to bud out in the upper left and lower right of this correlation. The upper left, where the [C ii] emission intensifies for a slowly strengthening $^{12}$CO $J = 6 \rightarrow 5$ emission, corresponds to the northeast of Her 36 where
\( \text{II} \) correlated the least with \( \text{I} \) with \([\text{C II}] \) has a correlation coefficient of \( r = 0.473 \) and again shows two different branches corresponding to different regions. The upper left, where \([\text{C II}] \) emission gets brighter for an almost constant \([\text{C II}] \) emission, corresponds to the northeast of Her 36. The branch in the lower right, similar to the situation shown in Fig. 5b, corresponds to the southwest of Her 36. In contrast to these correlations, \([\text{C II}] \) is well correlated with \(^{12}\text{CO} \) \( J = 2 \rightarrow 1 \) with \( r = 0.908 \). This resembles the case M17 SW, for which a correlation coefficient of \([\text{C II}] \) with \(^{13}\text{CO} \) \( J = 2 \rightarrow 1 \) was reported to be 0.942 (Pérez-Beaupuits et al. 2015c).

### 3.3. Channel maps

In order to investigate the differences in the distribution of ionized and atomic carbon, channel maps of the \(^2P_3/2 \rightarrow ^3P_1/2 \) transition of \([\text{C II}] \) are compared to those of the \([\text{C I}] \) \(^3P_1 \rightarrow ^3P_0 \) transition. Figure 6 shows that the emission from \([\text{C II}] \) (lower panels) is more spread out as compared to that from \([\text{C I}] \) (upper panels). In the velocity range from 2 to 6 km s\(^{-1}\) and 15 to 17 km s\(^{-1}\) there is no emission from \([\text{C I}] \) while there is emission from \([\text{C II}] \) close to Her 36 and toward the east of it, respectively. In the range from 7 to 9 km s\(^{-1}\) both \([\text{C I}] \) and \([\text{C II}] \) emission are found toward the west. These structures extend further toward the northeast for higher velocities in the range of 12 to 15 km s\(^{-1}\). This is very similar to the case of M17 SW, where the \([\text{C II}] \) channel map shows a strong spatial association with \([\text{C I}] \) and CO channel maps only at intermediate 10 to 24 km s\(^{-1}\) velocities. While at lower (<10 km s\(^{-1}\)) and higher (>24 km s\(^{-1}\)) velocity channels, \([\text{C II}] \) emission is mostly not associated with the other tracers of dense and diffuse gas (Pérez-Beaupuits et al. 2015c). Notably, our \([\text{C I}] \) channel maps show a clumpy structure at an offset of \((\Delta x = 60.0^\prime\prime, \Delta y = 27.0^\prime\prime) \) which is missing in the \([\text{C II}] \) maps; this complements the argument that the east of Her 36 is comprised of hot gas and strong UV fields capable of ionizing carbon, i.e., it is part of an HII region. This is consistent with the H\(\alpha\) and 5 GHz continuum VLA interferometer maps presented by Woodward et al. (1986) in their Figs. 1 and 4, which also have their peak intensities east from Her 36.

### 3.4. Ancillary data

For a multiwavelength view of M8 and in order to relate our observations to the dense and cold molecular cloud and the hot ionized gas in M8, we compared our data with observations obtained at other wavelength ranges. The surveys chosen

Notes. (a) The reference position is that of Her 36. (b) In units of main beam brightness temperature.

\[ [\text{C II}] \] is more extended. The lower right, where \(^{12}\text{CO} \) \( J = 6 \rightarrow 5 \) emission intensifies at a faster rate than \([\text{C II}] \), corresponds to the southwest of Her 36, where \(^{12}\text{CO} \) \( J = 6 \rightarrow 5 \) is much more prominent. The correlation of \([\text{C II}] \) with \([\text{C I}] \) has a correlation coefficient of \( r = 0.473 \) and again shows two different branches corresponding to different regions. The upper left, where \([\text{C II}] \) emission gets brighter for an almost constant \([\text{C II}] \) emission, corresponds to the northeast of Her 36. The branch in the lower right, similar to the situation shown in Fig. 5b, corresponds to the southwest of Her 36. In contrast to these correlations, \([\text{C II}] \) is well correlated with \(^{13}\text{CO} \) \( J = 2 \rightarrow 1 \) with \( r = 0.908 \). This resembles the case M17 SW, for which a correlation coefficient of \([\text{C II}] \) with \(^{13}\text{CO} \) \( J = 2 \rightarrow 1 \) was reported to be 0.942 (Pérez-Beaupuits et al. 2015c).

---

The reference position is that of Her 36. In units of main beam brightness temperature.
Fig. 6. Velocity channel maps of the $^3P_1 \rightarrow ^3P_0$ transition of [C I] (upper 16 panels) and the $^2P_{3/2} \rightarrow ^2P_{1/2}$ transition of [C II] (lower 16 panels) in a range of 2–17 km s$^{-1}$ with a channel width of 1 km s$^{-1}$ toward Her 36, which is the central position ($\Delta \alpha = 0$, $\Delta \delta = 0$) at RA(J2000) = 18$^h$03$^m$40.3$^s$ and Dec(J2000) = $-24^\circ$22′43″, denoted with a black asterisk. The contour levels of [C I] are 3 $\times$ rms in steps of 2 $\times$ rms, while those of [C II] are from 10% (>3 $\times$ rms) to 100% in steps of 10% of the corresponding peak emission. All maps are plotted using original beam sizes shown in the lower left of both panels.
for this comparison are as follows: firstly, we extracted data from the 870 µm APEX Telescope Large Area Survey of the Galaxy (ATLASGAL; Schuller et al. 2009) performed with the APEX 12 m telescope using the Large APEX BOlometer CAmera (LABOCA). The dust continuum emission probes dense and cold clumps in the ISM of our Galaxy. Figure 7a shows our [C ii] velocity integrated intensity map overlaid with the ATLASGAL dust continuum image that peaks at Her 36 and also traces the cold molecular cloud in the northwest. The dust emission morphology is similar to the 12CO, 13CO, and C18O distribution. Secondly, we used data from the National Radio Astronomy Observatory (NRAO)/Very Large Array (VLA) Archive Survey (NVAS). Figure 7b shows the [C ii] velocity integrated intensity map overlaid with the 1.3 cm radio

http://archive.nrao.edu/nvas/
continuum image\footnote{NRAO/VLA Archive Survey. (c) 2005–2007 AUI/NRAO.}, which peaks very close to Her 36 and traces free–free emission from the HII region NGC 6523/33. This compact HII region, which is also traced by the H recombination lines with the IRAM 30 m telescope, is also shown in Fig. 4 (right panel). Thirdly, the Wide-field Infrared Survey Explorer (WISE) imaged the sky at four mid-infrared wavelengths. Figure 7c and d compare the [C II] velocity integrated intensity map with WISE 3.4 $\mu$m (band 1) and 4.6 $\mu$m (band 2) continuum images, which peak closer to the [C II] peak. Overall, the mid-infrared emission that originates from hot dust shows the best agreement with the morphology seen in the [C II] image; both probe hot material from HII regions and warm surfaces of PDRs.

3.5. Spectra of $^{12}$CO, $^{13}$CO, [C I] and [C II] emission lines at different offsets

Figure 8 shows a comparison between the spectra of $^{12}$CO, $^{13}$CO, [C I], and [C II] emission lines at different offsets relative to Her 36. Line parameters of Gaussian fits to profiles are reported in Table 2. In several cases the profiles show evidence of two velocity components that were fit separately. The $^{12}$CO $J = 6 \rightarrow 5$ and $^{13}$CO $J = 1 \rightarrow 0$ transitions are representative of the general appearance of all $^{12}$CO and $^{13}$CO line profiles discussed in this paper. The different offsets were chosen along a curved line from the molecular cloud in the west to the east of Her 36 (see Fig. 7a): the secondary C$^+$ peak, which corresponds to the clump observed in the channel map of [C II] at $(\Delta \alpha = 60.0'', \Delta \delta = 27.0'')$; the C$^+$ peak, which is the emission peak of the $^2P_{1/2} \rightarrow ^2P_{1/2}$ transition of [C II] at $(\Delta \alpha = 30.0'', \Delta \delta = -2.0'')$; Her 36 is located at $(\Delta \alpha = 0.0'', \Delta \delta = 0.0'')$; the mid-$J$ CO peak, which is the mid-$J$ transition emission peak of $^{12}$CO and $^{13}$CO at $(\Delta \alpha = -13.0'', \Delta \delta = 8.0'')$; and the secondary ATLASGAL peak arises from deep into the molecular cloud to the west traced by ATLASGAL at $(\Delta \alpha = -53.0'', \Delta \delta = 23.0'')$.

A lower velocity (2–6 km s$^{-1}$) component is spectrally resolved at several positions. The higher velocity component emission lines have blue-shifted wings in the molecular cloud in the west, while the emission is red-shifted toward the [C II] peak toward the east compared to their emission peaking at 9 km s$^{-1}$ toward our reference position, Her 36. Furthermore, the peak of the lines shifts from the east to the west to lower velocities. The $^{12}$CO and $^{13}$CO line profiles are similar in being most intense with broadest line widths at the mid-$J$ transition emission peak of $^{12}$CO and $^{13}$CO $(\Delta \alpha = -13.0'', \Delta \delta = 8.0'')$ and at Her 36 itself, while getting less intense with narrower line widths at the

---

Fig. 8. Line profiles at different offsets (') relative to Her 36 are shown in different colors at five positions mentioned in the upper left plot. For the detailed positions, see Sect. 3.5. Upper panels: $J = 6 \rightarrow 5$ $^{12}$CO and $J = 1 \rightarrow 0$ $^{13}$CO spectra; lower panels: $^2P_{1/2} \rightarrow ^2P_{1/2}$ and $^2P_{1/2} \rightarrow ^2P_{1/2}$ transitions of [C I] and [C II]. All spectra were extracted from their original beam sizes as mentioned in Table 1.

Fig. 9. Line profiles toward Her 36 for [C I] $^1P_{1} \rightarrow ^1P_{0}$, $^{12}$CO $J = 6 \rightarrow 5$, $^{13}$CO $J = 6 \rightarrow 5$, and [C II] $^2P_{1/2} \rightarrow ^2P_{1/2}$. All spectra are extracted from maps that were convolved to the same beam size of 15$''$.

---

Fig. 7. Line profiles at different offsets toward Her 36 are shown in different colors at five positions mentioned in the upper left plot. For the detailed positions, see Sect. 3.5. Upper panels: $J = 6 \rightarrow 5$ $^{12}$CO and $J = 1 \rightarrow 0$ $^{13}$CO spectra; lower panels: $^2P_{1/2} \rightarrow ^2P_{1/2}$ and $^2P_{1/2} \rightarrow ^2P_{1/2}$ transitions of [C I] and [C II]. All spectra were extracted from their original beam sizes as mentioned in Table 1.
[C II] peak. The [C II] line profile gets most intense with broadest line width toward Her 36 itself with almost no emission from the clumpy structure in the HII region at an offset of (\(\Delta\alpha = 0, \Delta\delta = 27.0^\circ\)). As can also be seen from the comparison of various molecular transitions at Her 36 in Fig. 9, CO and [C II] are not associated with [C II] at lower and higher velocities (see also Figs. 5 and 6). This is very similar to M17 SW as reported by Pérez-Beaupuits et al. (2015c), where [C II] is not associated with other gas tracers at lower and higher velocities.

### 4. Analysis

In this section we determine the temperature and density in the PDR of M8 with several complementary methods. We start by using the data for the \(J = 6 \rightarrow 5\) transition of CO, which has the highest angular resolution, to estimate excitation temperatures and column densities throughout the PDR as probed by the mid-\(J\) CO emission.

#### 4.1. Excitation temperature and column density estimates

A detailed description of spectral line radiative transfer relevant here can be found in Draine (2011) and Mangum & Shirley (2016). For a constant excitation temperature \(T_{\text{ex}}\), we can integrate the radiative transfer equation to obtain the observable Rayleigh–Jeans equivalent temperature \(T_\text{R}^*\) (Eq. (1) in Peng et al. 2012). The background radiation temperature comprises the cosmic background radiation of 2.73 K and the radiation from warm dust. The latter was calculated using the results from the Spectral and Photometric Imaging Receiver (SPIRE) of the European Space Agency (ESA) Herschel Space observatory. Data obtained in the second band at 350 \(\mu\)m (close to the \(12\text{CO} \rightarrow 6\text{line}\) wavelength was used. The maximum intensity in the analyzed region around Her 36 is about 1200 MJy sr\(^{-1}\) near the dense molecular cloud, which corresponds to a Rayleigh–Jeans equivalent brightness temperature of about 0.06 K from dust. Thus, the total contribution from dust and background can be neglected as it contributes \(\lesssim 1\%\) to the resulting \(T_\text{R}\).

Assuming that the excitation temperature for \(12\text{CO}\) and \(13\text{CO}\) is the same and \(12\text{CO}\) is optically thick,

\[
\frac{T_\text{R}^*(12\text{CO})}{T_\text{R}^*(13\text{CO})} = \frac{1}{1 - e^{-\tau(13\text{CO})}} \tag{1}
\]

The excitation temperature of the \(12\text{CO} \rightarrow 5\text{ line}\) can be estimated by further assuming a beam filling factor of unity, i.e., \(T_\text{R} = T_\text{MB}\). This equation is written as

\[
T_{\text{ex}} = 33.2 \left[ \ln \left( 1 + \frac{33.2}{T_\text{MB}(12\text{CO})} \right) \right]^{-1} \text{K}, \tag{2}
\]

where \(T_\text{MB}\) is the main beam brightness temperature in K that is estimated from the peak temperature map of \(12\text{CO} \rightarrow 5\text{ line}\). The resulting \(T_{\text{ex}}\) distribution is shown in Fig. 10a. Formally, we show lower limits to the excitation temperature due to the assumption of a beam filling factor of unity. It is highest immediately in the northwest of Her 36 and decreases with distance from the star.

Using the computed \(T_{\text{ex}}\) and the main beam brightness temperature \(T_\text{MB}\) estimated from the peak temperature map of \(13\text{CO} \rightarrow 5\text{ line}\), the total column density (Fig. 10b) of \(13\text{CO}\) can be calculated over the complete velocity range of the source from

\[
N(13\text{CO}) = 1.06 \times 10^{12} (T_{\text{ex}} + 0.88) \exp \left( \frac{116.2}{T_{\text{ex}}} \right) \int T_\text{MB}(13\text{CO}) dv \text{ cm}^{-2}, \tag{3}
\]

where \(T_{\text{ex}}\) is in K and \(T_\text{MB}\) dv is in K km s\(^{-1}\). Figure 10b shows the resulting \(13\text{CO}\) total column density with a peak value of ~5 \(\times\) 10\(^{16}\) cm\(^{-2}\) northwest of Her 36. This results in a H\(_2\) column...
density $N(H_2)$ of $\sim 3.7 \times 10^{22}$ cm$^{-2}$ adopting an isotopic abundance ratio $^{12}$CO/$^{13}$CO of $\sim 63$ (Milam et al. 2005) and a CO abundance ratio $^{12}$CO/H$_2$ of $\sim 8.5 \times 10^{-9}$ (Tielens 2010). The mass of the warm CO gas can be computed by integrating the column density over the whole clump in a region of 3.12 arcmin$^2$, which results in a mass of $\sim 467 M_\odot$. Complementary to this, the cold gas mass in a region of 5.1 arcmin$^2$ has an estimated value of $10^7 M_\odot$, calculated from a flux of $\sim 133$ Jy at 870 $\mu$m measured with ATLASGAL (Schuller et al. 2009) assuming an absorption coefficient of $k_\nu = 1.85$ g cm$^{-2}$ and a temperature of 23 K (Urquhart et al. 2018), and not including potential uncertainties in the choice of these values. However, these mass estimations have an error of $\sim 26\%$, which accounts for errors of $\sim 16\%$ from the distance to the star (Tothill et al. 2008) and $\sim 20\%$ from the calibration.

4.2. Rotational diagrams of $^{13}$CO

With observations of CO lines with different J, rotational diagrams can be used to study the excitation of the CO emitting gas. In a rotational diagram or Boltzmann plot the natural logarithm of the column density $N_u/g_u$ of different lines is plotted against their upper energies $E_{uu}/k$. Here $g_u$ is the degeneracy of the upper energy level, ($=2J+1$), and $k$ is the Boltzmann constant. For a single temperature and optically thin emission these data points fall onto a straight line. Deviations from a straight line indicate then either optical depth effects or temperature gradients in the clouds. A complete derivation of rotational diagrams for a local thermodynamic equilibrium (LTE) case can be found in Goldsmith & Langer (1999).

Firstly, by assuming $^{13}$CO to be optically thin, i.e., the optical depth correction term, $C_\tau$ is unity in Eq. (24) of Goldsmith & Langer (1999), we plot $\ln N_{th}/g_u$ versus $E_{uu}/K$ as shown in Fig. 11 in black for the five $^{13}$CO lines observed toward Her 36. A curvature in a rotational diagram can be due to optical depth effects, therefore we estimate the expected optical depths for the computed column density from Eq. (25) of Goldsmith & Langer (1999) and apply the optical depth corrections $C_\tau$ that lead to the corrected diagram as shown in red in Fig. 11. The new temperatures and column densities are then calculated as shown in Table 3. Further iterations would lead to corrections smaller than the error bars. After the optical depth correction the curvature in the rotational diagram remains

Table 3. Physical parameters calculated from rotational diagrams.

| Transition | $\tau$ | Transition | $\tau$ |
|------------|--------|------------|--------|
| $J = 1 \rightarrow 0$ | 1.68 | $J = 1 \rightarrow 0$ | 1.92 |
| $J = 2 \rightarrow 1$ | 1.78 | $J = 2 \rightarrow 1$ | 2.20 |
| $J = 4 \rightarrow 3$ | 1.25 | $J = 4 \rightarrow 3$ | 0.74 |
| $J = 6 \rightarrow 5$ | 1.12 | $J = 6 \rightarrow 5$ | 0.28 |
| $J = 8 \rightarrow 7$ | 1.04 | $J = 8 \rightarrow 7$ | 0.10 |

Notes. $^{(a)}$Calculated for different gradients with their errors in the plot as indicated in Fig. 11.

Fig. 11. Rotational diagrams of $J = 1 \rightarrow 0$, $J = 2 \rightarrow 1$, $J = 4 \rightarrow 3$, $J = 6 \rightarrow 5$, and $J = 8 \rightarrow 7$ transitions of $^{13}$CO at Her 36. Shown in black is the rotational diagram when $^{13}$CO is assumed to be optically thin. In red the rotational diagram is shown including the optical depth correction factors. Rotation temperatures obtained from different slopes are indicated. Values of the velocity integrated intensities for different transitions were extracted from maps convolved to the same resolution of 31". The error bars were calculated from the maximum noise level of the integrated intensities of individual transitions and from calibration uncertainties of 20%.

and indicates temperature gradients in the gas, as expected in a PDR.

The $J = 1 \rightarrow 0$ and $J = 2 \rightarrow 1$ transitions of $^{13}$CO seem to originate from colder gas, while the $J = 4 \rightarrow 3$ and $J = 6 \rightarrow 5$ transitions probe hotter gas, which agrees with the analysis carried out for $J = 6 \rightarrow 5$ in Sect. 4.1. The $J = 8 \rightarrow 7$ transition appears to originate from the hottest gas.

4.3. RADEX modeling

We used the non-LTE radiative transfer program RADEX (van der Tak et al. 2007) to verify the calculations carried out in Sects. 4.1 and 4.2, which assumed LTE to determine the temperatures and densities. The RADEX program uses the escape probability approximation for a homogeneous medium and takes into account optical depth effects. We chose a uniform sphere geometry. The Leiden Molecular and Atomic Database\(^8\) (LAMDA; Schöier et al. 2005) provides rates coefficients for collisions of CO and H$_2$ used in the modeling. $^{12}$CO and $^{13}$CO transitions were modeled taking their line width from the average spectra of our data, i.e., 4 and 3 km s$^{-1}$, respectively. As input parameters we computed grids in temperature and volume density with a background temperature of 2.73 K, kinetic temperatures in the range of 50–250 K and H$_2$ densities in the range of $10^5–10^9$ cm$^{-3}$. For a linear molecule line ratios from different J depend on both temperature and density. To break this degeneracy, we computed with RADEX not only the line ratio of two $^{13}$CO transitions but also the temperature of the $^{12}$CO line. The latter is optically thick, probes the excitation temperature (cf. Sect. 4.1), and can therefore be used to break the degeneracy between temperature and density.

In our first approach to determine the dominant kinetic temperatures and densities in M8 near Her 36, we selected from the CO maps data points for column densities of $^{12}$CO in three ranges as follows: (a) $8 \times 10^{17}–1.8 \times 10^{18}$ cm$^{-2}$, (b) $1.8 \times 10^{18}–3.5 \times 10^{18}$ cm$^{-2}$, and (c) $3.5 \times 10^{18}–5.1 \times 10^{18}$ cm$^{-2}$. These

J = 6 → 5, the total column density (Fig. 10 (b)) of 13CO can be calculated over the whole clump in a region of 3.12 k″ measured with ATLASGAL (Schuller et al. 2009) assuming a column density over the complete velocity range of the source from 10^16 cm^-2 and for the modeling the input 12CO column density is 4 × 10^18 cm^-2.

Article number, page 12 of 18

the column density over the complete velocity range of the source from 10^16 cm^-2 and for the modeling the input 12CO column density is 4 × 10^18 cm^-2. In order to include all CO lines toward several positions in the RADEX analysis, their intensities as a function of J are compared to RADEX results in Fig. 13. To fit the modeling results to the observed data points we varied the column densities of 13CO and 12CO. While for 12CO a column density of 4 × 10^18 cm^-2 was chosen, for 13CO a column density of 8 × 10^16 cm^-2 could make the modeling results fit the data points. This 13CO column density exceeds the value obtained by the LTE calculations and corresponds to a 12CO/13CO ratio of 50. While this is lower than the assumed value of 63 in Sect. 4.1, it is still within the typical scatter of this ratio in the ISM (Milam et al. 2005). The 12CO and 13CO observed data is compared to the RADEX model at the peak of the mid-J CO transitions in the molecular cloud, at Her 36 and at the emission peak of [C II]. Panels a and b of Fig. 13 show results with the kinetic temperature varied from 50–250 K and keeping the H2 density fixed at 10^9 cm^-3, while panels c and d show results in which the H2 density is varied from 10^6–10^7 cm^-3 while keeping the kinetic temperature fixed at 120 K.

It can be seen that no single kinetic temperature or H2 density can fit all the observed data points. This suggests solutions with kinetic temperatures in the range of 100–150 K and H2 densities to be in the range of 10^9–10^10 cm^-3. Such a spread in the ambient temperature was also implied by the rotational diagram analysis. Furthermore, these values are similar to the temperature and density ranges found in OMC 1 (Peng et al. 2012).

4.4. CO, [C I] and [C II] luminosities

We obtained the total luminosities of the CO spectral line energy distributions (SLED) and of the [C I] 609 μm and [C II] lines over the total observed region seen in the maps in Figs. 2–4, as derived by Solomon et al. (1997), Carilli & Walter (2013). We scaled the luminosity for Galactic sources, i.e.,

\[ L = 1.04 \times 10^{-9} S \Delta V D_l^2, \]

where L is the line luminosity in L⊙, S ΔV is the velocity integrated flux in Jy km s^-1, v is the transition frequency in GHz, and D_l is the distance in kpc. A total CO luminosity of L_CO = 9.5 L⊙ was calculated for the observed transitions and by accounting for the luminosities of the missing transitions. A [C I] 609 μm line luminosity of L_[C I] = 0.11 L⊙ was obtained, which is a lower limit to the total [C I] luminosity since the [C I] 370 μm line was not observed. The estimated [C I] luminosity is
5. Discussion

5.1. Overview of the PDR and HII region around Her 36

In Fig. 14, we present a F487N filtered 4865 Å HST image⁹ (observation ID number: 6227, observed in the year 1995) of Her 36 and its surroundings overlaid with contours from low velocity [C II] channel maps. The [C II] at the lowest velocity (2 km s⁻¹) peaks at the Hourglass Nebula slightly to the east of Her 36. With increasing velocities, the [C II] follows the dark patches in the HST images that form a foreground veil covering parts of the bright nebulosity excited by Her 36. The strong correlation of [C II] and foreground absorption is particularly evident at the sharp southern edge of the veil seen at 7 km s⁻¹. Therefore we suggest that the low velocity [C II] probes directly the gas of the veil that forms a foreground PDR illuminated by Her 36. On a fainter level, weak emission from this veil is also seen in the CO maps at low velocities (5–7 km s⁻¹). This foreground veil is receding away from Her 36 toward us and to the west with a change in the line-of-sight velocity. This is consistent with both high velocity red-shifted and low velocity blue-shifted emission of Hα, [N II] and [S II] doublets, [O III], and absorption lines of the sodium D doublet as measured by Damiani et al. (2017). Assuming optically thin emission from [C II] in this warm veil in the velocity range of 2–7 km s⁻¹ and a kinetic temperature of 500 K (Tielens & Hollenbach 1985b), we calculated the [C II] column density using Eq. (A.1) with a peak value of ∼9.6 × 10¹⁷ cm⁻² at an offset of (∆α = 30″).

⁹ Based on observations made with NASA/ESA Hubble Space Telescope, and obtained from the Hubble Legacy Archive, which is a collaboration between the Space Telescope Science Institute (STScI/NASA), the Space Telescope European Coordinating Facility (ST-ECF/EISA), and the Canadian Astronomy Data Centre (CADC/NRC/CSA).
\[ \Delta \delta = 10'' \] from Her 36. Taking C/H $\sim 1.2 \times 10^{-4}$, assuming that all the carbon is in ionized form and from the column density of H$_2$, $N$(H$_2$) $= 9.4 \times 10^{20}$ cm$^{-2}$ (A$_v$/mag) (Kauffmann et al. 2008), we derived the visual extinction A$_v$. A maximum extinction of A$_v$ $\sim 4.25$ is obtained at the same position where the [C ii] column density peaks and the values get lower around it. This position is the same as position 13 in Fig. 5 of Woodward et al. (1986), where an A$_v$ $\sim 3.9$ was calculated.

In Fig. 15 (left) we show how the intensity of various tracers evolves along a path from the direction of 9 Sgr to Her 36 and then continuing to the northwest along the molecular cloud. Toward the northeast [C ii] and the mid-IR WISE emission dominate, probing the extended HII regions toward 9 Sgr and the resulting PDR. All of the tracers peak on or close to Her 36, showing the tight spatial correlation of the ultracompact HII region (as seen in the recombination line), a dense clump in the larger scale molecular cloud (870$\mu$m dust and molecular emission), and the bright PDR illuminated by Her 36 ([C ii] and WISE). To the northwest, emission from the molecular cloud dominates with the second dense but colder clump at an offset of about 70'' from Her 36. [C ii] diffuse emission is very extended in this region.

Taking this into consideration along with our analysis of the morphology carried out in Sects. 3 and 4, we propose a geometry of the region illuminated by Her 36 and 9 Sgr as presented in Fig. 15 (right). We propose that the cold dense molecular cloud is behind the bright stars Her 36 and 9 Sgr. Her 36 is still much closer to the dense part of the cloud in which it was born; in fact the foreground veil is part of the original cloud accelerated toward us by the strong radiation and wind of Her 36, showing the expansion of the nebula, blue shifted with respect to the molecular cloud (3–7 km s$^{-1}$) moving away from Her 36 ($\sim 9$ km s$^{-1}$) toward the observer and the west, while the red-shifted (11–13 km s$^{-1}$) [C ii] probes the background material toward the northeast of Her 36. The ultracompact HII region is fueled by Her 36 around its vicinity and the more extended diffuse HII region by 9 Sgr toward the east (Tothill et al. 2008).
5.2. Comparison with PDR of the Orion Bar

The Orion Bar is a well-known PDR and its properties are described in detail by Hollenbach & Tielens (1997) and Walmsley et al. (2000). It is part of the OMC-1 core at the edge of M42 and is illuminated by young massive stars, which form a trapezium at the center of the Orion Nebular Cluster, mainly from \( \theta^1 \) C, which is a O5-O7 star. Also, the PDR appears to be located at the edge of the HII blister tangential to the line of sight (Peng et al. 2012). A comparison of \( L_{\text{CO}-2,1} / L_{\text{FIR}} \) between M8 and the Orion Bar is presented in Table 4. For M8, the \( L_{\text{CO}-2,1} = 0.128 L_\odot \) (calculated in a similar way as in Sect. 4.4), \( L_{\text{CII}} \) is calculated in Sect. 4.4 and \( L_{\text{FIR}} \approx 10^5 L_\odot \) is obtained from White et al. (1998). The luminosities of the Orion Bar are taken from Goicoechea et al. (2015).

We calculated the FUV radiation field, \( G_0 \approx 0.6–1.12 \times 10^5 \) in Habin units and density, \( n \approx 0.97–1.93 \times 10^5 \text{ cm}^{-3} \) for the PDR of M8 by adopting an electron density \( n_e \) of 2000–4000 cm\(^{-3}\), electron temperature \( T_e \) of 7000–9000 K (Woodward et al. 1986; Esteban et al. 1999). We used the values of stellar luminosity and number of ionizing photons for an O7 star from Sect. 7.2.1 of Tielens (2010). The densities match values of stellar luminosity and number of ionizing photons for an O7 star from Sect. 7.2.1 of Tielens (2010). The densities match well with the RADEX calculations carried out in Sect. 4.4. Interestingly, these calculated values of \( G_0 \) and \( n \) also match very well with those calculated for the Orion Bar. This leads us to a direct comparison of the results of the PDR models of the Orion Bar (Tielens & Hollenbach 1985a, b; Jansen et al. 1995; Hogerheijde et al. 1995; Hollenbach & Tielens 1997, 1999; Andree-Labsch et al. 2017) with the PDR of M8 since we expect similar chemical and thermal conditions in both PDRs. Tielens & Hollenbach (1985a) and Hollenbach & Tielens (1999) calculated the structure of the Orion Bar as a function of visual extinction \( A_v \). They show a typical case in which \( H_2 \) does not self-shield until dust attenuation of the FUV photons creates an atomic surface layer. According to this, in the PDR of M8 the transition of atomic H to molecular H\(_2\) occurs at \( A_v = 2 \), the carbon balance shifts from \( \text{C}^+ \) to \( \text{C} \) and \( \text{CO} \) at \( A_v = 4 \), and except for the \( \text{O} \) in \( \text{CO} \), all oxygen is in atomic form until very deep into the molecular cloud at \( A_v = 8 \). The gas in the surface layer is much warmer at about \( 500 \text{ K} \) than the dust, which is at about \( 30–75 \text{ K} \). Complementary to the \( H_2 \) column density calculation carried out in Sect. 4.1, assuming a dust temperature of 75 K and a maximum flux value of 5000 mJy beam\(^{-1}\) obtained from ATLASGAL data, allowed us to calculate the \( H_2 \) column density at Her 36, \( N(H_2) \approx 3.75 \times 10^{12} \text{ cm}^{-2} \) which is in reasonable agreement with that calculated in Sect. 4.1 within a factor \( \sim 1.25 \).

Hogerheijde et al. (1995), Walmsley et al. (2000), and Andree-Labsch et al. (2017) described the geometry of the Orion Bar where the trapezium stars illuminate the PDR, which changes from a face-on to an edge-on orientation along the varying length of the line of sight. This geometry explains the \([\text{C}\text{II}]\) peak that is symmetric around the peak of the CO emission (Tauber et al. 1994). The \([\text{C}\text{II}]\) emission peak is also distributed symmetrically around the ionization front (Stacey et al. 1993). Contrary to this, in M8, we see that \([\text{C}\text{I}]\) peaks at the east of Her 36, \([\text{C}\text{I}]\) peaks at Her 36, while the CO transitions peak in the northwest of Her 36, which supports the proposition of a face-on geometry.

5.3. Comparison with the PDR of M17 SW

M17, the Omega nebula is also among the best nearby laboratories to study star formation. It has an edge-on geometry in contrast to the face-on geometry of M8. It has a bright HII region ionized by the rich cluster NGC 6618 (Povich et al. 2009) and beyond this HII region lies the bright PDR in the southwest of M17 (M17 SW), which is responsible for the photoelectric heating of the warm gas (Pérez-Beaupuits et al. 2015a). M17 SW also contains a wide ranged clumpy molecular cloud studied widely by Pérez-Beaupuits et al. (2010) and Pérez-Beaupuits et al. (2015a).

In Sect. 3.2, the scatter plots related to M8 show only a weak correlation of \([\text{C}\text{II}]\) with \([\text{C}\text{I}]\) and \([\text{CO}]\). The channel maps and line profiles at different offsets also show different morphologies of \([\text{C}\text{II}]\) compared with those seen in \([\text{C}\text{I}]\) and \([\text{CO}]\) except in a small range of intermediate velocities toward Her 36. This suggests that \([\text{C}\text{II}]\) and the molecular gas tracers on scales away from Her 36 do not originate from the same spatial region. This is similar to M17 SW as reported by Pérez-Beaupuits et al. (2015a). In Sect. 4.3, the comparison between the observed \([\text{CO}]\) and \([\text{CO}]\) data with non-LTE RADEX modeling results show that the UC HII region or molecular gas near the Her 36 region has the highest density and kinetic temperature, while the molecular gas near the eastern HII region has low density and lower kinetic temperature. In contrast to M17 SW (Pérez-Beaupuits et al. 2015b), the \([\text{CO}]\) SLED shapes we see in Fig. 13 toward Her 36 and mid-J CO positions follow a similar trend. Thus, they do not indicate large fluctuations in gas temperatures of the molecular gas. However, similarly to the case of M17 SW, the higher J CO lines show significantly lower intensities at the [C II] peak position. This is consistent with a PDR, where the [C II] peak emission is expected to arise from less dense gas than at the Her 36 position.

6. Conclusions

In this paper, we presented for the first time velocity integrated intensity maps of \( J = 11 \rightarrow 10, J = 13 \rightarrow 12, J = 16 \rightarrow 15 \) \([\text{CO}]\), and \([\text{C}\text{II}]\) 158 \text{ nm}, observed toward Her 36 in M8 using the dual-color Terahertz receiver GREAT on board the SOFIA telescope; \( J = 2 \rightarrow 1, J = 3 \rightarrow 2, J = 6 \rightarrow 5, \text{ and } J = 7 \rightarrow 6 \) \([\text{CO}]\) transitions; \( J = 2 \rightarrow 1, J = 4 \rightarrow 3, \text{ and } J = 6 \rightarrow 5 \) \([\text{CO}]\) transitions using the CHAMP*, FLASH*, and PI230 receivers of the APEX telescope; and \( J = 1 \rightarrow 0 \) transitions of \([\text{CO}]\) and \([\text{CO}]\) using the EMIR receiver of IRAM 30 m telescope.

Combining the information obtained from Sects. 3 and 5.1, we put forward the geometry of the region surrounding Her 36. M8 has a face-on geometry where the cold dense molecular cloud lies in the background with Her 36 being still very close to the dense core of the cloud from which it was born. Her 36 is powering the HII region toward the east of it along with 9 Sgr, while the foreground veil of a warm PDR is receding away (at lower velocities) from Her 36 toward the observer.

Using different techniques we studied the physical conditions in the molecular gas associated with M8. CO rotation diagrams indicate temperature gradients through the PDR. Low-
13CO transitions seem to originate from colder gas, while the $J = 8 \rightarrow 7$ transition seems to originate from the hottest gas. Quantitative analysis including LTE approximation methods and the non-LTE RADEX program were used to calculate the temperatures and H$_2$ number density in the PDR around Her 36. Kinetic temperatures ranging from 100–150 K and densities ranging from $10^4$–$10^6$ cm$^{-3}$ were obtained.

Appendix A: [C II] column density

For optically thin, thermalized [C II] emission and neglecting the effects from the background, the observed antenna temperature is found to be:

$$T_{\lambda}^* = 3.43 \times 10^{-6} [1 + 0.5e^{91.25/T_{\text{kin}}} - 1] \frac{N([\text{C II}])}{\delta v} \frac{K}{\text{cm}^{-2}}$$  

(A.1)

where $T_{\text{kin}}$ is the kinetic temperature, $N([\text{C II}])$ is the [C II] column density in cm$^{-2}$ and $\delta v$ is the line width in km s$^{-1}$.
