Abstract
We investigate the effect of a global degeneracy in the distribution of the entanglement spectrum in conformal field theories in one spatial dimension. We relate the recently found universal expression for the entanglement Hamiltonian to the distribution of the entanglement spectrum. The main tool to establish this connection is the Cardy formula. It turns out that the Affleck–Ludwig non-integer degeneracy, appearing because of the boundary conditions induced at the entangling surface, can be directly read from the entanglement spectrum distribution. We also clarify the effect of the non-integer degeneracy on the spectrum of the partial transpose, which is the central object for quantifying the entanglement in mixed states. We show that the exact knowledge of the entanglement spectrum in some integrable spin-chains provides strong analytical evidences corroborating our results.

Keywords: Cardy formula, entanglement spectrum, spin chains, conformal field theory, integrability, negativity spectrum

1. Introduction

During the 2000s, entanglement became a standard and powerful tool for the study of many-body quantum systems, both in and out of thermodynamic equilibrium (see, e.g. [1–4] as reviews); for example, entanglement is nowadays routinely used for the identification of critical and topological phases of matter. The central quantity to quantify the bipartite entanglement in a many-body system is the reduced density matrix $\rho_A = \text{Tr}_B \rho$, where $B$ is the complement of $A$, and $\rho$ is the density matrix of the
entire system. When the system is in a pure state $|\Psi\rangle$ and $\rho = |\Psi\rangle\langle\Psi|$, the entanglement can be measured by the von Neumann or Rényi entropies of $\rho_A$. However, it was pointed out long ago by Li and Haldane [5] that the reduced density matrix (RDM) encodes much more information than the entanglement entropy. Part of this information may be extracted by looking at the entire spectrum of $\rho_A$, which has been dubbed the entanglement spectrum. This observation triggered a systematic study of the entanglement spectrum, which proved to be an extremely powerful theoretical tool to analyse topological phases [5–10], symmetry-broken phases [11–15], disordered systems [16–19] and gapless one-dimensional phases [20–22]. Furthermore, a protocol for measuring the entanglement spectrum in cold-atom experiments has been proposed [23], which generalises the recent measurements of entanglement entropy [24, 25].

In [20], it has been pointed out that the distribution of the eigenvalues $\lambda_i$ of the reduced density matrix $\rho_A$ (also known as entanglement spectrum distribution)

$$P(\lambda) \equiv \sum_i \delta(\lambda - \lambda_i), \quad (1)$$

can be reconstructed from the analytic knowledge of the moments $\text{Tr}_{\rho_A^n}$ of $\rho_A$. In this respect, conformal invariant field theories represent a very useful playground. Indeed, for a conformal invariant system in one spatial dimension, for a finite interval $A$ of length $\ell$ embedded in an infinite system, the moments are given as [26, 27]

$$\text{Tr}_{\rho_A^n} = c_n \left( \frac{\ell}{\epsilon} \right)^{\frac{n-1}{n}}, \quad (2)$$

where $c$ is the central charge of the conformal field theory (CFT), $\epsilon$ an ultraviolet cutoff, and $c_n$ a non-universal and in general unknown $n$-dependent amplitude. Assuming $c_n$ to be constant, in [20] a super-universal form of the entanglement spectrum distribution has been explicitly worked out: it turned out to depend only on the central charge via the largest eigenvalue of $\rho_A$. Thus, when expressed in terms of the latter, the entanglement spectrum distribution does not depend on any parameter of the theory. This super-universal distribution leads to an extremely simple scaling law for the integrated distribution function $n(\lambda)$, i.e. the number of eigenvalues larger than $\lambda$, which is

$$n(\lambda) = I_0(\xi_\lambda), \quad \xi_\lambda = 2 \sqrt{(- \ln \lambda_{\text{max}}) \ln(\lambda_{\text{max}}/\lambda)}, \quad (3)$$

where $I_0(x)$ is the modified Bessel function and $\lambda_{\text{max}}$ the largest eigenvalues of $\rho_A$. Obviously, the only condition for the validity of (3) is the particular $n$-dependence in (2). Consequently, the same law (3) is valid in many other situations in CFT (finite systems, systems with boundaries, finite temperature, etc), as well as in proximity of quantum critical points, where the same scaling (2) holds with the replacement of $\ell$ with the correlation length [26]. Several numerical studies [4, 20, 28–31] found that the super-universal distribution (3) describes surprisingly well the spectrum of lattice models whose low-energy spectrum has an underlying CFT, despite the assumption of $c_n$ being constant. The exact knowledge of the distribution (3) also played a central role in understanding the performance of matrix product states algorithms [32].

In very recent times, a lot of activity has been devoted to the study of the operatorial form of the reduced density matrix [33–46]. For this goal, the reduced density matrix is written as

$$\rho_A = e^{-2\pi K_A}, \quad (4)$$

where $K_A$ is the entanglement (or modular) Hamiltonian. The first study of the modular Hamiltonian dates back to the seminal work by Bisognano and Wichmann [47], which proved that for an arbitrary relativistic quantum field theory in Minkowski space of generic
dimensionality and for a bipartition in two equal semi-infinite parts separated by an infinite hyperplane, the entanglement Hamiltonian may be expressed as an integral of the local energy density with a space-dependent weight factor. This theorem has been exploited, especially in CFTs in arbitrary dimensions, to relate entanglement Hamiltonians in different bipartitions [36, 38, 42]. In turn, these works relate the entanglement to the Hamiltonian spectrum, a result which we will exploit here.

This paper has many different goals which can be summarised as follows. On the one hand, we want to directly derive the entanglement spectrum distribution in [20] from the entanglement Hamiltonian in [42], also to understand the validity of the assumptions made in both [42] and [20]; in particular, the assumption of \( c_n \) being constant (see (2)). We anticipate that the relation between the distribution of the entanglement spectrum and that of the energy spectrum of the CFT is the famous Cardy formula [48]. This naturally poses the question about the effect of degeneracies of the spectrum of \( \rho_A \), which must be related to the Affleck–Ludwig boundary entropy [49] appearing in the Cardy formula on the annulus. In turn, this leads to a non-trivial \( n \)-dependence of the factor \( c_n \) in (2), which affects the entanglement spectrum distribution. Thus, this result shows that the physics at the entangling surface can be read off from the entanglement spectrum distribution. Finally, we will show that the degeneracy in the spectrum of \( \rho_A \) has non-trivial effects also on the distribution of the eigenvalues of the partial transpose of \( \rho_A \), i.e. the negativity spectrum of [50, 51].

This paper is organised as follows. In section 2, as a warming-up exercise, we work out with elementary methods the consequences of a global degeneracy in the entanglement spectrum on the distribution of eigenvalues and on the moments of the reduced density matrix. In section 3 we show that the entanglement spectrum distribution in [20] is a reparametrisation of the Cardy formula. This is one of the main results of this paper that allows us to understand also how the Affleck–Ludwig boundary entropy [49], induced by the physics at the entangling surface, affects the entanglement spectrum distribution. In section 4, we test the general results of the previous sections in some integrable spin-chains. In section 5 we explore the consequences of the degeneracy of the entanglement spectrum for the spectrum of the partially transposed density matrix, i.e. for the negativity spectrum. Finally, in section 6 we draw our conclusions.

2. Entanglement spectrum distribution and global degeneracies

We start by considering an elementary exercise about the effects of global degeneracy of the eigenvalues of the reduced density matrix (e.g. as a consequence of some internal or topological symmetry) on the entanglement spectrum distribution. This problem can be understood with several equivalents methods, but in the following we prefer to exploit the relation of the entanglement spectrum with the moments of the reduced density matrices (i.e. the Rényi entanglement entropy) so to make a direct contact with the derivation of the CFT entanglement spectrum distribution in [20]. We stress that there are no new findings in this section, but just a different view about well-known facts.

Let us consider the case in which all eigenvalues \( \lambda_j \) of the RDM have a degeneracy \( g \). Here \( j = 0, 1, 2, \ldots, Ng - 1 \), and the \( g \) consecutive eigenvalues with \( gi < j < g(i + 1) \) with \( i = 0, 1, 2, \ldots, N - 1 \) are all equal. We also introduce a set of non-degenerate eigenvalues \( \mu_i \) (with \( i = 0, 1, 2, \ldots, N - 1 \)), just by taking one of every \( g \)-degenerate eigenvalue \( \lambda_j \). Because of the normalisation \( \text{Tr} \rho_A = 1 \), the only way of doing so is by rescaling the eigenvalues by a factor \( g \), i.e.

\[
\mu_i = g \lambda_{gi}.
\]
so that
\[
\sum_i \mu_i = 1 \iff \sum_j \lambda_j = \sum_i g \frac{\mu_i}{g} = 1.
\] (6)

For the remaining part of this section, we will denote the RDM with eigenvalues \( \lambda_j \) as \( \rho_\lambda \) and the other with eigenvalues \( \mu_i \) as \( \rho_\mu \).

Clearly, the following relation for the moments of the reduced density matrix holds
\[
R_n(\mu) \equiv \text{Tr} \rho_\mu^n = \sum_i \mu_i^n,
\]
\[
\Rightarrow R_n(\lambda) \equiv \text{Tr} \rho_\lambda^n = \sum_j \lambda_j^n = \sum_i g \left( \frac{\mu_i}{g} \right)^n = g^{1-n} R_n(\mu).
\] (7)

For conformal field theories, this degeneracy does not alter the large \( \ell \) dependence of the moments \( R_\mu \) (see (2)), but it provides a relation between the multiplicative constants \( c_n \) in (2), such that
\[
c_n(\lambda) = g^{1-n} c_n(\mu).
\] (8)

Equation (8) is valid whenever a scaling like (2) occurs, e.g. close to a conformally invariant quantum critical point [26]. For the Rényi entropy \( S_n \equiv \frac{1}{1-n} \ln \text{Tr} \rho_\mu^n \), equation (7) implies
\[
S_n(\lambda) = S_n(\mu) + \ln g.
\] (9)
i.e. the degeneracy gives an additive constant which does not depend on \( \ell \) nor on \( n \). This indeed is the well-known topological term due to the degeneracy of the entanglement spectrum [52].

We now explore the consequences of this degeneracy on the entanglement spectrum distribution \( P_\lambda(\lambda) = \sum \delta(\lambda - \lambda_i) \) that can be reconstructed from the knowledge of the moments \( R_n(\mu) \) [20]. Indeed, after introducing the Stieltjes transform of \( \mu P_\mu(\mu) \)
\[
f_\mu(z) \equiv \frac{1}{\pi} \sum_{n=1}^\infty R_n(\mu) z^{-n} = \frac{1}{\pi} \int d\mu \frac{\mu P_\mu(\mu)}{z - \mu},
\] (10)
one has
\[
\mu P_\mu(\mu) = \lim_{\epsilon \to 0} \text{Im} f(\mu + i \epsilon).
\] (11)
The relation between \( \mu P_\mu(\mu) \) and \( P_\lambda(\lambda) \) easily follows from
\[
f_\lambda(z) \equiv \frac{1}{\pi} \sum_{n=1}^\infty R_n(\lambda) z^{-n} = \frac{1}{\pi} \sum_{n=1}^\infty g^{1-n} R_n(\mu) z^{-n} = g f_\mu(zg).
\] (12)

For the eigenvalue distribution this implies
\[
\frac{1}{\pi} \int d\lambda \frac{\lambda P_\lambda(\lambda)}{z - \lambda} = f_\lambda(z) = g f_\mu(zg) = \frac{g}{\pi} \int d\mu \frac{\mu P_\mu(\mu)}{zg - \mu} = \frac{1}{\pi} \int d\lambda g^2 \frac{\lambda P_\lambda(\lambda g)}{z - \lambda},
\] (13)
i.e. the final relation is
\[
P_\lambda(\lambda) = g^2 P_\mu(g \lambda).
\] (14)
Notice that \( \int d\lambda \lambda P_\lambda(\lambda) = 1 \) follows as a consequence of the normalisation of \( P_\mu(\mu) \). The factor \( g^2 \) (instead of \( g \)) can look awkward at first, but it is clearly due to the Jacobian necessary also for the normalisation.
As already mentioned in the introduction, in CFT a central quantity is the number distribution function of the entanglement spectrum, which is defined as the number of eigenvalues of the RDM larger than \( \lambda \), i.e.

\[
 n_\lambda(\lambda) \equiv \sum_{\lambda_i > \lambda} 1 = \int_{\lambda}^{\lambda_{\text{max}}} P_\lambda(x) dx.
\]

(15)

The relation between \( n_\mu(\mu) \) and \( n_\lambda(\lambda) \) is

\[
 n_\lambda(\lambda) = \int_{\lambda}^{\lambda_{\text{max}}} P_\lambda(x) dx = g^2 \int_{\lambda}^{\lambda_{\text{max}}} P_\mu(gx) dx = g \int_{\lambda_{\text{max}}}^{\mu_{\text{max}}} P_\mu(y) dy = gn_\mu(\lambda g),
\]

(16)

where we used \( \lambda_{\text{max}} = \mu_{\text{max}} / g \).

In a CFT with the assumption \( c_n = 1 \) (implying a non-degenerate spectrum), it has been shown [20] that \( n_\mu(\mu) \) can be written as (3). Then, for a model with a low-energy spectrum described by a CFT, but with a global degeneracy \( g \), since \( (\mu_{\text{max}} / \mu) = (\lambda_{\text{max}} / \lambda) \), at the leading order in \( \ln \ell \) for large \( \ell \), we have

\[
 n_\lambda(\lambda) \simeq gI_0(\xi),
\]

(17)

i.e. in the rescaled variables, the eigenvalue distribution gets multiplied by the degeneracy. This is a quite trivial result that we found instructive to derive within the methods of [20]. Since \( I_0(z) \) for large positive \( z \) grows exponentially, usually it is convenient to plot the logarithm of the number distribution, so that the net effect of \( g \) is an additive constant \( \ln g \).

3. Entanglement spectrum distribution from the Cardy formula

In this section we show how the entanglement spectrum distribution in a 1+1 dimensional CFT [20] can be obtained from the CFT density of states. In fact, we will show that the entanglement spectrum distribution is just a reparametrisation of the former. The main tool to obtain this result is the universal form for the CFT entanglement Hamiltonian which has been recently found in [42]. The leading term of the density of states for asymptotically large energies is the famous Cardy formula [48], which over the years has been investigated by many authors in order to include subleading terms [49, 53–55].

As explained in the introduction, the reduced density matrix can be always written as

\[
 \rho_A = e^{-2\pi K_A},
\]

(18)

where \( K_A \) is the entanglement Hamiltonian. For 1+1 dimensional CFTs, in the case when \( A \) is a finite interval of length \( \ell \) embedded in an infinite system, \( \rho_A \) is given by a path integral which is pictorially reproduced in figure 1. The rows and columns of the density matrix are labelled by the values of the fields on the upper and lower edges of the slit along \( A \), while along \( B \) the field is continuous. In any field theory, this representation of the reduced density matrix is plagued by ultraviolet divergences originated by the degrees of freedom in the vicinity of the boundary points between \( A \) and \( B \) (generally, the boundary between \( A \) and \( B \) is called the entangling surface and we will use this terminology, although in the case of interest here the surface is just made of one or two points). In a CFT, a very convenient way of regularising these ultraviolet divergencies is to remove small disks of radius \( \epsilon \) (the ultraviolet cutoff) around the endpoints of the interval [56, 57] (see figure 1). The price to pay is that some conformal invariant boundary conditions must be imposed on these disks. At this point, the spacetime in figure 1 has the topology of an annulus. Indeed, the mapping between this
spacetime and the annulus can be explicitly worked out and the resulting width \( W \) of the annulus is related to \( \ell \) as

\[
W = 2 \ln(\frac{\ell}{\epsilon}) + O(\epsilon)
\]

[42, 56]. An unexpected and surprising result is that the boundary conditions imposed at the small disks affect the value of physical quantities. In particular the Rényi entanglement entropies are [42]

\[
S_n = \frac{c}{6} \left( 1 + \frac{1}{n} \right) \ln \frac{\ell}{\epsilon} + \ln g,
\]

(19)

where the first term is the well-known universal leading logarithmic term [26, 56] and \( \ln g \) is the Affleck–Ludwig boundary entropy corresponding to the boundary conditions on the small disks. This should be regarded as surprising because the ultraviolet regularisation of the theory appears to affect physical observables. The explanation for this fact is that there are some physics at the entangling surface (see also [57]): the idea we have in mind is that, in a given microscopical model whose low-energy physics is described by a CFT, the partial trace over \( B \) induces boundary conditions (which could depend on the actual degeneracy of the ground state of the model that could not be unique as in a bulk CFT) and these affect physical quantities as in (19). We stress that the \( \ln g \) terms (19) is not the same as the one found in [26] which was instead due to the boundary entropy of the physical boundary of a CFT. This is instead analogous to equation (9) where \( \ln g \) enters as a true degeneration of the entanglement spectrum. The main difference between the two is that in CFT the degeneration \( g \) can be a non-integer.

At this point one could naively think that the actual value of \( \ln g \) in a given microscopical model can be always read out from the analysis of the Rényi entropies. This unfortunately is not the case because generically the additive constant term of the entanglement entropy gets non-universal contributions from ultraviolet physics in the bulk which are very difficult to disentangle from the \( \ln g \) term. This is evident if one tries to extract \( \ln g \) from some analytically known cases, as e.g. those in [58–62], and becomes even more cumbersome in numerics. (In addition, there are some cases when instead the appearance of \( \ln g \) is clear and these will be considered in the next sections to substantiate some of our findings in this section.) One of the consequence of the following analysis is that the actual value of \( g \) should be accessible in an easier manner from the analytic or numerical study of the entanglement spectrum distribution.

After this long discussion, we are ready to relate the CFT density of states and the entanglement spectrum distribution. In [42] the entanglement Hamiltonian has been related to the

---

**Figure 1.** Path integral for reduced density matrix \( \rho_A \) of an interval of length \( \ell \) embedded in an infinite system: the rows and columns of the density matrix are labelled by the values of the fields on the upper and lower edges of the slit along \( A \). The field theory expectation value is made finite by eliminating two circular regions of radius \( \epsilon \) at the two boundary points (entangling surface) with conformally invariant boundary conditions. The moments \( \text{Tr} \rho_A^n \) are computed by joining cyclically, along \( A \), \( n \) replicas of \( \rho_A \), thus leaving small holes at the entangling surface. The resulting manifold has the topology of an annulus.
generator of the translations around an annulus with the same conformally invariant boundary condition imposed on the boundaries of the small disks. By exploiting known results on the annulus, the eigenvalues $\kappa_\Delta$ of $K_A$ have been written as [42]

$$\kappa_\Delta = \frac{\pi}{W} \left( \Delta - \frac{c}{24} \right) + \text{const},$$  \hspace{1cm} (20)

where $\Delta$ are the conformal dimensions of the operators of the CFT (both the primaries and their descendants). Equation (20) implies that the eigenvalues $\lambda_\Delta$ of $\rho_A$ are in one-to-one correspondence with the spectrum of operators of the CFT as

$$\lambda_\Delta = e^{-2\pi \kappa_\Delta} = \lambda_0 e^{-2\pi (\Delta - c/24)/W},$$  \hspace{1cm} (21)

where the constant in (20) has been absorbed in $\lambda_0$. To fix the constant $\lambda_0$, let us consider the maximum eigenvalue $\lambda_{\Delta_{\text{max}}}$ of the RDM, which is obtained for the minimum value of $\Delta$ denoted by $\Delta_{\text{min}}$:

$$\lambda_{\Delta_{\text{min}}} = \lambda_0 e^{-2\pi (\Delta_{\text{min}} - c/24)/W} \xrightarrow{W \gg 1} \lambda_0 = \lambda_{\text{max}},$$  \hspace{1cm} (22)

i.e. the normalisation constant $\lambda_0$, in the limit of large $\ell$, is nothing but the largest eigenvalue of the RDM.

In the limit of large but finite $\ell$ (or equivalently, large $W$), the eigenvalues of the RDM form a continuum and their asymptotic distribution has been determined analytically in [20]. In this manuscript we reobtain this result by using the Cardy formula [48]. Our analysis allows us to find that the entanglement spectrum distribution also depends on the Affleck–Ludwig ground state degeneracy [49] which originates from the conformally invariant boundary states characterising the CFT on the annulus. This important feature has been overlooked in all the literature about the entanglement spectrum.

As a first step, let us write down explicitly the inverse function $\Delta = \Delta(\lambda)$. From (21) we find

$$\frac{\lambda_{\Delta_{\text{min}}}}{\lambda_0} \xrightarrow{W \gg 1} \frac{\lambda_{\text{max}}}{\lambda_0} \frac{\pi^2 c}{12} \ln \lambda_0 = \frac{6b}{\pi^2 c} \ln \lambda_0,$$

where, as in [20], we have introduced the parameter $b$ as $b = cW/12 = -\ln \lambda_{\text{max}}$. Actually, since we are considering the limit of large $\Delta$, the factor $c/24$ is a subleading correction, which we keep since it does not influence the final result.

Given the correspondence (21) between the eigenvalues of the RDM and the conformal spectrum, the distribution of eigenvalues $P(\lambda)$ of the RDM is

$$P(\lambda) = \int_{\Delta_{\text{min}}}^{\Delta_{\text{max}}} \rho(\Delta) \delta(\lambda - \lambda_\Delta) \, d\Delta = \int_{\Delta_{\text{max}}}^{\lambda_{\text{max}}} \rho(\Delta) \delta(\lambda - \lambda_\Delta) \frac{d\Delta}{d\lambda} \, d\lambda_\Delta$$

$$= -\theta(\lambda_{\text{max}} - \lambda) \frac{d\Delta(\lambda)}{d\lambda} \rho(\Delta(\lambda)), \hspace{1cm} (24)$$

where $\rho(\Delta)$ is the density of states in the CFT. This was introduced by Cardy [48] who derived for the first time its large $\Delta$ behaviour for a bulk CFT, known nowadays as the Cardy formula.

In the appendix A we have employed the modular invariance on the annulus to obtain a suitable expression of $\rho(\Delta)$ for large $\Delta$. In order to have a straightforward comparison with [20], we also have to take into account higher order terms in the expansion (see [55] for a similar calculation on the torus). The result reads (see (A.8))

$$\rho(\Delta) \approx g \frac{\pi^2 c}{3} I_1(\sigma(\Delta)) + g \delta(c - \Delta/24), \hspace{1cm} \text{with} \hspace{1cm} \sigma(\Delta) \equiv 2\pi \sqrt{\frac{c}{6} \left( \frac{\Delta - c}{24} \right)},$$  \hspace{1cm} (25)
where $I_1$ is the modified Bessel function of the first kind, $c$ is the central charge of the underlying CFT and $g \equiv g_\alpha g_\beta$ is the ground-state degeneracy induced by the non-trivial boundary conditions (which in a CFT can be non-integer). Here, $g_\alpha \equiv \langle 0 | a \rangle$ and $g_\beta \equiv \langle 0 | b \rangle$ are the degeneracies introduced by the two boundaries of the annulus. In the case of interest $g_\alpha = g_\beta$. Exponentially suppressed contributions have been neglected in (25). By expanding (25) for large $\Delta$ and taking the first subleading correction after the leading exponential term, the result of [49] is recovered (see (A.10)).

Equation (23) allows us to write the function $\sigma(\Delta)$ in (25) as a function of $\lambda$, obtaining

$$\sigma(\lambda) = \sigma(\Delta(\lambda)) = 2\sqrt{b \ln(\lambda_{\text{max}}/\lambda)},$$

with $b = -\ln \lambda_{\text{max}}$. Finally, plugging the Cardy formula (25) for the density of states in the distribution of the eigenvalues of the RDM (24) we have

$$P(\lambda) = \theta(\lambda_{\text{max}} - \lambda) \frac{6b}{\pi^2 c \lambda} \left[ g \frac{\pi c}{3} \frac{I_1(\sigma(\lambda))}{\sigma(\lambda)} \right] + g\delta(\lambda - \lambda_{\text{max}})$$

$$= \theta(\lambda_{\text{max}} - \lambda) g \frac{b}{\lambda} \frac{I_1(2\sqrt{b \ln(\lambda_{\text{max}}/\lambda)})}{\sqrt{b \ln(\lambda_{\text{max}}/\lambda)}} + g\delta(\lambda - \lambda_{\text{max}}),$$

which is exactly the same as the entanglement spectrum distribution of [20] multiplied by $g$. Denoting by $P_\mu(\mu)$ the above distribution for $g = 1$ and with $P_\lambda(\lambda)$ the one for arbitrary $g$, we have that equation (27) satisfies the relation (14)—found for integer $g$—in the limit $-\ln \lambda_{\text{max}} \gg 1$. Equation (27) then generalises the result of the previous section to the Affleck and Ludwig non-integer degeneracy [49], showing that it influences the entanglement spectrum distribution in a sensible way. However, in the present case, $g$ can be non-integer [49] and equation (27) cannot be derived with the elementary methods of the previous section. Overall, the net effect of the (non-integer) entanglement spectrum degeneracy in CFT is the same as found in the previous section for integer degeneracy. In particular, the number distribution in CFT is, like equation (17), given by

$$n(\lambda) = gI_0(\xi_{\lambda}).$$

We mention that equations (27) and (28) are also valid for the case of a finite system of length $L$ with periodic boundary conditions. Indeed, in this case, the worldsheet for $\rho_A$ can be mapped in the one of figure 1 by a conformal map. Thus, the only change will be the width of the annulus, which becomes $W = 2 \ln[[L/\pi \epsilon] \sin(\pi \ell/L)] + O(\epsilon)$, but this only affects the value of $\lambda_{\text{max}}$ and not equation (27). Finally, in appendix B we show how the above results minimally change in the presence of physical boundaries in CFT: the main difference is that there are two boundary entropies which may be different, one corresponding to the boundary entropy of the physical edge and the other being the boundary entropy introduced through the regularisation procedure at the entangling point, as done above.

4. Analytic results for the spin-1/2 XXZ chain

In this section we explore the general results of the previous sections in some integrable spin chains, for which the entanglement spectrum can be accessed exactly. We present explicit results for the gapped XXZ and Ising spin-chains and exploit their scaling behaviour close to quantum critical points. We use gapped spin-chains because the scaling of the moments of the reduced density matrices are identical to the CFT ones close to the quantum critical points and this also implies that the entanglement spectrum must be the same. Furthermore, the
entanglement spectrum of these gapped spin-chains is easily handled analytically, as shown in the following, but the same is not true even for the simplest gapless lattice models.

4.1. The anisotropic Heisenberg spin-chain

We consider here an anisotropic Heisenberg spin-chain (XXZ spin chain), which is defined by the Hamiltonian

\[ H_{XXZ} = \sum_j \left[ \sigma_j^x \sigma_{j+1}^x + \sigma_j^y \sigma_{j+1}^y + \Delta \sigma_j^z \sigma_{j+1}^z \right], \tag{29} \]

where \( \sigma_i^{x,y,z} \) are the Pauli matrices and \( \Delta \) is the anisotropy. We focus on the gapped and antiferromagnetic regime for \( \Delta > 1 \). At \( \Delta = 1 \) there is a conformal quantum critical point separating the gapped antiferromagnetic phase from the gapless conformal one. For \( \Delta \to 1^+ \), the correlation length diverges, and the scaling of the moments of \( \rho_A \) is given by equation (2) with \( \ell \) replaced by \( \xi \) [26, 63, 64]. This is true for the case of a bipartition in two semi-infinite lines, but also for a finite interval, as long as its length \( \ell \) is much larger than \( \xi \) (for smaller \( \ell \) a complicated crossover to the conformal results takes place [65]).

For the case of a bipartition in two semi-infinite lines, the RDM can be written from the corner transfer matrix as [26, 64, 66, 67]

\[ \rho_A = e^{-H_{CTM}} \frac{\text{Tr} e^{-H_{CTM}}}{\text{Tr}}, \tag{30} \]

where \( H_{CTM} \) is [66]

\[ H_{CTM} = \sum_{j=0,1}^{\infty} \epsilon_j \hat{n}_j, \tag{31} \]

where \( \hat{n}_j \) are fermion number operators with eigenvalues 0 and 1 and

\[ \epsilon_j = 2j\epsilon, \tag{32} \]

with

\[ \epsilon = \text{arccosh}\Delta. \tag{33} \]

A very important point for our paper is the initial value of \( j \) in the sum in (31). Indeed, \( j = 0 \) and \( j = 1 \) correspond to different ground states of the model. If the sum starts with \( j = 1 \), we are considering a symmetry breaking state (i.e. the one that for \( \Delta \to \infty \) converges to the Néel state). In this state, the largest eigenvalue of the RDM is non-degenerate. Conversely, if the sum starts from \( j = 0 \), we are considering the combination Néel plus its translation by one site (usually called an anti-Néel); the latter has zero staggered magnetisation and it does not break the \( Z_2 \) symmetry (but does not satisfy cluster decomposition, which is a fundamental property of physical states). In this case, the largest eigenvalue of the RDM is doubly degenerate, and the same is true for all the spectrum, as a consequence of the zero mode with \( j = 0 \).

Following [12, 51, 66], the entanglement spectrum is obtained by filling in all the possible ways the single particle levels \( \epsilon_j \) in (31) (i.e. setting all \( \hat{n}_j \) equal either to 0 or 1). The resulting eigenvalues of the reduced density matrix, with \( n = \sum_j j \) (see (31)), are

\[ \lambda_n = \lambda_0 e^{-2n\epsilon}, \tag{34} \]

\(^2\)Hereafter, \( \Delta \) should not be confused with the label of the CFT energy spectrum of the previous section.
(i.e. the logarithm of the eigenvalues, usually called entanglement levels, are equally spaced with spacing $2\epsilon$). The degeneracy of the $n$th eigenvalue is given by the number of ways of obtaining $n$ as a sum of smaller non-repeated integers. This is the problem of counting the number $q(n)$ of (restricted) partitions of $n$. The number $q(n)$ is conveniently generated as a function of $n$ via the generating function

$$G(z) \equiv \sum_{k=0}^{\infty} q(k) z^k = \prod_{k=1}^{\infty} (1 + z^k).$$

Thus, $q(n)$ is obtained from (35) as the coefficient of the monomial $z^n$. The degeneracy of the entanglement spectrum is given either by $q(n)$ or by $2q(n)$ depending on whether we are considering the symmetry breaking state or the symmetric one. This degeneracy of the entanglement spectrum can be written in a compact way as

$$\text{deg}(\lambda_n) = \gamma q(n),$$

with $\gamma = 1$ or $\gamma = 2$ depending on the considered ground state. The constant $\lambda_0$ in (34) is the largest eigenvalue of the RDM and can be simply fixed by the normalisation condition

$$\text{Tr} \rho_A = 1 = \sum_{\lambda} \gamma q(\lambda) \lambda_0 e^{-2\epsilon \lambda} \implies \lambda_0 = \frac{1}{\gamma G(e^{-2\epsilon})}.$$

(37)

Having obtained the analytical expression for the eigenvalues of the RDM and their degeneracies, it is now straightforward to write both the entanglement entropies and the distribution function of the eigenvalues. For example, the moments are

$$\text{Tr} \rho_n = \sum_{k=0}^{\infty} \gamma q(k) \lambda_0^k e^{-2\epsilon \lambda} = \lambda_0^m \gamma G(e^{-2\epsilon}) = \gamma^{1-n} \frac{G(e^{-2\epsilon})}{(G(e^{-2\epsilon}))^\pi}.$$ 

(38)

Notice the occurrence of the factor $\gamma^{1-n}$, in agreement with (7).

Let us now move to the number distribution function $n(\lambda)$, i.e. the number of eigenvalues of the RDM larger than $\lambda$. By definition this is nothing but the sum of the degeneracies $\text{deg}(\lambda_j)$ of all eigenvalues $\lambda_j$ larger than $\lambda$:

$$n(\lambda) = \sum_{\lambda_j > \lambda} \text{deg}(\lambda_j),$$

(39)

which using (34) and (36) can be written as

$$n(\lambda) = \sum_{m< \ln \lambda_0 / \lambda} \gamma q(m),$$

(40)

which can be straightforwardly evaluated up to very large $j$. Here, however, we are interested in the asymptotic behaviour of $n(\lambda)$, which can be obtained by expanding $q(m)$ for large $m$, using Meinardus theorem as in [51] to get

$$q(m) = \frac{1}{4 \cdot 3^{1/3} m^{1/3}} \exp(\pi \sqrt{m} \sqrt[3]{3}).$$

(41)

At this point, the asymptotic behaviour of the number distribution $n(\lambda)$ of the entanglement spectrum for small $\lambda$, i.e. for $\ln \lambda_0 / \lambda \gg \epsilon$, can be easily calculated by integrating (41) to obtain

$$n(\lambda) \simeq \gamma \frac{6^{1/4} \pi \epsilon \sqrt[3]{3}}{2 \pi \sqrt{\eta}},$$

(42)
where we introduced the scaling variable

\[ \eta \equiv \sqrt{\frac{\ln(\lambda_0/\lambda)}{\epsilon}} \gg 1. \]  

(43)

Notice that equation (42) is valid for arbitrary \( \epsilon \) in the regime when \( \eta \gg 1 \). Equation (42) is numerically tested in figure 2. Figure 2 shows the exact result for \( n(\lambda) \) obtained using equation (40) (symbols in the figure) plotted versus \( \eta \). The dash-dotted line is (42), and it is in perfect agreement with the exact result for large enough \( \eta \).

As already mentioned, \( \Delta = 1 \) corresponds to a quantum critical point with a correlation length diverging as

\[ \ln \xi = \frac{\pi^2}{2 \epsilon} + O(\epsilon^0). \]

(44)

Thus for \( \Delta \to 1^+ \), equation (42) should match the CFT scaling (28) with an appropriate value of \( g \). In order to work out this value of \( g \), we can consider the Rényi entropies in the limit \( \Delta \to 1^+ \) (or \( \epsilon \to 0 \)). Equation (38) can be expanded close to \( \epsilon \to 0 \) by standard methods [64], obtaining

\[ S_n = \frac{\pi^2}{24\epsilon} \left( 1 + \frac{1}{n} \right) - \frac{\ln 2}{2} + \ln \gamma + \ldots, \]

(45)

where the dots stands for exponentially small terms in \( \epsilon \) [64]. We can interpret the \( n \)-independent additive constant as the non-integer degeneracy of the ground state of the boundary CFT with the boundary condition induced at the entangling surface. Thus, one has

\[ g = \frac{\gamma}{\sqrt{2}}. \]

(46)

i.e. \( g = 1/\sqrt{2} \) or \( g = \sqrt{2} \) depending on whether \( \gamma = 1 \) or \( \gamma = 2 \).

We now compare the exact result (42) with the expected behaviour from CFT. In the limit \( \Delta \to 1^+ \) (equivalently, \( \epsilon \to 0 \)) the moments of the RDM exhibit conformal scaling. In this limit, taking into account the non-integer degeneracy \( g \) of the ground state, the number distribution function is equation (28) with \( g \) given in (46), i.e.
\( n(\lambda) \simeq \gamma I_0(\xi_\lambda)/\sqrt{2}, \) (47)

\( \xi_\lambda \) defined in (3). Using \( -\ln \lambda_0 \sim \pi^2/24\epsilon + O(1) \) (see (45) for \( n \to \infty \)) one has \( \eta \simeq \sqrt{6}\xi_\lambda/\pi \) for \( \epsilon \to 0 \). We then have that, both for \( \gamma = 1 \) and \( \gamma = 2 \), equation (42) in the limit \( \epsilon \to 1 \) coincides with equation (47) for large \( \xi_\lambda \), given that \( I_0(x) \simeq e^x/\sqrt{2\pi x} \) for \( x \gg 1 \).

Notice that, for the XXZ spin-chain in the regime considered here, the entanglement spectrum distribution function of [20] (i.e. (28) with \( g = 1 \)) does not correctly describe the spectrum for any of the two possible ground states.

### 4.2. The Ising spin-chain in a transverse field

An analysis similar to the one presented in the previous section also holds for the transverse field Ising chain, which is defined by the Hamiltonian

\[ H = -\sum_{j=1}^{L} (\sigma^x_j \sigma^x_{j+1} + h \sigma^z_j), \] (48)

where \( h \) is the external transverse magnetic field. At zero temperature the model is paramagnetic for \( h > 1 \), whereas it is an ordered ferromagnet for \( h < 1 \). At \( h = 1 \) there is a quantum critical point with a low-energy spectrum described by a CFT with \( c = 1/2 \). In the ferromagnetic region, in the limit \( L \to \infty \), there are two degenerate ground states, which are related by a \( \mathbb{Z}_2 \) symmetry. In contrast, in the paramagnetic region \( h > 1 \) the ground state is unique.

The entanglement spectrum in both regimes has the same structure (31) as the XXZ chain, although now the single particle entanglement spectrum levels are given by [66]

\[ \epsilon_j = \begin{cases} (2j + 1)\epsilon & h > 1, \\ 2j\epsilon & h < 1, \end{cases} \] (49)

with
with \( K(x) \) the complete elliptic integral of the first kind.

It should be clear that, due to the form of the entanglement levels (49), in the symmetry broken phase for \( h < 1 \) the entanglement spectrum distribution can be derived identically as in the previous section. Once again, the distribution depends on whether one considers the symmetric broken or symmetric ground state, obtained by letting the sum in \( j \) starting either from 0 or 1. The resulting distribution is then (47) with \( \gamma \) given by (46).

In the paramagnetic phase for \( h > 1 \) the entanglement spectrum distribution is instead different from the one of the XXZ model. In this case, the degeneracy of the entanglement spectrum at level \( m \) is related from (49) to the number of integer partitions \( q_o(m) \) of \( m \) involving only odd integers (in this case the sum always starts from \( j = 1 \) because the ground state is unique). The asymptotic behaviour for large \( m \) of \( q_o(m) \) is given as

\[
q_o(m) \approx \frac{1}{2 \cdot 24^{1/4} m^{3/4}} \exp\left(\pi \sqrt{m}/\sqrt{6}\right),
\]

and the corresponding distribution \( n(\lambda) \) is

\[
n(\lambda) \approx \frac{6^{1/4} e^{\pi \eta / \sqrt{6}}}{\sqrt{2\eta \pi}},
\]

where, as usual, \( \eta \equiv \sqrt{\ln(\lambda_0 / \lambda) / \epsilon} \gg 1 \). Approaching the critical point at \( h = 1 \), the correlation length diverges as

\[
\ln \xi = \frac{\pi^2}{\epsilon} + O(\epsilon^0),
\]

and the Rényi entanglement entropy as [64]

\[
S_n = \frac{\pi^2}{24\epsilon} \left(1 + \frac{1}{n}\right) + O(\epsilon).
\]

Notice, in particular, the absence of the constant term, suggesting \( \ln g = 0 \). By replacing \( \epsilon \) with \( \ln \lambda_0 \) (using (54)), one can straightforwardly show that (52) coincides with the large \( \xi_\lambda \) limit of \( I_0(\xi_\lambda) \), i.e. (28) with \( g = 1 \).

### 5. Consequences for the negativity spectrum

The partial transpose \( \rho^T_A \) of the reduced density matrix is a crucial object for quantifying the bipartite entanglement in mixed states [69–72] or, equivalently, the entanglement between two non-complementary parts in a pure state. The partial transpose \( \rho^T_A \) is defined as

\[
\langle \varphi_1 \varphi_2 | \rho^T_A | \varphi'_1 \varphi'_2 \rangle \equiv \langle \varphi_1 \varphi'_1 | \rho_A | \varphi_2 \varphi'_2 \rangle,
\]

with \{ \varphi_1 \} and \{ \varphi_2 \} two bases for \( A_1 \) and \( A_2 \), respectively. A computable measure of entanglement is the logarithmic negativity defined as the sum of the absolute values of the eigenvalues of \( \rho^T_A \) [71, 72]

\[
\mathcal{E} \equiv \ln \| \rho^T_A \|_1 = \ln \text{Tr}|\rho^T_A|,
\]

where the symbol \( \| \cdot \|_1 \) denotes the trace norm. The scaling behaviour of the negativity has been characterised analytically for the ground states of one-dimensional CFTs [73–75].

---

3The sequence \( q_o(m) \) is reported as A000700 in the OEIS.
Remarkably, the negativity is scale invariant at quantum critical points [73, 76–78]. Its scaling behaviour has been also worked out for finite temperature CFTs [79], in CFTs with large central charge [80], in disordered spin chains [81], in some holographic [86] and massive quantum field theories [87], for out-of-equilibrium models [82–85], topologically ordered phases [88, 89], Kondo-like systems [90–93], and Chern–Simons theories [94, 95]. Surprisingly, no analytical results are available yet for free-fermion models [96], in contrast with free bosonic model, for which the negativity can be calculated [97], also in $d > 1$ dimensions [98, 99].

On the same lines as for the entanglement spectrum, it is clear that the partial transpose contains more information than that condensed in the negativity. In analogy with what is explained above, part of this information can be reconstructed from the scaling of the moments of the reduced density matrix in a program initiated in [50]. As a fundamental difference compared to the entanglement spectrum, the partial transpose has both positive and negative eigenvalues which generically behave in a different manner. However, their asymptotic CFT distribution for very small eigenvalues turned out to be the same [50].

Here we first focus on the case of a bipartition of the ground state of a CFT, when the spectrum of the partial transpose can be written in terms of the spectrum of the RDM. Although in this case the partially transposed density matrix does not contain more information than the reduced density matrix itself (the two spectra can be simply related [50]), it is very useful to obtain the distribution of these eigenvalues to understand how the CFT non-integer ground-state degeneracy induced at the entangling surface affects the results for the negativity. For this bipartition, the moments of $\rho_T^2$ can be put in direct relation with those of $\rho_A^2$, as shown in [73], obtaining

$$\text{Tr}(\rho_T^2)^n = \begin{cases} \text{Tr} \rho_A^{n_n} e^{-c/6(n_n - 1/n_n)} & n_n \text{ odd}, \\ (\text{Tr} \rho_A^{n_e/2})^2 = c_T^{n_e} e^{-c/3(n_e/2-2/n_e)} & n_e \text{ even}. \end{cases}$$  \hspace{1cm} (56)$$

The relation between $c_T^n$ and $c_n$ depends on the parity of $n$ and it reads

$$c_T^n = c_n, \quad c_T^n = c_n^{2^{n_e}}. \hspace{1cm} (57)$$

In [50] the negativity spectrum distribution in CFT has been derived with the assumption $c_n = 1$ that implies $c_T^n = 1$.

It is now easy to understand the effect of a degeneracy (both integer and non-integer).

We have shown that in the presence of degeneracy $g$, see equation (8), the multiplicative constant $c_n$ gets multiplied by $g^{1-n}$, implying a non-trivial relation between the constants $c_T^n$ for the moments of the partial transpose. According to the equations in (57) we have

$$c_T^n (\lambda) = g^{1-n_n}, \quad c_T^n (\lambda) = (g^{1-n_e/2})^2 = g^{2-n_e}. \hspace{1cm} (58)$$

In [50] it was shown that the number distribution function for the case $c_n = 1$ is

$$n_{\text{pure}} (\lambda) = \frac{1}{2} \left[ \text{sgn} (\lambda) I_0 (\xi_\lambda) + I_0 (2 \xi_\lambda) \right], \hspace{1cm} (59)$$

where $\xi_\lambda$ is defined in analogy with equation (3) as

$$\xi_\lambda = 2 \sqrt{(- \ln \lambda_{\text{max}}) \ln (\lambda_{\text{max}} / |\lambda|)}, \hspace{1cm} (60)$$

where $\lambda_{\text{max}}$ is the maximum positive eigenvalue of the partial transpose (which in the case of a bipartite pure system is equal to $\lambda_{\text{max}}$ [50], but not in general). It is easy to check, following
the derivation in [50], that the first term comes from the odd moments of the partial transpose, while the second from the even ones.

Thus, to take into account the degeneracy $g$ in (59), the first term gets a factor $g$, whereas the second a factor $g^2$. Consequently, in the presence of a global degeneracy $g$, the negativity spectrum distribution is

$$n^{\text{pure}}(\lambda) = \frac{1}{2} \left[ \text{sgn}(\lambda) g I_0(\xi_\lambda) + g^2 I_0(2\xi_\lambda) \right].$$

(61)

This formula is quite interesting because $g$ enters in a different way in the two terms. In particular, it shows that for asymptotic small eigenvalues $\lambda$, i.e. large $\xi_\lambda$, positive and negative eigenvalues have the same distribution which gets multiplied by $g^2$, but the difference of the number distributions (i.e. $n^{\text{pure}}(\lambda) - n^{\text{pure}}(-\lambda)$) gets multiplied by $g$.

Let us briefly mention what we know about the very interesting case of a tripartite system, when the spectrum of the partially transposed density matrix cannot be written in terms of that of the reduced density matrix, because the two intervals are in a mixed state. We focus on the tripartition where two finite intervals $A_1$ and $A_2$ are adjacent and embedded either in the infinite line or in a finite system. We consider the reduced density matrix $\rho_{A^2} = \rho_{A_1 \cup A_2}$ and subsequently the partial transpose with respect to $A_2$. In this case, the conformal moments of $\rho_{T^2} A$ depend on the constants $c_n$ appearing in the moments of $\rho_{A}$ but also on some $n$-dependent structure constants [73, 74]. Assuming that all these parameters are equal to 1, the negativity spectrum distribution has been obtained in [50] and tested against numerical simulations in spin-chains. In the case when the two intervals have equal length, the final result can be written as [50]

$$n^{\text{mixed}}(\lambda) = \frac{1}{2} \left[ \text{sgn}(\lambda) I_0(\xi_\lambda) + I_0(\sqrt{2}\xi_\lambda) \right],$$

(62)

where $\xi_\lambda$ is defined in equation (60) and in this case $\lambda_{\text{max}}$ is different from $\lambda_{\text{max}}$. Note the $\sqrt{2}$ difference in the argument of $I_0$ as compared with (59). At this point, while it is known how the degeneracy factor $g$ affects the multiplicative factors $c^{\ell}_n$, the same is not true for the structure constants and its effect is not trivial. Indeed, for $n = 2$ we have $\text{Tr}(\rho_{T}^{2})^2 = \text{Tr}\rho_{A}^{2}$ [74] implying that these structure constants depend on $g$ and we cannot simply set to a constant when $g \neq 1$. In [51], the moments of the partial transpose, as well as the entire negativity spectrum, have been analytically worked out for the XXZ spin-chain in the gapped regime discussed in the previous section. While the leading behaviour for large correlation length $\xi$ is the same as in CFT for large $\ell$ (providing two different exponentials in $n(\lambda)$ as in (62)), the subleading terms are different and so not useful for understanding what happens for $g \neq 1$ in a CFT. It would be then very interesting to run some numerical simulations in gapless models with $g \neq 1$ to shed some light on this problem.

6. Conclusions

In this paper we established a relation between the entanglement spectrum distribution of conformal field theories (see [20]) and the CFT density of states described by the Cardy formula [48]. Indeed, we have shown that the entanglement spectrum distribution can be obtained as a re-parametrisation of the Cardy formula. This result allows us to understand the effect of the boundary conditions at the entangling surface on the entanglement spectrum and entropies. In particular, it shows that the multiplicative constant $c_n$ in the moments of the reduced density matrix, see equation (2), is affected by the degeneracies induced by these boundary
conditions, although the leading behaviour in $\ell$ of the moments remains the same. We tested our findings against exact calculations of the entanglement spectrum in integrable spin chains. Our result shows that the Affleck–Ludwig entropy $g$ due to the boundary conditions induced at the entangling surface appears as a multiplicative universal constant in the number distribution function (see equation (28)). Thus $g$ can be measured from the asymptotic behaviour of the entanglement spectrum distribution. This proposal appears to be more practical than the study of the additive constant of the Rényi entropies. Indeed, in microscopical models the latter depends on the universal physics at the entangling surface, but it is generically influenced by the non-universal ultraviolet physics [58–62] and it is not possible to disentangle the two effects.

We also explored the consequences of degeneracies for the negativity spectrum. In contrast with the entanglement spectrum distribution, which is expressed in terms of a single Bessel function, the negativity spectrum is the combination of two Bessel functions. Remarkably, the presence of a global degeneracy in the entanglement spectrum gives rise to different reparametrisations of the two functions.

A consequence of our findings is that the several numerical results already present in the literature [4, 20, 28–31] about the validity of the CFT results for the entanglement spectrum distribution (3) can be regarded as direct verifications of the Cardy formula, which has never been checked at the level of the Hamiltonian spectrum of microscopic models. The reason why the Cardy formula has not been tested from the Hamiltonian spectrum is that CFT describes the low-energy spectrum of microscopic models where the dispersion relation is relativistic, while the Cardy formula gives the scaling of the CFT spectrum for large energy, where in microscopic models non-relativistic effects become relevant. Conversely, the entanglement spectrum distribution is written only in terms of the ground state, and a continuum distribution for the eigenvalues is obtained in the limit $\ell \to \infty$.

**Appendix A. The Cardy formula on the annulus**

In this section we report a derivation of the Cardy formula starting from the partition function of a CFT on the annulus. A similar analysis has been done by employing the geometry of the torus in [54, 55] and of the Klein bottle in [100]. The aim of this computation is to show the occurrence of the boundary states of the annulus in the multiplicative factor of the CFT density of states for large scaling dimensions. This factor corresponds to the ground-state degeneracy introduced by Affleck and Ludwig [49].

The starting point is the partition function on the annulus of width $W$ [68] written as a sum over the states parametrised by their conformal dimension $\Delta$

$$Z(q) = q^{-c/24} \sum_{\Delta} \rho(\Delta) q^{\Delta},$$

(A.1)

where $q = e^{-2\pi \tau^2/W}$ is the modular parameter. Here $\rho(\Delta)$ is the Cardy density of states, which can be formally obtained by inverting the above relation as a complex integral in $q$. 

16
\begin{align}
\rho(\Delta) &= \frac{1}{2\pi i} \oint_{C_0} \frac{dq}{q^{\Delta+1}} q^{-c/24} Z(q),
\end{align}

in which \(C_0\) is an arbitrary closed path which encloses \(q = 0\).

By employing the modular invariance, the partition function \((A.1)\) can be written in terms of the dual modular parameter \(\tilde{q} = e^{-2\pi \tau}\) as \([48]\)

\begin{align}
Z(q) &= \tilde{q}^{-c/24} \sum_k \langle a | k \rangle \langle k | b \rangle \tilde{q}^{\delta_k},
\end{align}

where the sum is now over all allowed scalar bulk operators with dimensions \(\delta_k\), and \(|a\rangle\) and \(|b\rangle\) denote the boundary states at the two edges of the annulus. Plugging this into \((A.2)\) we have

\begin{align}
\rho(\Delta) &= \frac{1}{2\pi i} \oint_{C_0} \frac{dq}{q^{\Delta+1}} q^{-c/24} \tilde{q}^{-c/24} \sum_k \langle a | k \rangle \langle k | b \rangle \tilde{q}^{\delta_k}.
\end{align}

Let us know change the integration variable as

\begin{align}
q &= e^{-\tau}, \quad \tilde{q} = e^{-4\pi^2/\tau}.
\end{align}

Choosing \(C_0\) to be a circumference centred at the origin \(q = 0\), we have

\begin{align}
\rho(\Delta) &= \sum_k \langle a | k \rangle \langle k | b \rangle \frac{1}{2\pi i} \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}} dt e^{(\Delta-c/24) t} e^{(\gamma-\gamma_k)/\tau},
\end{align}

where we introduced

\begin{align}
\gamma \equiv \frac{\pi^2 c}{6}, \quad \gamma_k \equiv 4\pi^2 \delta_k.
\end{align}

Hereafter \(\gamma\) must not be confused with the integer degeneracy factor in the main text.

The above equation is an exact representation of the CFT density of states, valid for arbitrary values of \(\Delta\), but it is particularly convenient for a large \(\Delta\) expansion. Indeed, for large \(\Delta\) two main simplifications occur. First, the integrals are dominated by the saddle points at \(t = 0\), thus one can extend the integrals on the imaginary axis between \(\pm i\infty\) instead of \(\pm i\pi\). In the same spirit, it is reasonable to keep only the term with \(k = 0\), the others being expected to be exponentially suppressed. Thus, one has

\begin{align}
\rho(\Delta) \simeq \langle a | 0 \rangle \langle 0 | b \rangle \frac{1}{2\pi i} \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}} dt e^{(\Delta-c/24) t} e^{\gamma/\tau} \\
= \langle a | 0 \rangle \langle 0 | b \rangle \left[ \delta(\Delta - c/24) + 2\gamma \frac{I_1(2\sqrt{\gamma(\Delta - c/24)})}{2\sqrt{\gamma(\Delta - c/24)}} \right] \\
= \langle a | 0 \rangle \langle 0 | b \rangle \left[ \delta(\Delta - c/24) + \frac{\pi^2 c}{3} \frac{I_1(2\pi \sqrt{(c/6)(\Delta - c/24)})}{2\pi \sqrt{(c/6)(\Delta - c/24)}} \right],
\end{align}

where \(I_1\) is modified Bessel function of the first kind that is obtained by the inverse Laplace transform in \((A.8)\).

This result is employed in section 3 in a crucial way to recover for \(g = 1\) the result of \([20]\) from the CFT entanglement spectrum found in \([42]\). The formula \((A.8)\) exposes the role of the one-point structure constants \(\langle 0 | a \rangle\) and \(\langle 0 | b \rangle\) corresponding to the boundary states which characterise the underlying CFT on the annulus. The term \(\delta(\Delta - c/24)\) is often neglected in the literature (see, however, \([101]\)), because it is subleading for large \(W\), but we showed it in
order to stress the equivalence with the entanglement spectrum [20]. It is fair to mention that a very similar analysis, but in a slightly different context, has also been presented in [102].

We conclude this appendix by reporting the expansion of the density of states (A.8) for large $\Delta$. When $\Delta \gg 1$, we can use the following asymptotic behaviour of the Bessel functions

$$I_1(z) = \frac{e^z}{\sqrt{2\pi z}} \left( 1 - \frac{3}{8z} + O(1/z^2) \right),$$

(A.9)

to expand (A.8) as

$$\rho(\Delta) = \langle a|0\rangle \langle 0|b \rangle \frac{\sqrt{\gamma}}{\sqrt{\Delta}} \frac{e^{2\sqrt{\Delta}}}{\sqrt{4\pi(\gamma\Delta)^{1/2}}} = \langle a|0\rangle \langle 0|b \rangle \left( \frac{c}{96\Delta^4} \right)^{1/4} e^{2\pi \sqrt{\Delta/6}},$$

(A.10)

which is the result found in [49].

Appendix B. Entanglement spectrum distribution in the presence of boundaries

In this appendix we discuss how the result for the entanglement spectrum distribution slightly changes in the presence of real boundaries. We focus on the case in which the system is the semi-infinite line $x \geq 0$ and the subsystem is the interval $A = [0, \ell]$. The corresponding Euclidean spacetime is the half space $(x, y) \in \mathbb{R}^2$ with $x \geq 0$, whose boundary is the infinite line $x = 0$, which supports a conformally invariant boundary condition of the model. Following the same regularisation procedure adopted in section 3, we remove a small disk of radius $\ell$ centred at the entangling point $x = \ell$. A conformally invariant boundary condition is induced along the boundary of this small disk, which may be different from the one along the physical boundary at $x = 0$. The resulting spacetime is depicted in figure B1. It has the topology of an annulus where different conformally invariant boundary conditions may be present on the physical boundary (blue solid line) and on the boundary of the regularising disk (black solid line). In [42] the latter observation has been employed to study $K_A$ for this configuration, finding that for the corresponding entanglement spectrum equation (20) holds, but with $W = \log(2\ell/\epsilon) + O(\epsilon)$ in this case.

Thus, the analysis of section 3 can be repeated with the crucial difference that we cannot impose $g_a = g_b$ because we are allowed to have different conformally invariant boundary conditions. Denoting by $g_0$ the degeneracy introduced by the boundary encircling the endpoint $x = \ell$ and by $\tilde{g}$ the degeneracy corresponding to the conformally invariant boundary condition on the physical boundary, for the distribution of eigenvalues we obtain

$$\tilde{P}(\lambda) = \theta(\lambda_{\text{max}} - \lambda) \tilde{g} g_0 \frac{b}{\lambda} I_1 \left( \frac{2 \sqrt{\lambda \ln(\lambda_{\text{max}}/\lambda)}}{\sqrt{b \ln(\lambda_{\text{max}}/\lambda)}} \right) + \tilde{g} g_0 \delta(\lambda_{\text{max}} - \lambda),$$

(B.1)

being $b = -\ln \lambda_{\text{max}} = cW/12 = (c/12)\ln(2\ell/\epsilon) + O(\epsilon)$. Integrating (B.1), the mean number of eigenvalues larger than a given $\lambda$ is simply obtained as

$$\tilde{n}(\lambda) = \frac{\tilde{g} g_0 I_0(\xi_{\lambda})}{\lambda},$$

(B.2)

where $\xi_{\lambda}$ is defined in terms of $\lambda_{\text{max}}$ in (3).

Equation (B.1) is valid also for a finite system of length $L$ with conformal invariant boundary condition at the two ends and with $A = [0, \ell]$. Indeed, in this case, the worldsheet for $\rho_A$ can be mapped in the one of figure B1 by a conformal map. Thus, the only change is the width of the annulus which becomes $W = \ln[(2L/\pi\epsilon)\sin(\pi\ell/L)] + O(\epsilon)$, but this only affects the value of $\lambda_{\text{max}}$ and not equation (B.1).
