Intracranial Rosai Dorfman disease

T. M. Anoop, Jacob John, Sreejith G. Nair, Beela Sarah Mathew

Departments of Medical Oncology and Radiation Oncology, Regional Cancer Centre, Thiruvananthapuram, Kerala, India

A 30-year-old man presented with gradual loss of vision, headache and behavioral changes since 1 year. The patient had left temporal hemianopia initially and later developed complete loss of vision and bilateral optic atrophy. No lymph nodes were palpable. Systemic examination revealed unilateral pleural effusion.

Magnetic resonance imaging (MRI) of the brain showed a dural-based lesion seen in the frontal region involving the anterior half of the sagittal sinus with calcification. The patient underwent bifrontal craniotomy with excision of tumor with sinus and falx. Postoperatively, he developed extradural hematoma formation. A limited parietal craniotomy and hematoma evacuation was performed. Postoperative MRI showed residual lesion of size 6.5 cm × 6 cm × 4.4 cm attached to the falx. Histopathologically, the lesion was composed of sheets of large foamy histiocytes admixed with lymphoplasmacytic cells. Emperipolesis was noted. Immunohistochemistry was positive for S100 and Kp-1 + and negative for LCA, CD 1a, CD5, C Kit and MIB 10%. A diagnosis of non-Langerhans cell histiocytosis–Rosai Dorfman disease (RDD) was considered.

Sinus histiocytosis with massive lymphadenopathy, also known as RDD, is a rare histiocytic proliferative disorder of unknown etiology. It usually presents with painless cervical lymphadenopathy with or without extranodal manifestations. Intracranial involvement of this disease is extremely rare, and intracranial involvement with bilateral optic atrophy is rather rare. The most common imaging appearance of intracranial RDD is a dural-based enhancing mass, mimicking a meningioma. The MRI characteristics of this intracranial dura-based space-occupying lesion are very similar to that of meningioma.

The differential diagnosis of the imaging findings includes meningioma, eosinophilic granuloma, lymphoproliferative disorder, plasma cell granuloma and dural-based metastasis.

Hui Zhu et al. described similar imaging features of the central nervous system (CNS) in RDD, like an extraaxial, well-circumscribed, dura-based mass, isodense or hyperdense on CT, isointensity on T1-weighted imaging and isointensity with...
hypointensity on T2-weighted imaging. Typical representation of hypointensity within isointensity on T2-weighted or FLAIR image can suggest the diagnosis of RDD.

Histopathology is essential for diagnosis, and when total removal is achieved, the outcome is generally good. Involvement of the CNS in RDD appears to have a good prognosis, particularly in the absence of nodal disease. In a review of follow-up data of 43 patients with RDD, most patients (58%) were alive with disease.[3] Only two patients (4.7%) had died. No death was reported as a result of isolated intracranial RDD.[3]

Various treatment modalities such as surgery, steroids, chemotherapy and radiation therapy have been tried. Surgical resection has been found to be most effective.
