Abstract. Since its launch in the 2008, the Large Area Telescope, onboard of the Fermi Gamma-ray Space Telescope, has detected the largest amount of gamma rays, in the 20MeV - 300GeV energy range and electrons + positrons in the 7 GeV- 1 TeV range. This impressive statistics allows one to perform a very sensitive indirect experimental search for dark matter. I will present the latest results on these searches.

1. The Cosmic Ray Electron spectrum

Recently the experimental information available on the Cosmic Ray Electron (CRE) spectrum has been dramatically expanded as the Fermi-LAT Collaboration [1, 2] has reported a high precision measurement of the electron spectrum from 7 GeV to 1 TeV performed with its Large Area Telescope (LAT) [3, 4]. The spectrum shows no prominent spectral features and it is significantly harder than that inferred from several previous experiments. These data together with the PAMELA data on the rise above 10 GeV of the positron fraction[5] are quite difficult to explain with just secondary production [6], [7], [9]. The temptation to claim the discovery of dark matter is strong but there are competing astrophysical sources, such as pulsars, that can give strong flux of primary positrons and electrons (see [10], [11], [12], [13] and references therein). At energies between 100 GeV and 1 TeV the electron flux reaching the Earth may be the sum of an almost homogeneous and isotropic component produced by Galactic supernova remnants and the local contribution of a few pulsars with the latter expected to contribute more and more significantly as the energy increases.

Two pulsars, Monogem, at a distance of d=290 pc and Geminga, at a distance of d=160 pc, can give a significant contribution to the high energy electron and positron flux reaching the Earth and with a set of reasonable parameters of the model of electron production we can have a nice fit of the PAMELA positron fraction[5] and Fermi data (see figures 1 and 2), but it is true that we have a lot of freedom in the choice of these parameters because we still do not know much about these processes, so further study on high energy emission from pulsars are needed in order to confirm or reject the pulsar hypothesis.

Nevertheless a dark matter interpretation of the Fermi-LAT and of the PAMELA data is still an open possibility. In Figure 3 is shown the parameter space of particle dark matter mass versus pair-annihilation rate, for models where dark matter annihilates into monochromatic $e^\pm$ [13]. The preferred range for the dark matter mass lies between 400 GeV and 1-2 TeV, with larger masses increasingly constrained by the H.E.S.S. results. The required annihilation rates, when employing the dark matter density profile imply typical boost factors ranging between...
Figure 1. PAMELA data and a possible contribution from Monogem and Geminga pulsars [13]. Black-dotted line shows the background from secondary positrons in cosmic rays from GALPROP.

Figure 2. Electron-plus-positron spectrum (blue continuous line) for the same scenario as in figure 1. The gray band represents systematic errors on the Fermi-LAT data [3, 4].
Figure 3. The parameter space of particle dark matter mass versus pair-annihilation rate, for models where dark matter annihilates into monochromatic $e^\pm$. Models inside the regions shaded in gray and cyan over-produce $e^\pm$ from dark matter annihilation with respect to the Fermi-LAT and H.E.S.S. measurements, at the 2-$\sigma$ level. The red and blue contours outline the regions where the $\chi^2$ per degree of freedom for fits to the PAMELA and Fermi-LAT data is at or below 1.

20 and 100, when compared to the value $\langle \sigma v \rangle \sim 3 \times 10^{-26} \text{ cm}^3/\text{sec}$ expected for a thermally produced dark matter particle relic.

How can one distinguish between the contributions of pulsars and dark matter annihilations? Most likely, a confirmation of the dark matter signal will require a consistency between different experiments and new measurements of the reported excesses with large statistics. The observed excess in the positron fraction should be consistent with corresponding signals in absolute positron and electron fluxes in the PAMELA data and all lepton data collected by Fermi. Fermi has a large effective area and long projected lifetime, 5 years nominal with a goal 10 years mission, which makes it an excellent detector of cosmic-ray electrons up to $\sim 1 \text{ TeV}$. Future Fermi measurements of the total lepton flux with large statistics will be able to distinguish a gradual change in slope with a sharp cutoff with high confidence [14]. The latter, can be an indication in favor of the dark matter hypothesis.

Another possibility is to look for anisotropies in the arrival direction of the electrons.

The Large Area Telescope on board the Fermi satellite (Fermi-LAT) detected more than 1.6 million cosmic-ray electrons/positrons with energies above 60 GeV during its first year of operation. The arrival directions of these events were searched for anisotropies of angular scale extending from $\sim 10^\circ$ up to $90^\circ$, and of minimum energy extending from 60 GeV up to 480 GeV. Upper limit for the dipole anisotropy has been set to 0.5 - 5% depending on the energy [15].

The levels of anisotropy expected for Vela-like and Monogem-like sources (i.e. sources with similar distances and ages) seem to be higher than the scale of anisotropies excluded by the results (see figure 4 ). However, it is worth to point out that the model results are affected by
Figure 4. Dipole anisotropy $\delta$ versus the minimum energy for GALPROP (solid line), Monogem source (dashed line), and Vela source (dotted line). The 3$\sigma$ confidence level from the data is also shown with circles. The solar modulation was treated using the force-field approximation with $\Phi=550$ MV.

large uncertainties related to the choice of the free parameters.

2. The gamma-ray signals

A strong leptonic signal should be accompanied by a boost in the $\gamma$-ray yield providing a distinct spectral signature detectable by Fermi.

The Galactic center (GC) is expected to be the strongest source of $\gamma$-rays from DM annihilation, due to its coincidence with the cusped part of the DM halo density profile [16, 17]. A preliminary analysis of the data, taken during the first 11 months of the Fermi satellite operations, is shown in figures 5 and 6.

The reported results were obtained with a binned likelihood analysis, performed by means of the tools developed by the Fermi/LAT collaboration (gtlike, from the Fermi analysis tools [18]). For this analysis:

- a ROI of $7^\circ \times 7^\circ$ was considered. This ROI was used in order to minimize the background contribution and to avoid significative leakage of the gamma ray signal under study;
- the ROI was centred at the position $\text{RA} = 266.46^\circ$, $\text{Dec} = -28.97^\circ$, i.e. the position of the brightest source;
- the Data taken during the first 11 months (8/2008-7/2009) have been used;
- the events were selected to have energy between 400MeV and 100GeV;
- only events classified of "diffuse" class were and which converted in the front part of the tracker have been selected for the analysis. The selection in energy, event classification and conversion provided us with events with very well reconstructed incoming direction and data have been binned into a $100 \times 100$ bins map;
- the IRF and the events classification are those relative to the Pass6V3 version of the Fermi/LAT analysis software.
Figure 5. Spectra from the likelihood analysis of the Fermi/LAT data (number of counts vs reconstructed energy) in a $7^\circ \times 7^\circ$ region around the Galactic Center (number of counts vs reconstructed energy). The likelihood analysis is the standard one used with the LAT data. The main analysis steps are: (1) to select data of high quality (selection cuts on events energy, zenith angle, reconstruction and classification quality); (2) to build an emission model of the region, based on the previous knowledge and experimental evidence of new excesses with enough statistical significance; (3) to apply the likelihood analysis to the data and the considered model. For each model component a fit of the free parameters and the computation the statistical significance is obtained. Here in the plot, from above to below: -the black point are the observed data; -the black line is the sum of all the components; -the red line is the Galactic diffuse emission; - the lower black line is the isotropic extragalactic; -other components are the sources detected. These results are preliminary.

Figure 6. Residuals $(\text{exp.data} - \text{model})/\text{model}$ of the above likelihood analysis. The blue area shows the systematic errors on the effective area. These results are preliminary.
In order to perform the likelihood analysis for the LAT data, a model of the already known sources and the diffuse background should be built. The model in use for the presented analysis contains 11 sources in the Fermi 1 year catalog [19] which are located into or very close to the considered ROI. These sources have a point-like spatial model and a spectrum in the form of a power-law. The model also contains the diffuse gamma-ray background which is made of two components:

(i) the Galactic Diffuse gamma-ray background. The observed Galactic Diffuse emission was modelled by means of the GALPROP code [20] and [21], and the realization of the galactic emission named gll\_iem\_54\_87XexpH7S.fit was used. During the likelihood maximization only the normalization of the GALPROP model is varied, not its components;

(ii) the Isotropic Background. This component should account for both the Extragalactic gamma-ray emission and residual charged particles. It is modelled as an isotropic emission with a template spectrum.

The diffuse gamma-ray backgrounds and discrete sources, as we know them today, can account for the large majority of the detected gamma-ray emission from the Galactic Center. Nevertheless a residual emission is left, not accounted for by the above models [22].

Improved modelling of the Galactic diffuse model as well as the potential contribution from other astrophysical sources (for instance unresolved point sources) could provide a better description of the data. Analyses are under-way to investigate these possibilities.

An excess in gamma-ray should also be seen in the Galactic diffuse spectrum. Figure 7 (left) shows the LAT data averaged over all Galactic longitudes and the latitude range $10^\circ \leq |b| \leq 20^\circ$. The hatched band surrounding the LAT data indicates the systematic uncertainty in the measurement due to the uncertainty in the effective area described above. Also shown on the right are the EGRET data for the same region of sky where one can see that the LAT-measured spectrum is significantly softer than the EGRET measurement [23]. Figure 7 (right) compares the LAT spectrum with the spectra of an a priori diffuse Galactic emission (DGE) model. While the LAT spectral shape is consistent with the DGE model used in this paper, the overall model...
emission is too low thus giving rise to a $\sim 10 - 15\%$ excess over the energy range $100 \text{ MeV}$ to $10 \text{ GeV}$. However, the DGE model is based on pre Fermi data and knowledge of the DGE. The difference between the model and data is of the same order as the uncertainty in the measured CR nuclei spectra at the relevant energies. Overall, the agreement between the LAT-measured spectrum and the model shows that the fundamental processes are consistent with our data, thus providing a solid basis for future work understanding the DGE.

Also at higher latitudes for the moment we did not observed any excess. In figure 8 it is shown the diffuse $\gamma$-rays in a mid-latitude region in the third quadrant (Galactic longitude $l$ from $200^\circ$ to $260^\circ$ and latitude $|b|$ from $22^\circ$ to $60^\circ$). The region contains no known large molecular cloud and most of the atomic hydrogen is within $1 \text{ kpc}$ of the solar system. The contributions of $\gamma$-ray point sources and inverse Compton scattering are estimated and subtracted. The residual $\gamma$-ray intensity exhibits a linear correlation with the atomic gas column density in energy from $100 \text{ MeV}$ to $10 \text{ GeV}$. The differential emissivity from $100 \text{ MeV}$ to $10 \text{ GeV}$ agrees with calculations based on cosmic ray spectra consistent with those directly measured, at the $10\%$ level. The results obtained indicate that cosmic ray nuclei spectra within $1 \text{ kpc}$ from the solar system in regions studied are close to the local interstellar spectra inferred from direct measurements at the Earth within $\sim 10\%$ [24].

The high-energy diffuse $\gamma$-ray emission is dominated by $\gamma$-rays produced by cosmic rays (CR) interacting with the Galactic interstellar gas and radiation fields, the so-called diffuse Galactic emission (DGE). A much fainter component, commonly designated as “extragalactic $\gamma$-ray background” (EGB) by definition has an isotropic sky distribution and is considered by many to be the superposition of contributions from unresolved extragalactic sources including active
Figure 9. Fermi-LAT extragalactic intensity compared with EGRET-derived intensities. Fermi-LAT derived spectrum is compatible with a simple power-law with index $\gamma = 2.41 \pm 0.05$ and intensity $I(> 100 \text{ MeV}) = (1.03 \pm 0.17) \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ where the uncertainties are systematics dominated.

galactic nuclei, starburst galaxies and $\gamma$-ray bursts and truly-diffuse emission processes.

Figure 9 shows the spectrum of the EGB above 200 MeV derived with the data taken during the first 11 months [25], and from EGRET data [26], [27]. Our intensity extrapolated to 100 MeV based on the power-law fit, $F(> 100 \text{ MeV}) = (1.03 \pm 0.17) \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$, is significantly lower than that obtained from EGRET data: $I_{\text{EGRET}}(> 100 \text{ MeV}) = (1.45 \pm 0.05) \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$. Furthermore, our spectrum is compatible with a featureless power law with index $\gamma = 2.41 \pm 0.05$. This is significantly softer than the EGRET spectrum with index $\gamma_{\text{EGRET}} = 2.13 \pm 0.03$. To check that the different spectra are not due to the instrumental point-source sensitivities, we adopt $F(> 100 \text{ MeV}) = 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$, comparable to the average EGRET sensitivity, and attribute the flux of all detected LAT sources below this threshold to the EGB. We obtain an intensity $I_{\text{res}}(> 100 \text{ MeV}) = (1.19 \pm 0.18) \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ and a spectrum compatible with a power-law with index $\gamma_{\text{res}} = 2.37 \pm 0.05$. Therefore, the discrepancy cannot be attributed to a lower threshold for resolving point sources. Our EGB intensity is comparable to that obtained in the EGRET re-analysis by [27] with an updated DGE model, $I_{\text{SMR}}(> 100 \text{ MeV}) = (1.11 \pm 0.1) \times 10^{-5} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$. However, our EGB spectrum does not show the distinctive harder spectrum above $\geq 1 \text{ GeV}$ and peak at $\sim 3 \text{ GeV}$ found in the same EGRET reanalysis.

3. Dwarf spheroidal galaxies and Clusters of galaxies
Local Group dwarf spheroidal galaxies, the largest galactic substructures predicted by the cold dark matter scenario, are attractive targets for such indirect searches for dark matter because they are nearby and among the most extreme dark matter dominated environments. With the data taken during the first 11 months no significant $\gamma$-ray emission was detected above 100 MeV from the candidate dwarf galaxies. So we can determine upper limits to the $\gamma$-ray flux...
assuming both power-law spectra and representative spectra from WIMP annihilation. The resulting integral flux above 100 MeV is constrained to be at a level below around $10^{-9}$ photons cm$^{-2}$s$^{-1}$ [28]. Using recent stellar kinematic data, the $\gamma$-ray flux limits can be combined with improved determinations of the dark matter density profile in 8 of the 14 candidate dwarfs to place limits on the pair annihilation cross-section of WIMPs in several widely studied extensions of the standard model, including its supersymmetric extension and other models that received recent attention. With the present data we are able to rule out large parts of the parameter space where the thermal relic density is below the observed cosmological dark matter density and WIMPs (neutralinos here) are dominantly produced non-thermally, e.g. in models where supersymmetry breaking occurs via anomaly mediation. These $\gamma$-ray limits also constrain some WIMP models proposed to explain the Fermi and PAMELA $e^+e^-$ data, including low-mass wino-like neutralinos and models with TeV masses pair-annihilating into muon-antimuon pairs (see figure 10).

**Figure 10.** (Left) MSSM models in the $(m_{\text{wimp}}, \langle \sigma v \rangle)$ plane consistent with all accelerator constraints. Red points have a neutralino thermal relic abundance corresponding to the inferred cosmological dark matter density (blue points have a lower thermal relic density, and we assume that neutralinos still comprise all of the dark matter in virtue of additional non-thermal production processes). The lines indicate the Fermi 95% upper limits obtained from likelihood analysis on the selected dwarfs. (Right) Constraints on the annihilation cross-section for a $\mu^+\mu^-$ final state based on the 95% confidence limits on the $\gamma$-ray flux compared to dark matter annihilation models which fit well either the PAMELA or Fermi $e^+ + e^-$ measurements. The constraints are for the Ursa Minor dwarf including both $\gamma$-ray emission from IC scattering and final state radiation. Here we consider two different diffusion coefficients and show the effect of the uncertainties in the Ursa Minor density profile.

The same kind of analysis can be done with the clusters of galaxies. Nearby clusters and groups of galaxies are potentially bright sources of high-energy gamma-ray emission resulting from the pair-annihilation of dark matter particles. However, no significant gamma-ray emission has been detected so far from clusters in the first 11 months of observations with the Fermi Large Area Telescope. We interpret this non-detection in terms of constraints on dark matter particle properties. In particular for leptonic annihilation final states and particle...
masses greater than \( \sim 200 \text{ GeV} \), gamma-ray emission from inverse Compton scattering of CMB photons is expected to dominate the dark matter annihilation signal from clusters, and our gamma-ray limits exclude large regions of the parameter space that would give a good fit to the recent anomalous Pamela and Fermi-LAT electron-positron measurements [29]. For an example see figure 11.

Finally a line at the WIMP mass, due to the \( 2\gamma \) production channel, could be observed as a feature in the astrophysical source spectrum [14]. Such an observation is a “smoking gun” for WIMP DM as it is difficult to explain by a process other than WIMP annihilation or decay and the presence of a feature due to annihilation into \( \gamma Z \) in addition would be even more convincing.

Up to now however no lines was observed and we obtain \( \gamma \)-ray line flux upper limits in the range \( 0.6 - 4.5 \times 10^{-9} \text{ cm}^{-2}\text{s}^{-1} \) [30] and corresponding DM annihilation cross-section and decay lifetime limits shown in figure 12 and in figure 13.

4. Conclusion

Recent accurate measurements of cosmic-ray positrons and electrons by PAMELA, and Fermi have open a new era in particle astrophysics. The CRE spectrum measured by Fermi-LAT is significantly harder than previously thought on the basis of previous data. Adopting the presence of an extra \( e^\pm \) primary component with \( \sim 2.4 \) spectral index and \( E_{\text{cut}} \sim 1\text{ TeV} \) allow to consistently interpret Fermi-LAT CRE data, HESS and PAMELA. Such extra-component can be originated by pulsars for a reasonable choice of relevant parameters or by annihilating dark matter for model with \( M_{DM} \sim 1\text{ TeV} \). Improved analysis and complementary observations (CRE anisotropy, spectrum and angular distribution of diffuse \( \gamma \), DM sources search in \( \gamma \)) are required to possibly discriminate the right scenario. Their exotic origin has to be confirmed by
Figure 12. Cross-section limits for various dark matter halo profiles for the annihilation in monochromatic gamma-rays

Figure 13. Lifetime limits for various dark matter halo profiles for the decay in monochromatic gamma-rays channel

complimentary findings in \(\gamma\)-rays by Fermi and atmospheric Cherenkov telescopes, and by LHC in the debris of high-energy proton destructions. A positive answer will be a major breakthrough and will change our understanding of the universe forever. On the other hand, if it happens to be a conventional astrophysical source of cosmic rays, it will mean a direct detection of particles accelerated at an astronomical source, again a major breakthrough. In this case we will learn a whole lot about our local Galactic environment. However, independently on the origin of these
excesses, exotic or conventional, we can expect very exciting several years ahead of us.
