1. Introduction

In a recent study, it was shown that the nanoscale wettability of a hydrogen-terminated diamond surface was lower than that of regions that had been oxidized using an atomic force microscope tip [1]. The difference in wettability between modified diamond surfaces suggests the application of controlled wettability of modified carbon surfaces in the fields of medicine and biotechnology, which could also be extended to diamond-like carbon (DLC) films.

Diamond-like carbon films are known to be hard, low friction and chemically inert materials. Numerous in vitro and in vivo experiments have indicated that DLC can have both excellent biocompatibility and hemocompatibility [2–5]. In the past, the wettability of DLC coatings has been modified by selective doping using both metal and non-metal dopants [6–8]. For instance, both silicon and fluorine can be used to increase the surface energy and reduce the contact angle with water. In one study [6], researchers modified the surface energy of DLC by incorporating oxygen and silicon into the bonding network, thus avoiding the use of harmful fluorine-containing hydrocarbon gases. However, the silicon-containing DLC coatings had 20 times lower wear resistance than undoped DLC films. In another recent study [9], phosphorus-doped DLC films were deposited by applying hybrid plasma immersion ion implantation and deposition (PIIID) techniques; the good wettability exhibited by P-doped DLC samples leads to an increase in hemocompatibility. However, in this study the mechanical properties of the modified films were not analyzed. In a different study [5], substrates with various substrate roughness were employed to investigate the attachment of human osteoblast cells to amorphous carbon films with different surface textures. This study concluded that cell attachment increased monotonically with surface roughness. However, smooth surfaces are critical in the vast majority of biomedical applications and topological functionalization of the surface cannot be seen as a wide-range solution.
As a result, there is a current need for inexpensive surface processing technologies that can modify the surface energy of DLC films without altering the excellent mechanical properties of DLC films. Actually, there is a search for new ways to apply atmospheric plasma discharges that can modify the wettability, surface energy and chemistry of modern materials. In this regard, atmospheric dielectric barrier discharges (DBD) techniques can be used for the cleaning of surfaces as well as for the activation of polymer-like surfaces [10–13]. Polymers are materials of great interest in biomedical fields such as tissue engineering. Therefore, DBD processes are being used to functionalize polymeric materials by inducing changes in the surface energy, and modifying their cell-attachment behavior [14]. Stable glow plasmas from reactive gases such as N₂ at atmospheric pressure can be easily obtained by using helium as a carrier gas [15]. Helium has a higher metastable energy level than argon, and this allows for the ionization of the nitrogen molecule, N₂, which is known as Penning effect [16,17].

This suggests that DBD could also be useful in modifying the adhesion of cells and proteins to DLC films that are used in diagnostic and medical device applications. In the present study, we have employed open-air N₂/He DBD plasmas to functionalize the surface of hydrogen-free DLC films. The films were prepared by the filtered cathodic arc which is a well-known technique for the deposition of DLC films with very low-hydrogen content [18–20]. Surface analysis and characterization after functionalization of the surfaces by DBD were performed using X-ray photoelectron spectroscopy and contact angle measurements. We have analyzed the influence of these DBD plasma treatments on the attachment of osteoblast MC3-T3 cells.

2. Experimental

Four hydrogen-free DLC films have been deposited using a pulsed filter cathodic arc deposition system that contained a "triggerless" mini-gun incorporating a 6.3-mm diameter graphite rod, which was used as cathode [21]. The pulsed operation of the cathode was controlled using custom National Instruments' LabView™ software. Once the computer has sent a signal to the arc power supply, pulsed arc discharges on the cathode was triggered simply by application of a high open-circuit voltage, typically 600 V, fed by a pulse-forming network [18]. The plasma stream produced by the source was injected into a 90° filter to remove most of the macroparticles, which were formed during the cathodic arc process. In the system, the substrates were negatively biased with 2 μs, 1 kV pulses with a pulse duty cycle of 12.5%. The deposited DLC films had an approximate thickness of 45 nm.

The in-house open-air DBD plasma system employed to functionalize the deposited DLC films is shown in Fig. 1. The discharge was generated by a 5-kV AC power supply, which run at a frequency of 25 kHz. The base electrode of the plasma source was a flat aluminum disk of 4 in. (≈100 mm) in diameter, which contained a center hole (1 mm in diameter). The aluminum electrode was connected to the high-voltage output of the AC power supply. High purity helium (99.995%) and nitrogen (99.99%) were mixed and injected through the center hole, and allowed to expand throughout the discharge gap. The dielectric barrier was a 3.0-mm thick quartz plate, with dielectric constant of 3.07. In our design, water was used as a top transparent electrode, which allowed us to adequately capture the emission spectra of the various surface treatments through an optical fiber connected to an UV–vis spectrometer. In addition, a 50-Ω resistor was placed between the top (water) electrode and the ground, which allowed us to record the current waveforms using a digital oscilloscope (Tektronix TDS 210). To ensure stable plasma operation, the gap width was limited to 1 mm. The list of the various surface treatments applied is shown in Table 1; all three plasma treatments had a duration of 30 min.

X-ray photoelectron spectroscopy (XPS) data were recorded with a triple channeltron CLAM2 analyzer and Mg Kα radiation from the samples whose description is given in Table 1. The wide-scan spectra were recorded using a constant pass energy of 100 eV, whereas the narrow-scan spectra were recorded at a constant pass energy of 20 eV. All the spectra were recorded at take-off angles of 90°. The base pressure in the analysis chamber was typically around 6 × 10⁻⁹ mbar (6 × 10⁻⁷ Pa).

A KRUSS DAS 100 instrument was used for contact angle measurements. This computer-controlled contact angle analyzer allowed us to measure static and dynamic contact angle along with surface tension and surface energy. The position of the sample stage can be precisely adjusted along the x-, y-, or z-axis. An optical system using variable intensity illumination controls the degree of backlighting. The optics can be tilted by up to 3° allowing us to choose the angle of view required for rough or uneven surfaces. The instrument contains a stepping motor-controlled syringe system for precise and repeatable liquid drop formation and application. This insures that a reproducible drop volume is applied to the surface. The micro-syringe attachment facilitates rapid and precise formation of water drop specimens. Following placement of a sessile drop, the syringe is easily swung from the field of view. It will return to its exact working location for placement of the

---

**Table 1**

| Sample | He flow (sccm) | N₂ flow (sccm) | Dominant species |
|--------|----------------|----------------|-----------------|
| A      | 100            | 0              | N₂, NO          |
| B      | 100            | 50             | N₂, NO          |
| C      | 100            | 20             | N₂, N₂⁺, NO    |
| D      | 100            | 0              | N₂⁺, He, O₁, OH |
subsequent drop. Alternatively, it can remain at the working location, allowing continuously adding or withdrawing fluid from a sessile drop for the purpose of forming advancing or receding contact angles. After placing the water droplet, the contact angle was measured using the circular curve fit option of the software.

Cell survival and proliferation were determined using mouse MC3T3 osteoblastic cells that were seeded on coated glass cover slips at an initial density of $5 \times 10^4$ cells per disc. The MTT assay was used to quantify the number of viable cells after 3 days of culture. This test is a quantitative colorimetric method to determine cell proliferation. It utilizes the yellow tetrazolium salt (MTT), which is metabolized by mitochondrial succinic dehydrogenase activity of proliferating cells to yield a purple formazan reaction product. Data from DLC-coated and plasma-treated samples were normalized to those from specimens not plasma-treated.

3. Results and discussion

3.1. Characteristics of the open-air He/N₂ dielectric barrier discharges

The current waveforms for the open-air atmospheric plasma discharges employed to treat DLC samples are shown in Fig. 2. The overall shape of the waveforms for the three plasma treatments is controlled by the width and repetition rate of the high-voltage pulses produced by the power supply, however, the noise of the current waveform decreased monotonically with N₂ gas flow. This indicates a higher degree of homogeneity for glow discharges of He/air in comparison to that of He/N₂. Visual observations of the atmospheric pressure plasma indicated that the three DBD processes were stable.

Optical emission spectroscopy was applied to identify the chemical species formed in the discharge. Fig. 3 compares the emission spectra for the various gas mixtures. Because the atmospheric plasma treatments were carried out in open air, the decrease in N₂ flow from 50 to 0 sccm implies that the N₂ flow is replaced by laboratory air. The list of the possible reactions happening between N₂ and He is shown in Table 2. In samples B (N₂ flow = 50 sccm) and C (N₂ flow = 20 sccm), transfer of energy from the helium 19.8 eV metastable energy level induces dissociation of the N₂ molecule, which produces the formation of NO, as can be observed in Fig. 3. The presence of OH band in the emission spectra for sample D (100 sccm He, 0 sccm N₂) reveals the presence of water in the plasma because the gas flow is reduced for this sample. In this case, OI and HeI emission is observed which can come from a direct electron excitation, while nitrogen N₂⁺ and OH are likely due to Penning ionization via the metastable He* [22].

3.2. X-ray photoelectron spectroscopy

The wide-scan spectra recorded from the different samples are presented in Fig. 4. As expected, intense C 1s peaks dominate the spectra. All the spectra show noticeable oxygen contributions. Besides that, all the plasma-treated samples showed nitrogen contributions, which are an indication that nitrogen has been incorporated into the DLC films, even in the sample that has been treated in a flow of He and air (sample D). Table 3 collects the relative atomic concentrations obtained from the XPS data. It is interesting to note that the sample treated with the highest N₂ flow (50 sccm) presents the highest nitrogen content among all treated samples, while the other two have lower, comparable nitrogen contents.

Fig. 5 shows the narrow-scan C 1s spectra recorded from all the samples. The spectra have been fitted considering four different

**Fig. 3.** Emission spectra of open-air atmospheric plasma discharge.

| Table 2 | Description of possible reactions in He/N₂ dielectric barrier discharge (DBD) plasma |
|---------|-------------------------------------------------------------------------------------|
| $\text{He} + e^{-, 22.2 eV} \rightarrow \text{He}^+ + e_{\text{slow}}$ | |
| $\text{He}^+ + e^{-, 20.5 eV} \rightarrow \text{He} + e_{\text{slow}}$ | |
| $\text{N}_2 + e^{-, 11.05 eV} \rightarrow (\text{N})_2^+ + e_{\text{slow}}$ | |
| $\text{N}_2^+ + e^{-} \rightarrow \text{N}_2 (N_2^+) + e_{\text{slow}}$ | |
| $\text{He}^+ + \text{N}_2 \rightarrow \text{He} + (\text{N}_2^+) + e_{\text{slow}}$ | Penning ionization |
| $\text{N}_2^+ + e_{\text{slow}} \rightarrow (\text{N}_2^+) + e_{\text{slow}}$ | |

$\text{He}^+$ is excited atom of He which cause of He I radiation; $\text{He}^+$ is meta-stable ($2^3S$) atom of He; $(\text{N}_2^+)^*$ is excited of nitrogen molecule which cause of N₂ species; $(\text{N}_2^+) + e_{\text{slow}}$ is excited of nitrogen molecule ion which cause of N₂⁺ species.
carbon peaks. The results of the fit are presented in Table 4. In the case of the DLC film, the peak appearing at 284.6 eV corresponds to the sp² contribution characteristic of DLC [23,24], while that at 285.5 eV corresponds to the sp³ contribution [23,24]. In the present case, the peak at 287.1 eV does not necessarily correspond to a different chemical species rather, more likely, it accounts for the high-binding energy side asymmetry, which is known to exist in the sp² contribution [23,24]. Finally, the peak at 288.6 eV corresponds to the presence of C–O bonds. As shown in Table 4, the contribution of the peak appearing at 284.6 eV increases slightly due to the application of DBD surface treatments.

Table 3
Relative atomic concentrations calculated from the XPS data

| Sample | Carbon (at%) | Oxygen (at%) | Nitrogen (at%) |
|--------|--------------|--------------|----------------|
| A      | 94           | 6            | -              |
| B      | 88           | 9.5          | 2.5            |
| C      | 86           | 13           | 1              |
| D      | 87           | 12           | 1              |

Since the wide-scan spectra have shown that nitrogen was incorporated into the DLC films, the contributions at 284.6, 285.5, 287.1 and 288.6 eV present in the spectra of the treated samples can also be associated with the presence of C–C, C–N, C=N or C≡N and C–O bonds, respectively [24]. We must take into account, however, that the amount of N present in the samples is very small (1–2.5%), therefore, these contributions must represent only a small fraction of the total peak area. In general, all the spectra recorded from the treated samples were very similar.

Table 4
XPS binding energies and relative spectral areas of the different contributions present in the C 1s spectra

| Sample | BE (eV) | BE (eV) | BE (eV) |
|--------|---------|---------|---------|
|        | C1      | C2      | C3      | C4      |
| A      | 284.6   | 285.5   | 287.1   | 288.6   |
| B      | 284.6   | 285.5   | 287.1   | 288.6   |
| C      | 284.6   | 285.6   | 287.1   | 288.8   |
| D      | 284.6   | 285.6   | 287.0   | 288.6   |

The N 1s spectra recorded from the treated samples are shown in Fig. 6. All of them show three contributions (see also Table 5). The one appearing at 398.8 eV can be associated with the presence of C–N or C≡N bonds, the main one at 399.9 eV can be assigned to C≡N bonds and, finally, the contribution at 401.7 eV might arise either from the existence of N–O bonds [25,26] and/or quaternary nitrogen (N bonded to three C atoms within a graphitic domain) [27–29]. The intensity of this latter contribution is noticeably higher in the spectrum recorded from the sample treated in He and air (sample D) than in the other two samples (Table 5).
Finally, we note that all the O 1s spectra recorded from all the samples were very similar and were composed by a quite symmetric peak centered at 532.6 eV.

### 3.3. Contact angle measurements

The evolution of the contact angle for the different DBD plasma treatments for an aging time up to 300 days is shown in Fig. 7. The first observation concerns the uniformity of the untreated DLC film (sample A), which had a contact angle \( \theta = 75^\circ \) for the entire sampled ageing time. The sample treated with the highest N\(_2\) flow (sample B, \( N_2 = 50 \text{ sccm} \)) evolved from an initial hydrophilic behavior (contact angle = 53\( ^\circ \)) to a hydrophilic/hydrophobic behavior similar to the one observed for the untreated DLC sample. The fast degree of recovery for this sample suggests that the presence of molecular N\(_2\) species in the DBD plasma does not produce any long-term change in surface energy of the DLC surface, although it can increase the atomic percentage of nitrogen in the surface of the DLC.

In the case of the sample treated with the lower N\(_2\) flow (sample C, \( N_2 = 20 \text{ sccm} \)), the behavior is hydrophilic immediately after plasma treatment, however, after 30 days of aging, this behavior changed to hydrophobic (contact angle = 88\( ^\circ \)), and its hydrophobic behavior increases further over time. The contact angle after 270 days of aging time increased to 99\( ^\circ \). The hydrophobic behavior is probably a consequence of the higher presence of C–N or C\(_\beta\)N bonds as it was reported in the previous section, and as shown in Fig. 6 and Table 5. The cause for the observed decrease in surface energy could also be related to the strong presence in the discharge of ionized N\(_2^+\) (instead of neutral gas molecules N\(_2\)), as it was observed in Fig. 3. Finally, in the case of the sample treated with He and air (sample D, \( N_2 = 0 \text{ sccm} \)), the evolution of the contact angle indicates that the sample behaves and remains hydrophilic even after 270 days.
of the applied DBD treatment. In this case, the presence of air in the DBD plasma can affect the bonding of nitrogen to the surface. In the previous section, it was shown that this sample contained the highest contribution of N–O bonds and/or quaternized nitrogen moieties, in comparison to the other two surface treatments. The observed behavior is therefore expected since the presence of more N–O bonds and/or the presence of an ionic species as the quaternized nitrogen on the surface of the DLC sample would result in a strong polarity.

3.4. Cell viability

The results for cell proliferation after 3 days of culture for all the treated samples (with respect to untreated specimens) are shown in Fig. 8. Statistical analyzes on the cell culture data were performed by means of a paired t-test. Overall, it can be observed that the percentage of attached cells for all surface treatments is near 100% that of the untreated hydrogen-free DLC film, which is an indicator of a high biocompatibility. In a very recent study, we have reported that the cell viability of non-treated hydrogen-free DLC film, which is an indicator of a high biocompatibility. In a very recent study, we have reported that the cell viability of non-treated hydrogen-free DLC film, which is an indicator of a high biocompatibility.

In a very recent study, we have reported that the cell viability of non-treated hydrogen-free DLC film, which is an indicator of a high biocompatibility.

Further work will examine the influence of these DBD plasma-treated DLCs on the differentiation of DNA molecules.

Acknowledgments

Helpful discussions with Prof. S. Santucci (CASTI) are gratefully acknowledged. Authors are also grateful to P. De Marco for her help in measuring the contact angle of water. Financial support from the Marie Curie Outgoing Fellowship Grant MoIF-CT-2005-02195 is gratefully acknowledged. Work at Lawrence Berkeley National Laboratory was supported by the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. Financial support from the Spanish Ministry of Education under project MAT2004-01451 is also gratefully acknowledged.
