Summary

Background Harnessing CD8+ T cell responses is being explored to achieve HIV remission. Although HIV-specific CD8+ T cells become dysfunctional without treatment, antiretroviral therapy (ART) partially restores their function. However, the extent of this recovery under long-term ART is less understood.

Methods We analyzed the differentiation status and function of HIV-specific CD8+ T cells after long-term ART initiated in acute or chronic HIV infection ex vivo and upon in vitro recall.

Findings ART initiation in any stage of acute HIV infection promoted the persistence of long-lived HIV-specific CD8+ T cells with high expansion (P<0.0008) and cytotoxic capacity (P=0.02) after in vitro recall, albeit at low cell number (P=0.003). This superior expansion capacity correlated with stemness (ρ=0.99, P=0.006), measured by TCF-1 expression, similar to functional HIV-specific CD8+ T cells found in spontaneous controllers. Importantly, TCF-1 expression in these cells was associated with longer time to viral rebound ranging from 13 to 48 days after ART interruption (ρ=0.71, P=0.09). In contrast, ART initiation in chronic HIV infection led to more differentiated HIV-specific CD8+ T cells lacking stemness properties and exhibiting residual dysfunction upon recall, with reduced proliferation and cytolytic activity.

Interpretation ART initiation in acute HIV infection preserves functional HIV-specific CD8+ T cells, albeit at numbers too low to control viral rebound post-ART. HIV remission strategies may need to boost HIV-specific CD8+ T cell numbers and induce stem cell-like properties to reverse the residual dysfunction persisting on ART in people treated after acute infection prior to ART release.

non-human primate models, CD8+ T cell responses are responsible for viral control since their depletion causes an increase in viremia in spontaneous controller animals,14-suppressed ART-treated animals,15,16 and post-treatment controller animals.17 CD8+ T cells are also responsible for viral control in people who are spontaneous controllers.18-20 However in most people living with HIV, in the absence of treatment, HIV-specific CD8+ T cells become dysfunctional during chronic HIV infection (CHI), concomitant with the upregulation of immune checkpoint molecules including PD-1, because of continuous HIV antigen burden.21-24 Dysfunction of HIV-specific CD8+ T cells begins after peak viremia in AHI, and includes metabolic dysfunction and an inability to survive and differentiate into long-lived memory T cells.24 ART initiation in AHI before peak viremia prevents loss of cytokine productivity and memory potential of HIV-specific CD8+ T cells.2,3 Previous studies also suggested that early ART initiation preserves T cell function on ART16,37 and reduces persistent immune activation.26,38-40 Post-treatment controllers are more frequently found in people treated from AHI than from CHI.31,32 These characteristics make individuals treated from AHI the ideal group in which to study the role of CD8+ T cells in post-treatment viral control.33 However, most people treated in AHI rebound without significant delay compared to people treated in CHI,2,3,5,6 bringing to question the quality of their immune response. There is very limited knowledge on the preservation of long-term HIV-specific CD8+ T cells and immune correlates that induce post-treatment control or delayed viral rebound in people treated from AHI.41,42 Furthermore, data showing whether initiation of ART in AHI improves the quality of the HIV-specific CD8+ T cell recall response, either in vitro or in vivo after ART interruption, are lacking.

We and others have analyzed HIV-specific CD8+ T cells in people treated from CHI before and after ART and shown that ART normalizes the expression of checkpoint proteins and the IL-7 receptor, suggesting that ART restored cell survival and functionality of HIV-specific CD8+ T cells.37-42 Other studies showed that HIV-specific CD8+ T cells people treated from CHI were less functional than cells from spontaneous controllers, suggesting that functional defects persisted during ART.33-40 Overall, the extent to which HIV-specific CD8+ T cells regain function or have persistent dysfunction in people treated from CHI is not clear due to these conflicting data. HIV-specific CD8+ T cell functionality has not yet been characterized in people treated from AHI. Spontaneous controllers do not experience an increase in viremia in spontaneous controller animals,14-suppressed ART-treated animals,15,16 and post-treatment controller animals.17 CD8+ T cells are also responsible for viral control in people who are spontaneous controllers.18-20 However in most people living with HIV, in the absence of treatment, HIV-specific CD8+ T cells become dysfunctional during chronic HIV infection (CHI), concomitant with the upregulation of immune checkpoint molecules including PD-1, because of continuous HIV antigen burden.21-24 Dysfunction of HIV-specific CD8+ T cells begins after peak viremia in AHI, and includes metabolic dysfunction and an inability to survive and differentiate into long-lived memory T cells.24 ART initiation in AHI before peak viremia prevents loss of cytokine productivity and memory potential of HIV-specific CD8+ T cells.2,3 Previous studies also suggested that early ART initiation preserves T cell function on ART16,37 and reduces persistent immune activation.26,38-40 Post-treatment controllers are more frequently found in people treated from AHI than from CHI.31,32 These characteristics make individuals treated from AHI the ideal group in which to study the role of CD8+ T cells in post-treatment viral control.33 However, most people treated in AHI rebound without significant delay compared to people treated in CHI,2,3,5,6 bringing to question the quality of their immune response. There is very limited knowledge on the preservation of long-term HIV-specific CD8+ T cells and immune correlates that induce post-treatment control or delayed viral rebound in people treated from AHI.41,42 Furthermore, data showing whether initiation of ART in AHI improves the quality of the HIV-specific CD8+ T cell recall response, either in vitro or in vivo after ART interruption, are lacking.

We and others have analyzed HIV-specific CD8+ T cells in people treated from CHI before and after ART and shown that ART normalizes the expression of checkpoint proteins and the IL-7 receptor, suggesting that ART restored cell survival and functionality of HIV-specific CD8+ T cells.37-42 Other studies showed that HIV-specific CD8+ T cells people treated from CHI were less functional than cells from spontaneous controllers, suggesting that functional defects persisted during ART.33-40 Overall, the extent to which HIV-specific CD8+ T cells regain function or have persistent dysfunction in people treated from CHI is not clear due to these conflicting data. HIV-specific CD8+ T cell functionality has not yet been characterized in people treated from AHI. Spontaneous controllers do not experience sustained levels of viremia and have protective genetic backgrounds such as CCR5Δ32 or protective HLA alleles that are different from most people living with HIV.44-47 Therefore, HIV-specific CD8+ T cells in spontaneous controllers might not be the best

Research in context

Evidence before this study

Finding a therapeutic intervention that could lead to HIV remission is still challenging. Optimizing HIV-specific CD8+ T cell responses has been considered as one strategy since these cells play a critical role in killing HIV-infected cells. Treatment initiation in hyperacute HIV infection preserved the functionality of HIV-specific CD8+ T cells shortly after ART initiation compared with no treatment but these cells did not have enhanced proliferative and cytolytic potential. ART initiated later in infection only partially restores the function of HIV-specific CD8+ T cells exhausted by chronic HIV infection, but the extent of this remaining dysfunction and ways to revert it are still unknown.

Added value of this study

We showed here that long-term treatment initiated in acute infection leads to functional HIV-specific CD8+ T cells with enhanced proliferative and cytolytic potential regardless of the stage of acute infection at which treatment is initiated. In contrast, even if long-term treatment sharply reduces HIV-specific CD8+ T cell dysfunction in people treated later, these cells exhibit a residual dysfunction and are more prone to become dysfunctional again upon recall. Albeit at lower numbers, functional HIV-specific CD8+ T cells in people treated in acute infection exhibited more stemness, reflected by TCF-1 expression, that correlated with longer time to viral rebound after treatment interruption.

Implications of all the available evidence

HIV remission in people living with HIV on ART will likely require a combination of strategies aimed at reversing the residual dysfunction of HIV-specific CD8+ T cell under ART prior to boosting them, and reprogramming their stemness through targeting TCF-1 could be a potential therapeutic strategy.

Introduction

According to UNAIDS (www.unaids.org/en/resources/fact-sheet), over 28 million people living with HIV are currently taking antiretroviral therapy (ART), with the majority achieving control of viral replication to levels under the limit of detection. However, the virus rebounds once ART is interrupted, even when ART was initiated in acute HIV infection (AHI).1-6 therefore people living with HIV require ART for life.7-9 However, long-term ART-free HIV remission is possible as evidenced by a few individuals, called post-treatment controllers, who are able to control viral replication after discontinuation of ART.9-12 Boosting HIV-specific CD8+ T cell responses has been explored as a strategy to induce HIV remission since these cells play a critical role in limiting viral replication early in AHI.12,13 In
CD8+ T cells in people treated from AHI and CHI to analyzed the quantity and quality of memory HIV-specific in CHI and are followed after treatment. Here, we ana-

To better understand the functional restoration or residual dysfunction of memory HIV-specific CD8+ T cells after initiation of ART, we investigated these cells after long-term ART in people who initiated treatment in AHI and CHI. The RV254/SEARCH010 AHI cohort follows a unique population of people in Bangkok, Thailand, who are enrolled upon diagnosis in different AHI stages, initiate ART immediately after diagnosis, and are followed after treatment. The RV304/SEARCH013 cohort is a matched cohort of people living with HIV in Bangkok, Thailand, who initiate ART during CHI and are followed after treatment. Here, we analyzed the quantity and quality of memory HIV-specific CD8+ T cells in people treated from AHI and CHI to define whether early initiation of ART in AHI confers the capacity to mount an efficient recall response in persisting memory HIV-specific CD8+ T cells after long-term ART and define the extent of the remaining dys-

HIV-1 sequence analysis

HIV-1 sequences were generated from samples collected prior to ART initiation from AHI and CHI participants via Sanger sequencing using endpoint dilution; the corresponding HIV-1 Gag, Pol, Env and Nef sequences were translated. Circling HIV-1 CRF01_AE sequences were downloaded from the Los Alamos National Labs HIV database (https://www.hiv.lanl.gov/) to create alignments of independent Gag (n=1049), Pol (n=323), Env (n=849) and Nef (n=548) sequences. CD8+ T cell epitopes were predicted for each amino acid (AA) sequence using NetMHCPan 4.1. Epitopes are defined as strong binders if the predicted eluted ligand percentile ranks (Rank EL (%)) are below 0.5.

| Pre-ART HIV infection stage | AHI (n=14) | Chronic (n=13) | P value |
|----------------------------|------------|----------------|--------|
| Percentage of male         | 100%       | 100%           |        |
| Pre-ART Age (years), median [IQR] | 26 (23-31) | 28 (27.5-33) | 0.07   |
| Pre-ART viral load (copies/mL), median [IQR] | 859,219 (443,546-8,460,425) | 28,962 (9,426-92,155) | <0.0001 |
| Pre-ART CD4 count cells/mm³ in plasma, median [IQR] | 366 (290-425) | 402 (319-503) | 0.28   |
| Pre-ART CD8 count cells/mm³ in plasma, median [IQR] | 592 (315-1202) | 1230 (831-1922) | 0.01   |
| Duration of ART (years), median [IQR] | 1.6 (1.59-2.61) | 1.9 (1.2-2.0) | 0.02   |
| On ART Age (years), median [IQR] | 27 (25-33) | 30 (29-33) | 0.10   |
| On ART CD4 count cells/mm³ in plasma, median [IQR] | 601 (517-785) | 680 (519-784) | 0.79   |

Table 1: Clinical characteristic of study participants longitudinally analyzed before and during ART. P values from Mann-Whitney are shown.
Flow cytometry analysis
Thawed or cultured peripheral blood mononuclear cells (PBMCs) were first stained for peptide-MHC class I complex tetramer, cell surface markers, and then fixed/permeabilized for intracellular/intranuclear staining. Detailed methods and related reagents are found in Supplementary Methods.

In vitro memory CD8+ T cell recall assay
Thawed PBMCs from HIV-infected individuals were labeled with CellTrace Violet (Thermo Fisher Scientific) at 1 μM according to the manufacturer’s protocol. The cells were then plated at 5 x 10^6 cells/well in 24 well plate in CellGenix GMP DC Medium (CellGenix) containing recombinant human (rh) IL-7 (1 ng/ml, PeproTech) to support minimal T cell survival and rh FLT3L (50 ng/ml, PeproTech) to mobilize primary DCs. After 24 hours (day 1), cognate CD8 epitope peptides from HIV or EBV were added to the culture at 1 μg/ml. On day 2, human serum (Access Biologicals) and rh IL-2 (Miltenyi Biotec) were added at final concentrations of 8% (volume/volume) and 20 U/ml, respectively. Half of the medium was replaced with RPMI-1640 containing 8% human serum, rh IL-2 (20 U/ml), and penicillin-streptomycin (100 U/ml, Quality Biological) on days 5, 7 and 9. HIV and EBV-specific CD8+ T cells in the culture were analyzed by flow cytometry on days 6 and 12.

Assay for cytotoxic activity
A cytotoxicity assay based on CFSE labeled target cells was used as previously described, with some modifications. Autologous PBMCs (1 x 10^6 cells) were expanded with phytohemagglutinin-L (1 μg/ml, Sigma-Aldrich) in RPMI-1640 medium supplemented with 8% human serum, rh IL-2 (10 ng/ml), natural human IL-7/TCGF (5 B.M. U/ml, ZeptoMetrix), antiretrovirals (100 nM efavirenz, 180 nM zidovudine, and 200 nM raltegravir), and penicillin-streptomycin (100 U/ml) for 12 days. CD4+ T cells were isolated from the expanded PBMCs using magnetic negative selection (STEMCELL Technologies) and used as target cells. Autologous CD4+ T cells were labeled with two different concentrations of CFSE, 20 nM for CFSElow, or 200 nM for CFSEhigh. CFSElow labeled target cells were pulsed with cognate epitope peptides (1 μg/mL) for 45 min and mixed with CFSEhigh cells (no peptide pulse) at a ratio of 1:1. Twenty thousand each of CFSEhigh and CFSElow target cells were co-cultured for 4 hours with cells from day 13 of the in vitro memory CD8+ T cell recall assay at increasing E/T ratios (1, 2, 4, and 8) based on the frequency of HIV- or EBV-specific CD8+ T cells in the culture at day 12. The cells were analyzed by flow cytometry for the number of remaining live target cells and tetramer stained HIV or EBV-specific CD8+ T cells. The percentage of specific cell lysis was calculated as the proportion of live, peptide-pulsed cells (CFSElow) to live, non-peptide pulsed cells (CFSEhigh), and the accurate E/T ratio was determined by ratio of tetramer+ cell number to number of non-peptide pulsed target cells. The final percentage of specific cell lysis at E/T ratio 2 was determined by linear regression of the percentage specific cell lysis and observed E/T ratio calculated from the flow cytometry.

Ethics
All study participants provided informed consent approved by the Chulalongkorn University and Walter Reed Army Institute of Research institutional review boards. The investigators have adhered to the policies for protection of human participants as prescribed in AR-70-25.

Statistical analysis
Statistical analyses were performed using the nonparametric Kruskal-Wallis test (more than 2 groups) or Mann-Whitney test (2 groups) for group comparisons, and the Wilcoxon matched-pairs signed-rank test for the longitudinal samples before and after ART initiation. The nonparametric Spearman test was used for all of the correlation analyses, and the Benjamini-Hochberg procedure was used to correct for multiple comparisons (FDR < 0.1). Original data unit from available data was used for all statistical analysis and no logarithm transformation was performed. Above statistical analysis was performed with GraphPad Prism 9. SPICE was used to perform a chi-square permutation test comparing the distribution of the CD8+ T cell subsets among the groups. P < 0.05 was considered significant.

| AHI 4G stage (S) upon ART initiation | AHI (n=44) | Chronic (n=28) | P value |
|-------------------------------------|------------|----------------|---------|
| Percentage of male                  | 93%        | 79%            | 0.86    |
| Duration of ART (years), median (IQR) | 2.0 (1.6-2.5) | 1.9 (1.7-2.8) | 0.0005  |
| Age (years), median (IQR)                | 27 (25-33)  | 33 (29-39)     |         |
| CD4 count cells/mm³ in plasma, median (IQR) | 613 (563-814) | 560 (464-726) | 0.14    |
| CD8 count cells/mm³ in plasma, median (IQR) | 654 (479-778) | 845 (699-1088) | 0.002   |

Results

Lower numbers of HIV-specific CD8⁺ T cells are sustained when ART is initiated in acute infection than in chronic infection

CD8⁺ T cells specific for five different HIV epitopes restricted by HLA-A*1101 and Cw*0102, dominant alleles in the Thai population, were analyzed in this study, and one EBV epitope restricted by HLA-A*1101 was analyzed as an internal comparator (Table S1). These five HIV-1 CD8⁺ T cell epitopes corresponded to highly conserved peptides in the HIV-1 proteome (Figure 1a). Viral sequences were available from a subset of participants (21 AHI, 8 CHI) and used to predict CD8⁺ T cell epitopes for each participant’s sequences. Most predicted epitopes were identical to the epitopes tested, and a subset (7/30) showed one mutation with the tested epitope (Tables S2 and S3). Importantly, predicted epitopes with mutations had similar binding affinities as the tested epitopes (Table S4). Only one epitope in Nef (GK10 with the G83E mutation) was predicted to have weaker binding affinity but this variant epitope was only found in one of ten sequences in one participant (Tables S2 and S4). In previous work, the A11 QK10 variant and the original epitope were similarly recognized by HIV-specific CD8⁺ T cells within the same people carrying HLA-A11. The A11 AK9 variant was not found in our participants. These data indicate that the impact of virus variants on the HIV-specific CD8⁺ T cell response was minimal.

To understand the effect that reducing viral burden with ART has on HIV-specific CD8⁺ T cells, we analyzed longitudinally samples from before and after at least 1 year of treatment initiated in AHI in the RV254/SEARCH010 cohort and in CHI in the RV304/SEARCH013 cohort (Table 1). Before ART initiation, HIV-specific CD8⁺ T cell subsets were at higher numbers in people in CHI (UnTx CHI) than in people in AHI (P = 0.02; UnTx AHI), and at higher numbers than EBV-specific CD8⁺ T cells (P = 0.0004; Figure 1b). ART initiated in both AHI (Tx AHI) and CHI (Tx CHI) resulted in a drastic reduction of cell numbers (AHI P = 0.003; CHI P < 0.0001 compared to UnTx) (Figure 1c). Participants treated from AHI had significantly lower numbers of HIV-specific CD8⁺ T cells in blood after ART than people who initiated ART during CHI (Table 2, P < 0.0001; Figure 1d). People who initiated treatment in the earliest detectable stage of AHI, Stage 1, exhibited the lowest numbers of HIV-specific CD8⁺ T cells, even lower than EBV-specific CD8⁺ T cells from the same individuals (P < 0.0001 against CHI, P = 0.004 against EBV; Figure S1).

HIV-specific CD8⁺ T cells exhibit phenotypes of effector cells in AHI and exhausted cells in CHI before ART initiation

Before ART initiation, HIV-specific CD8⁺ T cells in both AHI and CHI were mostly found in short-lived transitional memory (Ttm) and effector memory (Tem) T cell subsets (Figure 2a, S2, and S3A), as previously reported. However, in AHI, the majority of them were Ki-67⁺Bcl-2low activated effector cells as we and others reported and expressed the transcriptional factor T-bet, important for effector CD8⁺ T cell differentiation, at higher level than their counterparts in CHI and EBV-specific CD8⁺ T cells (Figure 2b and c). This was consistent with a trend toward higher expression of the cytolytic molecule Perforin (Figure S3b). We also confirmed that HIV-specific CD8⁺ T cells during CHI had an exhausted phenotype with higher expression of the transcription factor associated with T cell exhaustion, TOX, and a strong trend toward higher expression of the activation/check point protein PD-1 compared to those in AHI (Figure 2d and e). These data indicate that HIV-specific CD8⁺ T cells in AHI are effector T cells and those in CHI are exhausted cells.

Initiation of ART in AHI promotes the differentiation of HIV-specific CD8⁺ T cells with self-renewal and long-lived memory phenotypes

As numbers of HIV-specific CD8⁺ T cells drastically declined after ART initiation in both AHI and CHI (Figure 1c), we assessed their differentiation phenotype under long-term ART. The distribution of HIV-specific CD8⁺ T cell subsets was significantly different between AHI-treated and CHI-treated participants as well as with EBV-specific cells from the same individuals (P < 0.0001 for all combinations; Figure 3a). People treated from AHI had significantly higher percentages of T cell subsets endowed with potent self-renewal and long-lived capacities, such as stem cell memory (Tscm) and central memory (Tcm) cells, compared to people treated from CHI (P = 0.0002 and P = 0.004, respectively; Figure S4a). Participants treated from AHI also had higher frequencies of HIV-specific CD8⁺ T cells with naive-like phenotype (Tna) (P = 0.03), which were similarly found in vaccine-induced yellow fever- and influenza-specific memory CD8⁺ T cells. In contrast, HIV-specific CD8⁺ T cells from individuals treated during CHI were still predominantly found in short-lived Ttm and Tem subsets as they were pre-ART (Figure 2a and Figure S3a). EBV-specific CD8⁺ T cells were predominantly composed of Tcm and Ttm subsets.
Consistent with these T cell phenotypes, HIV-specific CD8+ T cells from participants treated from AHI showed significantly higher expression of CD127 than those from participants treated from CHI (P < 0.0001) but comparable to those of EBV-specific CD8+ T cells (Figure 3b), with a trend toward the highest expression of CD127 occurring in the group treated from AHI Stage 1 (Figure S4b). Consistent with their long-lived phenotype, HIV-specific memory CD8+ T cells in participants treated from AHI showed persisting T cell receptor (TCR) clonotypes within HIV Nef-specific CD8+ T cells between 2 visits during ART, as shown by the high Morisita-Horn index for both alpha and beta chains of the TCR (Table S5) and maintenance of dominant and subdominant clonotypes (Figure S4c) as seen in people treated in CHI. In addition, the frequency of HIV-specific CD8+ T cells was sustained at low but stable levels over 5 years of ART in this cohort. On the other hand, memory HIV-specific CD8+ T cells in people treated from CHI showed a trend toward higher expression of TOX and significantly higher PD-1 expression than cells in people treated from AHI (P > 0.0001 and P = 0.05, respectively; Figure 3c and d). These data indicate that early initiation of ART in AHI promotes differentiation of memory T cells with self-renewal and long-lived phenotypes and that the cells are stably sustained throughout treatment. Of note, ART initiation in any stage of AHI, including post-peak, led to the generation of long-lived HIV-specific memory cells.
HIV-specific CD8+ T cells from people who initiated ART in AHI exhibit higher proliferative capacity than those treated from CHI

To further assess the quality of memory HIV-specific CD8+ T cells during long-term ART, we analyzed the quality of their response upon recall. For that, we designed an in vitro memory T cell recall assay in which we stimulate HIV-specific CD8+ T cells with a cognate HIV epitope peptide for 12 days, measuring their proliferation capacity at 6 and 12 days (Figure 4). The number of HIV-specific CD8+ T cells was significantly higher after recall when cells came from people treated in CHI compared to those treated from AHI (P = 0.003; Figure 5a), as the ex vivo number of memory HIV-specific CD8+ T cells was more than 7 times higher when ART was initiated in CHI (Figure 1d). However, the magnitude of cell expansion 12 days after stimulation was significantly higher when ART was initiated in AHI than in CHI (P = 0.0008; Figure 5b). The magnitude of expansion in both groups positively correlated with the cell number on day 12 (r = 0.45, P = 0.006 and r = 0.73, P < 0.0001, respectively; Figure S5a and b). The blunted expansion capacity of cells from people treated in CHI was associated with a higher combined frequency of short-lived T cell subsets in ex vivo HIV-specific CD8+ T cells (Ttm, Tem, and Ttd; r = -0.49, P < 0.0001; Figure 5c), as well as of the Ttm subset alone (r = -0.66, P < 0.0001; Figure 5d), suggesting that skewed differentiation toward short-lived cells prevents cell expansion. Expression of T-bet positively correlated with cell expansion only when treatment was initiated in AHI (r = 0.63, P < 0.0001, Figure 5d). These data suggest that memory HIV-specific CD8+ T cells in people treated from AHI, though lower in number, have a higher proliferative capacity.

HIV-specific CD8+ T cells from people treated from AHI differentiate into functional effector CD8+ T cells with higher cytolytic capacity than those treated from CHI

Before in vitro recall, HIV-specific CD8+ T cells from individual treated from CHI showed significantly
higher expression of the cytolytic molecule Granzyme B than cells in people treated from AHI \( (P = 0.001, \text{Figure} \ 6a) \). To assess the cytolytic capacity after recall, we measured their specific killing on day 13 of the in vitro memory recall assay (Figure 4). We found a significantly higher expression of T-bet and the cytolytic molecule perforin at day 12 in recalled HIV-specific CD8\(^+\) T cells from participants treated from AHI compared to those treated from CHI \( (P = 0.005 \text{ and } P = 0.002; \text{Figure} \ 6b \text{ and } c, \text{respectively}) \). Consistent with this, cytolytic activity of the recalled HIV Nef GK10-specific CD8\(^+\) T cells was significantly higher in people treated from AHI than CHI \( (P = 0.02 \text{ at E/T2 and } P = 0.04 \text{ at E/T1; Figure} \ 6d \text{ and Figure} \ S6a, \text{respectively}) \). A similar trend toward superior cytolytic capacity was confirmed for recalled HIV-specific CD8\(^+\) T cells specific for 4 other HIV epitopes \( (P = 0.11; \text{Figure} \ S6b) \). The blunted cytolytic capacity of HIV-specific CD8\(^+\) T cells from people treated in CHI was not due to a defect in antigen presentation or resistance of target cells to CD8\(^+\) T cell killing since EBV-specific CD8\(^+\) T cells from the same individuals showed superior cytolytic capacity than HIV-specific CD8\(^+\) T cells against the same autologous target cells loaded with peptides. We hypothesized that this dampened cytolytic activity in CD8\(^+\) T cells from people treated during CHI might be due to cell exhaustion, as PD-1 was expressed at the highest levels on ex vivo HIV-specific CD8\(^+\) T cells in people treated from CHI (Figure 3d). The elevated PD-1 expression was indeed maintained on these cells even after in vitro recall (Figure 6c, \( P < 0.0001 \text{ against Tx AHI} \). These data suggest that recalled HIV-specific CD8\(^+\) T cells in people treated from CHI exhibit residual dysfunction even after long-term ART whereas memory HIV-specific CD8\(^+\) T cells in people treated from AHI, though lower in number, have better capacity to differentiate into functional effector CD8\(^+\) T cells that can eliminate HIV-infected cells upon secondary antigen stimulation.
TCF-1 expression associates with recall response and viral control after treatment interruption

Since HIV-specific CD8+ T cells from people treated from AHI have characteristics of long-lived memory T cells (Figure 3), higher expansion potency (Figure 5b), and cytolytic capacity after recall (Figure 6d), we hypothesized that TCF-1, a transcription factor important for self-renewal capacity,66-68 maintains their functionality under long-term ART and supports a sustained effective immune response required to control rebounding viral replication after ART stop. Although TCF-1 is thought to be downregulated in effector cells, HIV-specific CD8+ T cells from prior to ART initiation in AHI showed TCF-1 expression comparable to that of EBV-specific CD8+ T cells and a trend toward higher TCF-1 expression than the cells in CHI (Figure 7a, \(P = 0.12\)). Initiation of ART recovered the expression of TCF-1 in both AHI and CHI (Figure 7b), but HIV-specific CD8+ T cells from people treated from AHI expressed significantly higher TCF-1 than those from participants treated from CHI (\(P = 0.0003\, \text{Figure 7c}\)). Some RV254 participants treated from AHI underwent analytic treatment interruption (ATI) as part of 3 clinical trials although all participants experienced viral rebound ranging from 14 to 48 days (Figure S7a). In the participants who had detectable ex vivo memory HIV-specific CD8+ T cells, TCF-1 expression levels in these cells positively correlated with in vitro cell expansion in our memory recall assay (\(r = 0.90, \text{P} = 0.006\); Figure 7d). There was no correlation between HIV reservoir size prior to the ATI and time to viral rebound (Figure S7b). However, we observed that TCF-1 expression 12 days after in vitro recall positively correlated with longer time to viral rebound during ATI (\(r = 0.71, \text{P} = 0.03\); Figure 7e). These data suggest that early initiation of ART prevents the loss of TCF-1 expression and enables the maintenance of long-lived HIV-specific CD8+ T cells with effective recall response that can contribute to limiting viral rebound during ATI. These data further suggest that higher numbers of functional memory HIV-specific CD8+ T cells will be needed to impact durable viral control.

Discussion

In this study, we analyzed how initiation of ART in AHI or in CHI affects the quantity and quality of memory HIV-specific CD8+ T cells and their recall response after long-term viral suppression. We compared memory HIV-specific CD8+ T cells after ART in both groups in contrast to previous reports that studied people with...
viremia or spontaneous controllers off ART as comparators. In people who initiated ART during CHI, HIV-specific CD8+ T cells mainly displayed a Ttnm phenotype before ART initiation, and even though ART resulted in decreased expression of PD-1 and increased expression of survival markers on these cells, as previously reported,37 it did not induce their differentiation into long-lasting memory subsets, such as Tscm. This Tscm subset, endowed with stem cell-like capacity, is important as it was shown to be associated with improved prognosis of HIV infection.69 In contrast to people treated in CHI, initiation of ART in AHI induced higher frequencies of Tna, Tscm, and Tcm within HIV-specific CD8+ T cells, similar to the distribution observed with successful preventive vaccines such as the yellow fever vaccine.62,63 This finding is in agreement with lower expression of PD-1 and higher expression of CD127 on memory HIV-specific CD8+ T cells when ART is initiated in AHI. A previous study reported that early treatment in AHI Fiebig Stages I and II promoted the differentiation of HIV-specific CD8+ T cells into a Tem subset.25 Although these data are different from our observations, they can be explained by the fact that this previous study analyzed HIV-specific CD8+ T cell responses shortly after ART initiation whereas ours analyzed them after long-term ART. Indeed, in acute infection or successful live-vaccine immunization, only a minor portion of effector CD8+ T cells survive through the contraction phase after pathogen clearance and differentiate into long-lived memory T cells.63,70 We also showed that memory HIV-specific CD8+ T cells under long-term ART initiated in AHI not only exhibited a long-lived phenotype but also greater cell expansion and cytotoxic effector function after recall

Figure 5. Magnitude of recalled memory CD8+ T cells from people treated in AHI and CHI. (a) Number of HIV- or EBV-specific CD8+ T cells in culture 12 days after peptide stimulation. Thirty-three individuals treated from AHI and 27 individuals treated from CHI were analyzed. (b) Fold expansion of HIV- or EBV-specific CD8+ T cells from day 0 (ex vivo) to day 12 after peptide stimulation. (c) Correlation between the fold expansion of HIV-specific CD8+ T cells and combined ex vivo frequency of Ttnm, Tem, and Ttd in HIV-specific CD8+ T cells of people treated from CHI. (d) Correlation between the fold expansion of HIV-specific CD8+ T cells of people treated from AHI. Differences among groups were analyzed by Kruskal-Wallis test (**P < 0.01; ***P < 0.001; ****P < 0.0001). Correlations were analyzed by Spearman correlation with the Benjamini-Hochberg procedure for multiple comparisons (FDR < 0.1).
than those from people treated during CHI. These data contrast with data generated shortly after ART initiation in AHI, where it was found that HIV-specific CD8+ T cells did not have restored proliferation potency and cytolytic activity compared to those in untreated CHI.25 These contrasting results can also be explained by differences in the timing of analysis after ART initiation. Importantly, the gain of function seen after long-term ART was similar between individuals treated at the different AHI stages from Stage 1 to 5, suggesting that these cells are able to generate functional memory cells during ART independent of their differentiation state during AHI. These data indicate that intervention studies focused on boosting CD8+ T cell responses in early treated individuals from AHI and CHI. Differences among groups were analyzed by Kruskal-Wallis test (*P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001). Correlations were analyzed by Spearman correlation with the Benjamini-Hochberg procedure for multiple comparisons (FDR < 0.1).

Figure 6. Effector function of recalled memory CD8+ T cells from people treated in AHI and CHI. (a) Expression of Granzyme B in ex vivo HIV/EBV-specific CD8+ T cells from people treated from AHI and CHI. (b, c, and f) Expression of T-bet (b), perforin (c), and PD-1 (f) in/on HIV/EBV-specific CD8+ T cells 12 days after stimulation. (d) Cytotoxic capacity of day 13 recalled HIV Nef GK10- or EBV-specific CD8+ T cells cultured with autologous CD4+ T cells at an effector/target ratio of 2. (e) Expression level of PD-1 on day 12 recalled HIV/EBV-specific CD8+ T cells from individuals treated from AHI and CHI. Differences among groups were analyzed by Kruskal-Wallis test (*P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001). Correlations were analyzed by Spearman correlation with the Benjamini-Hochberg procedure for multiple comparisons (FDR < 0.1).
CD8+ T cells from people treated from CHI increased spontaneous controller-like features in these cells including high metabolic plasticity, survival capacity, homeostatic proliferation, and antiviral capacity. Therefore, sustained expression of TCF-1 during the recall response could play an important role in limiting viral rebound after ATI, as evidenced by the correlation between higher expression of TCF-1 and longer time to viral rebound after ATI, although it is not sufficient for post-treatment control since all participants experienced virus rebound within 48 days.

We describe here that memory HIV-specific CD8+ T cells from people treated in AHI are superior in terms of long-lived phenotype, proliferation, and cytotoxic capacity upon recall compared to those from people treated in CHI, yet, they do not have an impact on viral rebound after ART interruption. This was also observed in the non-human primate model where CD8+ T cells reduced the viral set point post-ART interruption but not viral rebound. This might be partially explained by the very low absolute numbers of memory HIV-specific CD8+ T cells in people who initiated ART in AHI, putting them at a disadvantage against a fast-replicating virus even if they do have high proliferative capacity. One explanation for the very low absolute numbers of memory HIV-specific CD8+ T cells in people who initiated ART in AHI is that they have been exposed to a limited amount of antigen before ART initiation also leading to a limited amount of antigen size. Indeed, the number of ex vivo HIV-specific CD8+ T cells in spontaneous controllers is significantly higher (2 to 20-fold) than people treated from CHI, who have even 2 to 7 times higher HIV-specific CD8+ T cells than people treated from AHI. Thus HIV-specific CD8+ T cells need...
might need to be explored. HIV-specific CD8+ T cells in people treated from CHI showed higher absolute cell numbers before and after recall than those treated from AHI, but these cells were still endowed with an exhausted phenotype and function after in vitro recall, providing some explanation for the inability of previous interventions aimed at boosting HIV-specific CD8+ T cells in people treated from CHI to induce post-ART control. HIV remission strategies will likely require a combination of strategies aimed at reversing the remaining T cell dysfunction and improving immune boosting prior to ATI in order to achieve higher quantities of HIV-specific CD8+ T cells with sustainable effector functions, targeting TCF-1 might be a good candidate to evaluate in future studies.

This study has several limitations. It would have been very informative to perform a direct comparison of HIV-specific CD8+ T cells from spontaneous controllers and people treated from AHI as spontaneous controllers have effective HIV-specific CD8+ T cell responses associated with viral control. Unfortunately, we do not have spontaneous controllers in our Thai cohorts. This might be in part due to the fact that HIV CRF01_AE, largely predominant in Thailand, is associated with higher viral set point compared to other HIV-1 subtypes. Although we were unable to make this direct comparison, previous studies have shown that HIV-specific CD8+ T cells from spontaneous controllers expressed higher levels of TCF-1 compared to people treated from CHI and that induction of TCF-1 in HIV-specific CD8+ T cells of people treated from CHI increased spontaneous controller-like features in these cells. These data are in line with our observation that early ART induces preserved HIV-specific CD8+ T cells expressing higher levels of TCF-1, similar to HIV-specific CD8+ T cells in spontaneous controllers. A second limitation of this study was the very strict ART resumption criteria of the ATI studies. Unfortunately, we do not have effective HIV-specific CD8+ T cell responses associated with viral control. Unfortunately, we do not have spontaneous controllers in our Thai cohorts. This might be in part due to the fact that HIV CRF01_AE, largely predominant in Thailand, is associated with higher viral set point compared to other HIV-1 subtypes. Although we were unable to make this direct comparison, previous studies have shown that HIV-specific CD8+ T cells from spontaneous controllers expressed higher levels of TCF-1 compared to people treated from CHI and that induction of TCF-1 in HIV-specific CD8+ T cells of people treated from CHI increased spontaneous controller-like features in these cells.
