Abstract

Persistent hepatitis B viral (HBV) infection results in chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma (HCC). An efficient control of virus infections requires the coordinated actions of both innate and adaptive immune responses. In order to define the role of innate immunity effectors against HBV, viral clearance was studied in a panel of immunodeficient mouse strains by the hydrodynamic injection approach. Our results demonstrate that HBV viral clearance is not changed in IFN-α/b receptor (IFNAR), RIG-I, MDAS, MYD88, NLRP3, ASC, and IL-1R knock-out mice, indicating that these innate immunity effectors are not required for HBV clearance. In contrast, HBV persists in the absence of tumor necrosis factor-alpha (TNF-α) or in mice treated with the soluble TNF receptor blocker, Etanercept. In these mice, there was an increase in PD-1-expressing CD8⁺ T-cells and an increase of serum HBV DNA, HBV core, and surface antigen expression as well as viral replication within the liver. Furthermore, the induction of TNF-α in clearing HBV is dependent on the HBV core, and TNF blockage eliminated HBV core-induced viral clearance effects. Finally, the intra-hepatic leukocytes (IHLs), but not the hepatocytes, are the cell source responsible for TNF-α production induced by HBcAg. These results provide evidences for TNF-α mediated innate immune mechanisms in HBV clearance and explain the mechanism of HBV reactivation during therapy with TNF blockage agents.

Introduction

Hepatitis B virus (HBV) infection causes acute and chronic necroinflammatory hepatitis. In an acute HBV infection, cessation of virus replication and clearance of viral transcripts and antigens from the liver depends on HBV-specific cytotoxic T cells [1,2]. An efficient control of virus infections requires the coordinated actions of both innate and adaptive immune responses [3–6]. Innate immunity induces an antiviral state in infected cells by producing interferons (IFN), and supports the efficient maturation and site recruitment of adaptive immunity through the production of pro-inflammatory cytokines, in particular, tumor necrosis factor-α (TNF-α) [4]. However, in chronic HBV infection, impaired HBV-specific immune responses failed to eliminate infected hepatocytes, resulting in the persistence of HBV.

Experimental viral infection in both chimpanzees and wood-chucks found only limited or even non-activation of innate immunity being demonstrated in acute HBV infection [3,5,7,8]. Nevertheless, a transient though slight activation of IFN-α genes was detected in human hepatocytes infected by HBV in chimeric mice [9], in support of the innate immunity to sense and react to HBV. However, the mechanisms responsible for sensing HBV within the infected cells have not been elucidated yet, and which molecular components of the HBV actually recognized by the pattern recognition receptors (PRR) triggering the antiviral response is still undefined. In addition, a number of recent studies [10–12] have been investigated in suggesting the involvement of NK cells in chronic HBV infection and they could play a role in liver damage during reactivation.

TNF plays long been considered as a key cytokine in HBV eradication. Higher intrahepatic levels of TNF-α have been associated with the increased expression of HLA class I molecules and an enhanced CD8⁺ T cell response to HBV, which leads to the more effective destruction of HBV-infected hepatocytes [13]. In chronic HBV infection, CD8⁺ T cells lack the ability to secrete enough TNF to kill HBV-infected hepatocytes, the so-called “exhausted phenotype.” This is a functional HBV-specific CD8⁺ T cell impairment that is detectable at the peak of the disease when
the majority of HBV-specific CD8+ T cells are activated but have little ability to proliferate and are functionally exhausted, probably due to upregulation of programmed death (PD)-1 [14,15]. Studies have demonstrated that genetic polymorphisms leading to lower constitutive or inducible TNF-α expression are related to an increased risk of progression toward chronic HBV infection [16,17]. Clinically, an anti-TNF regimen also reportedly increased the number of cases of HBV reactivation [18,19]. However, pro-inflammatory cytokines are often undetectable during the early phases of HBV infection, and when present their production is lower during HBV infection [7,20].

In this study, we investigated the role of TNF in viral clearance and persistence in a murine model of HBV persistence [21–23]. The model was used to identify the viral antigen crucial for HBV persistence, and it demonstrated that knocking out HBeAg led to persistence in mice [22], indicating that HBeAg is critical in determining HBV persistence [22–24]. We demonstrate here that a deficiency of TNF-α reduces viral clearance and increases HBV persistence in this mouse model, indicating that TNF is crucial for mounting an effective anti-HBV immune response.

Materials and Methods

Ethics Statement

All animal work have been conducted according to relevant national and international guidelines. Mice were housed in pathogen-free facilities. They were housed in plastic cages at 25°C. All animals were monitored every 6–8 hours for signs of distress and endpoints including hunching, decreased socialization, anorexia, weight loss of 15% or more, the inability to evade handling. All hydrodynamic injections were performed under anesthesia, and all efforts were made to minimize suffering. For sacrifice, animals were humanely euthanized via CO2 asphyxiation followed by cervical dislocation and were considered non-survivors.

Animal

BALB/c and C57BL/6 mice were obtained from National Laboratory Animal Center, Taiwan. Interferon-α receptor (IFN-αR) knockout mice were kindly provided by Dr. Guann-Yi Yu (National Health Research Institute, Taiwan). TNF-α knockout mice were obtained from Dr. Nien-Jung Chen (National Yang-Ming University, Taiwan). The ASC and NALP-3 knockout mice were obtained from Dr. Jenny Ting (University of North Carolina, NC). The RIG-I and MDA-5 knockout mice were obtained from Dr. Akira (Osaka University, Japan). The IL-1 receptor (IL-1R) knockout mice were obtained from Jackson laboratory (Bar Harbor, ME). All animals were maintained under SPF condition. Mice at 6–8 weeks of age were used. All animal experiments were performed according to the regulations approved by the Animal Ethical Committee of National Taiwan University.

Hydrodynamic injection (HDI)

C57BL/6 mice and BALB/c (male, 6–7 weeks old) were anesthetized with ketamine and xylazine. Ten micromgs of HBV plasmid DNA in a volume equivalent to 8% of the mouse body weight was injected via a tail vein in 5 s. Plasmid DNA was purified by using EndoFree Maxi plasmid kit (Qiagen, Hilden, Germany). For the transcomplementation assay, 10 μg of pAAV/core-null was combined with 10 μg of pFLAG-CMV2/HBe or pFLAG-CMV2/HBe132A mutant [23]. Serum HBsAg were assayed as indicated time points to monitor the state of HBV persistence.

Preparation of intrahepatic leukocytes

Livers were perfused with 0.2% bovine serum albumin (BSA)/phosphate-buffered saline (PBS), passed through a nylon mesh, and digested in collagenase-I and DNase-I (Sigma-Aldrich, St. Louis, MO) for 30 min. Hepatocytes were removed by centrifugation for 5 min at 100 g and washed with 0.2% BSA/PBS twice at 100 g for 3 min. The supernatant containing intrahepatic leukocytes (IHLs) was pelleted by 300 g centrifugation at 4°C for 10 min. Cell pellets were resuspended in 40% HBSS and layered in upper 70% percoll (GE Healthcare, Piscataway, NJ) gently. Next, cells were centrifuged at 1200 g for 20 min at 25°C. IHLs were collected, washed with 15 mL HBSS, and centrifuged at 300 g for 10 minutes at 4°C. Cell pellets were collected for further applications.

Detection of the HBV antigen, antibody (Ab), and DNA

Serum levels of HBsAg, HBeAg, anti-HBe, and anti-HBs Abs were determined using the AXSYM system kit (Abbott Diagnostika, Wiesbaden, Germany). The cutoff value for determining HBsAg positivity was a signal-to-noise (S/N) ratio of ≥2 and a signal-to-cutoff (S/CO) ratio of ≥1. To detect serum HBV DNA, each serum sample was pretreated with 25 units of DNase I (Roche Diagnostics, Mannheim, Germany) at 37°C overnight, and total DNA was extracted and HBV DNA was detected by real-time PCR [21,22]. Serum alanine transferase (ALT) was measured on a TBA-200FR automated clinical chemistry analyzer (Toshiba, Tokyo, Japan) [21,22].

Flow cytometry

For flow cytometry, allophycocyanin (APC)-conjugated anti-mouse CD3 (BD Biosciences, Palo Alto, CA), phycoerythrin (PE)-conjugated anti-mouse PD-1, fluorescein isothiocyanate (FITC)-conjugated CD127, and PE-Cy5.5-conjugated anti-mouse CD4 or CD8 (BD Biosciences Pharmingen) monoclonal (m) Abs were used for flow cytometry. For the flow cytometric analysis, 10⁶ cells were labeled in a fluorescence-activated cell sorter (FACS) buffer (PBS/2% FCS/0.1% sodium azide), fixed in 1% paraformaldehyde (Sigma-Aldrich, St. Louis, MO), and analyzed on a FACS Calibur using CellQuest software (Becton Dickinson, Mountain View, CA).

Liver tissue preparation and immunoblotting

Mice were anesthetized and then subjected to intracardiac perfusion with PBS prior to liver tissue collection. For Southern blotting, 50 mg of mouse liver tissue was lysed in 700 μl of DNA extraction buffer (10 mM Tris-HCl, pH 8.0, 100 mM NaCl, 1 mM EDTA, 0.5% SDS, 0.5 mg of proteinase K) at 37°C overnight. Mouse DNA was digested with 40 units of HindIII (NEB) at 37°C overnight before gel electrophoresis. RNA was extracted by TRIzol (Invitrogen, Carlsbad, CA) according to manufacturer instructions. Purified 10 μg RNA was used for Northern blotting. Both Southern and Northern blot analyses were performed using a digoxigenin (DIG)-labeled probe system. DIG-HBx and DIG-mouse glyceraldehyde-3-phosphate dehydrogenase (DIG-mGAPDH) probes were used to analyze HBV DNA/RNA and mouse GAPDH mRNA, respectively.

For Western blotting of HBeAg, fifty micromgrams of protein lysates were separated by 15% SDS-PAGE and then transferred to a PVDF membrane. The membrane was blotted by using rabbit anti-HBeAg (LTK BioLaboratories), mouse anti-β-actin (Sigma-Aldrich, St. Louis, MO), and horseradish peroxidase (HRP)-conjugated goat anti-rabbit (Promega, Madison, WI). The
membrane was developed in an ECL system (Amersham Biosciences, Arlington Heights, IL).

**Immunohistochemistry**

The perfused liver samples were embedded in optimal cutting temperature compound (OCT). Intrahepatic HBeAg or HBsAg were detected by immunohistochemical staining with rabbit anti-HBe (Dako, Glostrup, Denmark) or anti-HBs antibodies (Biomedica, Foster City, CA) and Envision System, HRP (DAB) (Dako, Glostrup, Denmark). Hematoxylin was used to stain liver section nuclei.

**Interferon (IFN-γ) enzyme-linked immunospot (ELISpot) assay**

At the indicated time points after hydrodynamic injection, liver mononuclear cells were cultured and assayed for the frequency of antigen-specific IFN-γ-secreting cells using an ELISpot kit (BD Biosciences, San Jose, CA). Briefly, 1×10^5 live mononuclear cells were co-cultured with 1 μg/ml of rHBeAg (ID Labs, London, Canada) in 200 μl RPMI 1640 supplemented with 10% fetal calf serum (FCS). Cell suspensions were incubated for 20 h. Spot-forming cells were revealed with a biotin-conjugated antibody, streptavidin-horseradish peroxidase (HRP), and AEC substrates (Sigma-Aldrich), and were analyzed using the ImmunoSpot series 5 analyzer (Cellular Technology Limited, Cleveland, OH).

**Preparation of recombinant FLAG-tagged HBc protein**

Human 293 cells were transfected with FLAG-tagged WT HBc or HBcY132A-expressing vectors for 48 hours by Effectene according to the manufacturer’s instruction (Qiagen, Venlo, Netherlands). Cell lysates were harvested and subjected into immuno-precipitation by anti-FLAG sepharose (Sigma-Aldrich, St. Louis, MO) at 4°C with gentle rotation for 2 hours. After extensive washing by lysis buffer, the FLAG-HBc or FLAG-Y132A were eluted by 3xFLAG peptide (Sigma-Aldrich, St. Louis, MO) at 4°C for 30 min.

**Co-culture assay**

C57BL/6 mice were injected with pAAV/HBV1.2 or pAAV/core-null plasmids hydrodynamically. The hepatocytes were isolated at 3 days postinjection. The intrahepatic leukocytes were prepared from naïve C57BL/6 mice and cocultured with hepatocytes for 24 hours. Cell-culture supernatants were collected and TNF-α levels were detected by ELISA kit according to manufacturer’s instructions (eBioscience, San Diego, CA).

**Results**

The TNF-α rather than IFN-mediated pathway is critical in HBV clearance

Although the chronicity of HBV infection is the result of impaired HBV-specific immune responses that cannot efficiently eliminate or cure infected hepatocytes, however, this likely a result from the failure of immune responses at the first exposure to HBV. Therefore, we tested a panel of KO mice with specific deficiency in the innate immune sensors or effectors for their capability in clearing HBV after hydrodynamic injection (HDI) of a replication competent HBV DNA. This approach generated HBV persistence in C57BL/6 mice but not in BALB/c mice [21–23]. To identify the immune effectors of innate immunity that eliminate HBV from the liver, we monitored the persistence of HBsAg in a panel of gene knockout mice, including Nod-like receptor family protein 3 (NLRP3), apoptosis-associated speck-like protein containing a caspase recruitment domain (ASC), myeloid differentiation primary response gene 88 (MYD88), IL-1 receptor (IL-1R), IFN-α/β receptor (IFNAR), and TNF-α. The results (Figure 1) demonstrate that HBV viral clearance is not significantly different from wild type C57BL/6 mice in IFNAR, RIG-I, MDA5, MYD88, NLRP3, ASC, and IL-1R knock-out mice, indicating that these effectors are not required for HBV clearance. In contrast, only TNF-α knockout mice showed a markedly higher HBV-positive rate and prolonged HBV persistence compared to other strains, suggesting that TNF-α is an important effector cytokine that is required to clear HBV from the liver. The results (Figure 1 and Figure S1) demonstrated that the HBV persistence rate and serum HBsAg levels was similar between IFNAR knock-out mice and wild type C57BL/6 mice, indicating that IFN-mediated pathways are not essential for clearing HBV in this animal model. We further investigated the roles of innate cytokines TNF-α during HBV infection (Figure 2). There were very little or no TNF-α production could be detected in the liver in mice receiving pAAV/HBV1.2 plasmid (Figure S2). However, in contrast to IFNR knock-out mice, significantly impaired HBV clearance and enhanced HBV persistence was observed when TNF-α was neutralized with the soluble TNF receptor Etanercept in HBV-cleared mouse strain BALB/c, suggesting that TNF-α is required for HBV clearance (Figure 2A). Similarly, the HBV persistence rate and serum HBsAg levels was significantly enhanced in TNF-α knockout mice compared to wild-type C57BL/6 mice (Figure 2B). Taken together, these results indicate that TNF rather than the IFN-mediated pathway is required for HBV clearance, and TNF blockage enhances HBV persistence in vivo.
Recent studies in viral infection indicate that the interaction between the PD-1 on lymphocytes and its ligands plays a critical role in T-cell exhaustion by inducing T-cell inactivation and displayed lower levels of interleukin (IL)-7 receptor CD127, which had previously been described in association with the exhausted phenotype [26,27]. The results in Figure 3A demonstrate that PD-1 is more highly expressed by intrahepatic CD8+ cells in BALB/c mice hydrodynamically injected with HBV constructs and treated with Etanercept. Also, among intrahepatic PD-1-expressing CD8+ populations, CD127 expression was significantly reduced in mice treated with Etanercept. Interestingly, there are no such differences noted for the spleen. Our results indicate that there are differences noted for the spleen. Our results indicate that there are populations, CD127 expression was significantly reduced in mice hydrodynamically transfected with the pAAV/HBV1.2 plasmid. Differences in percentages (left) and serum levels (right) of HBsAg-positive mice were quantified. *p<0.05.

**Figure 3. Liver-infiltrating CD8+ lymphocytes in Etanercept-treated and TNF-α knockout mice displayed the PD-1hiCD127low-exhausted phenotype and impaired HBcAg-specific IFN-γ T cell response.** (A) BALB/c mice were hydrodynamically injected with WT pAAV/HBV1.2 plasmids in the presence or absence of Etanercept treatment. Eight weeks after injection, intrahepatic lymphocytes from HBsAg-positive mice were isolated and the PD-1, CD127 expressions of liver-infiltrating lymphocytes and splenocytes were analyzed by flow cytometry. (B) Wild type C57BL/6 and TNF-α knockout mice were hydrodynamically injected with WT pAAV/HBV1.2 plasmids. Differences in percentages (left) and serum levels (right) of HBsAg-positive mice were quantified. *p<0.05. The data are representative of at least six independent experiments.

doi:10.1371/journal.pone.0103008.g003

**Figure 2. Delayed HBsAg clearance in mice with TNF deficiency.** (A) BALB/c mice were treated with the recombinant soluble TNF-α receptor, Etanercept, on the day before hydrodynamic injection of the pAAV/HBV1.2 plasmid. Etanercept treatment was performed twice a week over the detection period. HBsAg levels in mice serum were determined by an ELISA. HBsAg-positivity was defined as an S/N ratio greater than 2. Differences in percentages (left) and serum levels (right) of HBsAg-positive mice with or without Etanercept were quantified. (B) Wild type C57BL/6 or TNF-α knockout mice were hydrodynamically transfected with the pAAV/HBV1.2 plasmid. Differences in percentages (left) and serum levels (right) of HBsAg-positive mice were quantified. *p<0.05.

doi:10.1371/journal.pone.0103008.g002

TNF-α deficiency leads to cytotoxic T lymphocyte dysfunction against HBV

We then asked whether TNF-α deficiency is associated with an impaired T cell response to HBV in mice with HBV persistence. Recent studies in viral infection indicate that the interaction between the PD-1 on lymphocytes and its ligands plays a critical role in T-cell exhaustion by inducing T-cell inactivation and displayed lower levels of interleukin (IL)-7 receptor CD127, which had previously been described in association with the exhausted phenotype [26,27]. The results in Figure 3A demonstrate that PD-1 is more highly expressed by intrahepatic CD8+ cells in BALB/c mice hydrodynamically injected with HBV constructs and treated with Etanercept. Also, among intrahepatic PD-1-expressing CD8+ populations, CD127 expression was significantly reduced in mice treated with Etanercept. Interestingly, there are no such differences noted for the spleen. Our results indicate that there are significantly increased liver-infiltrating PD-1hiCD127low-exhausted CD8+ lymphocytes in Etanercept-treated HBV infected mice. Similar results were observed in TNF-α knockout mice (Figure 3B). Both results indicate that liver-infiltrating CD8+ lymphocytes in response to HBV in mice with TNF-α deficiency displayed the PD-1hiCD127low-exhausted phenotype.

We then evaluated T cell response to HBV in mice with HBV persistence after an infection. The HBV core-specific IFN-γ-T cell response in mice hydrodynamically injected with HBV DNA in the presence and absence of TNF-α were analyzed by an ELISpot assay. Results in Figure 3C demonstrate that the frequency of HBcAg-specific IFN-γ-secreting cells was significantly reduced in TNF-α knockout C57BL/6 mice or Etanercept-treated BALB/c mice. Taken together, our results indicate TNF-α is correlated with the anti-HBV T cell response in vivo.

**Figure 4. TNF blockage-induced elevation of serum HBV viral loads and maintained HBV viral gene expression within the liver**

Our results indicate that TNF-α deficiency is associated with the impaired T-cell response to HBV. We then investigated the effects of TNF blockage on HBV viral load and viral replication. The results (Figure 4A) show the control group BALB/c mice were almost cleared of HBV viral loads in the initial five weeks after hydrodynamic transfection of HBV. In contrast, persistently elevated HBV viral loads in serum were observed in BALB/c mice treated with Etanercept. TNF-α knockout mice showed similar results with persistently elevated HBV viral loads in serum compared to the wild type C57BL/6 mice. We then analyzed the HBV transcripts in the livers of mice transfected with HBV by Northern blotting after hydrodynamic injection (Figure 4B). The HBV transcripts remained detectable in the liver of TNF-α knockout and Etanercept-treated BALB/c mice up to Day 42 post-transfection. In contrast, the HBV transcripts were almost undetectable in wild type C57BL/6 mice on Day 42 post-
transfection. Similarly, the results from an immunohistochemistry analysis also revealed that the staining for HBcAg and HBsAg remained detectable in the livers of TNF-α knockout and Etanercept-treated BALB/c mice on Day 42 post-transfection. However, HBcAg and HBsAg staining was much lower in wild type C57BL/6 mice on Day 42 post-transfection, which is correlated with serum viral loads and HBV transcripts in the liver (Figure 4C). Moreover, administration of TNF-α reduced serum HBcAg levels in mice hydrodynamically transfected with plasmid containing capsid assembly-defect mutant pAAV/Y132A or capsid deficiency pAAV/core-null mutant (Figure S3). These results indicate that TNF-α is responsible for HBcAg clearance and TNF-α deficiency impacts viral clearance and increases HBV viral load and viral replication in vivo.

Lack of TNF-α eliminates HBcAg-induced HBsAg clearance

Previous studies showed that the immune response triggered in mice by HBcAg during exposure to HBV is important in determining HBV clearance [22–24]. We then test whether HBcAg can induce TNF-α production in vivo. C57BL/6 mice were hydrodynamically injected with purified recombinant HBcAg. The results indicate the functional HBcAg/capsid could induce TNF-α production (Figure S4). To further define the role of TNF-α in the HBV core-induced HBV clearance in this mouse animal model, BALB/c mice were hydrodynamically injected with pAAV/core-null plasmid containing a core-deleted HBV construct [22] to induce persistent elevation of HBsAg in mice serum on Day-7, and then the mice were injected with purified recombinant HBV core protein on Day 0 in the presence or absence of Etanercept. Serum levels of HBcAg significantly decreased after injection with recombinant HBV core protein (Figure 5A). However, in mice treated with Etanercept, the effect of HBV core-induced clearance of HBsAg was eliminated. In addition, the introduction of a plasmid containing capsid assembly-defect mutant form of HBcY132A [25] failed to reduce the serum level of HBcAg (Figure 5B). However, co-injection of pAAV/core-null HBV plasmids with a plasmid encoding HBcAg efficiently decreased HBsAg levels. In contrast, when administered with Etanercept to neutralize TNF-α, the effect of HBV core-induced HBsAg clearance was abrogated. Similarly, the effect of HBV core-induced HBcAg clearance was also diminished in TNF-α knockout mice having elevated levels of HBsAg after hydrodynamic transfection with HBV (Figure 5C). To further confirm the T cell dysfunction in the pAAV/core-null transffected mice, the intrahepatic lymphocytes from mice receiving pAAV/HBV1.2 or pAAV/core-null were analyzed. Our results indicate there are significantly increased liver-infiltrating PD-1<sup>hi</sup>CD127<sup>low</sup>-exhausted CD8<sup>T</sup> lymphocytes in mice infected with pAAV/core-null mutant (Figure 5D). Furthermore, the frequency of HBcAg-specific IFN-γ-secreting cells was significantly reduced in mice infected with pAAV/core-null mutant (Figure 5E). Taken together, these results indicate that TNF-α mediates the effects of HBV core-induced HBV clearance in this mouse animal model.

Intra-hepatic leukocytes, in contrasting with HBcAg Containing hepatocytes, were responsible for HBcAg-induced TNF-α production

Our results indicate that TNF-α is required for an effective T-cell response to HBV and the immune response triggered in mice by HBcAg during exposure to HBV is critical in HBV clearance. We then investigated the cellular source of TNF-α, which is responsible for HBV core-induced HBV clearance. We used an ex vivo system with isolation of intra-hepatic leukocytes (IHL) from mice receiving pAAV/HBV1.2 or pAAV/core-null plasmids and co-cultured with primary syngeneic hepatocytes. The results (Figure 6) demonstrate that the IHLs, but not the hepatocytes, are the cell source responsible for TNF-α production induced by HBcAg in this mouse animal model. There was no TNF-α production when adding the IHLs isolated from mice receiving pAAV/core-null plasmids or from TNF-α deficient mice in this ex vivo co-culture. Taken together, our results indicate that the production of HBcAg-induced TNF-α by IHLs is required for an effective T cell response to HBV.

Discussion

In this study, we demonstrate that a TNF blockade using a soluble TNF receptor, Etanercept, or mice with a TNF-α gene deficiency all suffer delayed viral clearance and enhanced HBV persistence in this mouse model. Previous studies revealed that several innate inflammatory cytokines had potential modulating effects on HBV gene expression, including IFN-α, IL-1α, IL-6 [28], and TNF-α [29–31]. However, due to experimental limitations, only limited or even non-activation of innate immunity could be demonstrated in acute HBV infection. The role of innate immunity on HBV clearance is still uncertain. To address the role...
However, only CD8+ studied previously in a panel of immunodeficient mouse strains the immune effectors required in HBV viral clearance has been to study their effects on HBV persistence in this mouse model. Our were not addressed [6]. To clarify the effects of innate effectors on roles of TNF and other innate effectors in HBV viral clearance cellular effectors mediating HBV clearance from the liver, and the innate cytokine TNF-α increases HBV persistence in this mouse model, indicating that the innate pathways (RIG-I, NOD, inflammasome) to be dispensable for HBV clearance. In this study, after examining the gene-specific KO panel of knock-out mice by a single hydrodynamic injection of HBV DNA. In this study, after examining the gene-specific KO results indicate that HBV triggers innate immunity via a TNF-dependent process to induce an effective T cell response to HBV. The results are consistent with findings in previous study by Yang et. al. concluding that TNF is required to eliminate both the HBV DNA and HBcAg from the liver [6]. Although IFN-α/β receptor deficiency mice seemed to be impaired in their ability to eliminate the transcriptional template from the liver in that study, their ability to clear HBcAg remained intact [6], suggesting that the IFN pathway was not sufficient to clear the HBV and therefore might play a supporting role in HBV clearance. This is consistent with the results of other studies in humans and animal models that type I IFNs are often undetectable during the early phases of HBV infection, and when present their production is decreased [7,20]. Accumulating evidence suggests that HBV infection induces host immunotolerance [21,32]. Persistent HBV infection sustains the suppression of antiviral immunity, and high HBV titers or particle loads can inhibit innate immune response activation, particularly innate PRRs and their downstream signals in hepatocytes [3,33,34]. Nevertheless, in support of the innate immunity to sense and react to HBV, in this study, our results indicate that HBV triggers innate immunity via a TNF-dependent process to induce an effective T cell response to HBV.

As an innate cytokine, the induction of TNF-α not only triggers an inflammatory response but also activates adaptive immunity against HBV and may regulate the balance of virus replication and clearance within the liver. In this study, mice with TNF-α deficiency demonstrated an increase in exhausted-phenotype of CD8+ T cells and impaired T cell response to HBV. In addition,
TNF blockade significantly increased the serum HBV DNA, the expression of HBV core, and HBV viral replication within the liver, indicating that TNF-α is crucial for mounting an effective anti-HBV immune response. TNF has direct anti-viral effect on HBV [31,35]. In addition, TNF alpha is the key mediator that drives local intrahepatic proliferation of T cells (iMATEs: ‘intrahepatic myeloid-cell aggregates for T cell population expansion’) [36], and the effect of TNF in HBV clearance in this mouse model could be due to such iMATEs. Therefore, the effects of HBV clearance by TNF in this mouse system may not exclusively due to the direct anti-HBV effect, and it is likely due to triggering the innate immunity by HBeAg/capsid to induce T cell response to HBV, and both cytotoxic and noncytotoxic mechanisms are involved [35,37,38].

Our results also demonstrate that the HBV core is critical for inducing TNF-α to clear HBV and for TNF blockade to eliminate HBV core-induced viral clearance effects in mice. It implies that the HBV core induces TNF-α through an innate immune sensor to trigger a host anti-HBV immune response that leads to viral clearance. However, the mechanisms responsible for sensing HBV within the infected cells, and which molecular components of the HBV DNA, RNA or viral proteins are actually recognized by the PRR triggering the antiviral response is still undefined. In this study, our results demonstrate that the HBV core is critical for inducing TNF-α and enhancing the clearance of HBV. In addition, TNF blockade abolished the HBV core-induced viral clearance effects in mice, suggesting that host innate immunity senses the HBV core through the innate immune sensor and induces TNF-α. Taken together, these results indicate that blockade of TNF-α inhibits the effects of HBV core-induced HBV clearance in this mouse animal model. In addition, the introduction of a capsid assembly-defect mutant form of HBcY132A [25] failed to trigger the HBV core-induced viral clearance effects, suggesting the assembled viral capsid is critical for sensing HBV within the infected cells through the innate immune sensor. The innate sensors that recognize and bind to the HBV core or capsid still require further investigation.

Anti-TNF-α is effective for the treatment of rheumatoid arthritis, seconger negative spondyloarthropathy, and inflammatory bowel disease. However, there are limited reports on its effect on HBV persistence and reactivation in chronic HBV infection during anti-TNF therapy [18,19]. We demonstrate in this study that TNF blockade reduces viral clearance, induces elevated serum HBV viral loads, enhances HBV viral gene expression, and increases HBV persistence in a mouse model. Therefore, treatment with TNF blockade agents may reduce the clearance of HBV and enhance HBV replication and viral persistence. In conclusion, TNF-α deficiency significantly increased serum HBV DNA and viral replication within the liver, indicating that TNF-α is crucial for mounting an effective anti-HBV immune response. Thus, our results provide evidence that therapy with TNF blockade agents may impair the T cell response and enhance viral replication during chronic HBV infection.

**Supporting Information**

**Figure S1** No significant difference in HBsAg clearance between wildtype C57BL/6 and IFNAR knockout mice.

**Figure S2** Hepatic TNF-α expression was not induced in mice receiving hydrodynamical injection with pAAV/HBV1.2 plasmid. C57BL/6 mice were hydrodynamically injected with pAAV vector, pAAV/HBV1.2 or pAAV/core-null plasmid. The liver samples were collected at the indicated time points. Total RNA and protein were extracted, and the TNF-α level in mice liver was analyzed by quantitative RT-PCR (A) and ELISA kit (B).

**Figure S3** Administration of TNF-α suppressed serum levels of HBsAg in mice with HBV persistence. C57BL/6 mice were in vivo transfected with plasmid pAAV/HBVY132A (A) or pAAV/core-null (B) by hydrodynamic injection. The mice received intraperitoneal injection of 200,000 U of recombinant TNF-α every other day. The serum samples were collected at the indicated time points, and the titers of HBsAg were measured by immunoassay [IU/ml].

**Figure S4** Hepatitis B viral core capsid triggered TNF-α production in vivo. HEK293 cells were transfected with FLAG tagged HBeAg-expressing plasmid. The FLAG-HBc was purified from cell lysates by anti-FLAG affinity gel. The FLAG-HBc absorption was performed by anti-HBc antibody precipitation [rHBc(−)] and analyzed by SDS-PAGE analysis. To verify the formation of FLAG-HBc capsid, the purified FLAG-HBc was subjected into native agarose gel electrophoresis followed by immunoblotting with anti-FLAG antibody. C57BL/6 mice were divided into four groups and administrated with the indicated reagents, including PBS solution, 20 μg recombinant FLAG-HBc (A) or FLAG-HBeY132A (B), preparation after anti-HBc antibody absorption [rHBc(−)], or 5 μg poly I:C by hydrodynamic injection, respectively. Serum samples were collected at the indicated time points. The levels of TNF-α was measured by ELISA kits.

**Acknowledgments**

We thank Dr. Jenny Ting (University of North Carolina, NC) and Dr. Akira (Osaka University, Japan) for kindly provided the knockout mice. We also thank the Department of Medical Research and core laboratory of National Taiwan University Hospital for facility support.
