We show that the dynamical Casimir effect in an optomechanical system can be achieved under incoherent mechanical pumping. We adopt a fully quantum-mechanical approach for both the cavity field and the oscillating mirror. The dynamics is then evaluated using a recently-developed master equation approach in the dressed picture, including both zero and finite temperature photonic reservoirs. This analysis shows that the dynamical Casimir effect can be observed even when the mean value of the mechanical displacement is zero. This opens up new possibilities for the experimental observation of this effect. We also calculate cavity emission spectra both in the resonant and the dispersive regimes, providing useful information on the emission process.

I. INTRODUCTION

One of the most surprising predictions of quantum field theory is that the vacuum of space is not empty, but it has plenty of short-lived virtual particles. Real observable particles can be produced out from the quantum vacuum providing energy to its fluctuations [1–5]. Vacuum fluctuations have measurable consequences, such as the Lamb shift of atomic spectra [6] and the modification of the electron magnetic moment [7], even when real particles are not generated. For years, scientists and researchers wondered if it was possible to achieve a direct observation of the virtual particles composing the quantum vacuum or, at least, if their conversion into real particles was achievable. The answer arrived only forty years ago, when Moore [2] suggested that a variable length cavity undergoing relativistic motion could be able to convert virtual photons into real ones. This phenomenon was later called the dynamical Casimir effect (DCE). Fulling and Davis [3] demonstrated that photons can be also generated by a single mirror subjected to a non-uniform acceleration. The DCE effect was first studied in the context of electromagnetic resonators with oscillating walls or containing a dielectric medium with time-modulated internal properties [8–11].

This concept was later generalized for other bosonic fields, e.g., cold atoms [12], phononic excitation of ion chains [13], optomechanical systems [14], and Bose-Einstein condensates [15, 16]. Moreover, it has been shown that photon pairs can be emitted out from the vacuum by switching or modulating the light-matter coupling strength in cavity QED systems [17–21]. In 1996, it was shown [22] that a significant number of photons can be produced also in realistic high-$Q$ cavities with moderate mirror speeds, taking advantage of resonance-enhancement effects. Unfortunately, the resonance conditions require the mechanical frequency $\omega_m$ to be, at least, twice the first cavity mode frequency $\omega_c$, i.e., $\omega_m \simeq 2n\omega_c$, where $n \in \mathbb{N}$. This is a significant obstacle for experimental observations.

Additional theoretical studies on the DCE have been presented in, e.g., [3, 23–29]. Some of these proposals suggested to use alternative experimental setups where the boundary conditions of the electromagnetic field are modulated by an effective motion [17, 30–35]. Specifically, the link between the DCE and superconducting circuits was theoretically proposed for the first time in Ref. [36] and elaborated later on in Ref. [37]. In this context, the experimental results did not take long to arrive. In fact, the emission of photon pairs was observed in a coplanar transmission line terminated by a SQUID whose inductance was modulated at high frequency [38]. The experimental realization of the DCE gives further evidence of the quantum nature of the dynamical Casimir radiation, indicating that the produced radiation can be strictly nonclassical with a measurable amount of intermode entanglement [39]. Reference [40] reviews vacuum amplification phenomena with superconducting circuits. Photon pairs were also produced by rapidly modulating the refractive index of a Josephson metamaterial embedded in a microwave cavity [41]. However, these do not demonstrate the conversion of mechanical energy into photon pairs, so these experiments can also be regarded as quantum simulator.

Most theoretical studies on the DCE are based on a quantum mechanical description of the electromagnetic field and a classical description of the time-dependent boundary conditions. Recently, the DCE in cavity optomechanical systems has been investigated without linearising the dynamics and describing quantum-mechanically both the cavity field and the vibrating mirror [42–44]. Within this full quantum description, it turns out that the resonant generation of photons from the vacuum is determined by several ladders of mirror-field vacuum Rabi-like splittings. The resulting general resonance condition for the photon pairs production is $k\omega_m \simeq 2(n+\gamma)\omega_c$, $(k,n \in \mathbb{N})$. This corresponds to processes where $k$ phonons in the mechanical oscillator are converted into $n$ cavity photon pairs. This generalized resonance condition enables a resonant production of pho-
tons out from the vacuum even for mechanical frequencies lower than the lowest cavity-mode frequency, thus removing one of the major obstacles for the experimental observation of this effect.

In addition, it has been shown that a vibrating mirror prepared in an excited state (mechanical Fock state) can spontaneously emit photons like a quantum emitter. In this case, however, a photon pair is emitted instead of a single photon.

Moreover, it has been recently demonstrated that virtual Casimir photon pairs can be used to enable a coherent motional coupling between two spatially separated moveable mirrors, allowing this kind of optomechanical system to also operate as a mechanical parametric down-converter even at very weak excitations [45]. Entangled photons from the vacuum can be also generated by using microwave circuit-acoustic resonators [46].

The approach considered in Ref. [44] also extends the investigation of the DCE to the optomechanical ultrastrong-coupling (USC) regime, where the optomechanical coupling rate is comparable to the mechanical frequency [47–53]. This regime, which attracted great interest also in cavity QED giving rise to a great variety of novel quantum effects [20, 54–56], turned out to be an essential feature for the realization of new interesting proposals in quantum optomechanics [57–59].

Temperature effects also play an important role for the generation of photons in a resonantly vibrating cavity [60–63]. Specifically, it turns out that the thermal contributions in these systems under the influence of time-dependent boundary conditions leads to a strong enhancement of photon pairs production at finite temperatures.

Encouraged by the results obtained in Ref. [44], here we investigate the dynamics of an optomechanical system in a fully quantum-mechanical framework, under incoherent mechanical excitation, using a master equation approach. This allows to demonstrate that a remarkable Casimir photon pairs flux is produced even considering a thermal-like noise source coupled only to the mechanical degree of freedom. For ultra-strongly coupled hybrid quantum systems [64–68], the standard quantum-optical master equation breaks down, and a dressed master equation approach is needed [54, 69, 70]. Furthermore, if the energy level spectrum displays a quasi-harmonic behaviour [49], like in optomechanical systems, a new dressed master equation [71, 72] not involving the usual secular approximation is required.

The outline of this article is as follows: in Sec. II we briefly introduce the theoretical model and the dressed master equation approach for quasi-harmonic hybrid systems. Section III is devoted to the presentation of the energy-level structure, focusing the attention on the avoided level crossings giving rise to the DCE. In Sec. IV we apply the generalized master equation [72] to calculate the dynamics of the system at finite temperatures and, using the quantum regression theorem, we present the power spectra in the weak and strong light-matter coupling regimes. We conclude in Sec. V.

II. MODEL

We study a standard optomechanical system constituted by an optical cavity with a movable end mirror [see Fig. 1]. Moreover, we consider a radiation pressure coupling between the first cavity mode and a single mechanical mode.

The system Hamiltonian can be written as:

$$\hat{H}_S = \hat{H}_0 + \hat{V}_{om} + \hat{V}_{DCE},$$

where ($\hbar = 1$ throughout the paper)

$$\hat{H}_0 = \omega_c \hat{a}^\dagger \hat{a} + \omega_m \hat{b}^\dagger \hat{b}$$

is the uncoupled Hamiltonian, and

$$\hat{V}_{om} = g \hat{a}^\dagger \hat{a} (\hat{b}^\dagger + \hat{b}^\dagger)$$

is the standard optomechanical interaction Hamiltonian. Here, $\omega_c$ is the resonator frequency, $\omega_m$ is the mechanical frequency, $g$ is the optomechanical coupling strength and $\hat{a}$ ($\hat{a}^\dagger$, $\hat{b}^\dagger$, $\hat{b}$) are, respectively, the bosonic creation (annihilation) operators for the cavity and mechanical modes. Finally, the perturbation term determining the DCE is

$$\hat{V}_{DCE} = \frac{g}{2} (\hat{a}^2 + \hat{a}^\dagger 2)(\hat{b} + \hat{b}^\dagger).$$

Since in this case the $\hat{V}_{DCE}$ term only couples bare states having energy differences $2\omega_c \pm \omega_m$ much larger then the coupling strength $g$, it can be neglected. Also, this interaction term is often neglected when describing most of the experimental optomechanical systems, where the mechanical frequency is much smaller than the cavity frequency.

The resulting total Hamiltonian conserves the photon number and can be diagonalized separately in each n-photon subspace. The general quantum state of such system is:

$$|n,k_m\rangle = |n\rangle \otimes \hat{D}(n\eta)|k\rangle,$$
where the integer $k_n$ represents the vibrational excitations of the mechanical resonator in the corresponding $n$-photon subspace, and

$$|k_n\rangle = \hat{D}(n\eta)|k\rangle$$  \hspace{1cm} (6)

represents the displaced mechanical Fock state determined by the displacement operator $\hat{D}(n\eta)$, where

$$\eta \equiv g/\omega_m$$  \hspace{1cm} (7)

is the normalized coupling strength. In the manifold with $n = 0$, the states $|0,k_0\rangle$, simply labeled $|0,k\rangle$, are the eigenstates of the harmonic oscillator decoupled from the cavity. When considering ultrahigh-frequency mechanical oscillators with resonance frequencies

$$\omega_m \simeq \omega_c,$$  \hspace{1cm} (8)

the $\tilde{V}_{\text{DCE}}$ term cannot be neglected. In this case, the photon number is no longer conserved and there is no analytical solution for the system eigenstates. Moreover, it turns out that the introduction of the $\tilde{V}_{\text{DCE}}$ term increases the degree of anharmonicity, slightly modifying the levels structure but still preserving the quasi-harmonic behaviour. Consequently, the system dynamics has to be described using a generalized master equation developed without performing the usual secular approximation. A suitable approach, able to describe the time evolution of the density matrix operator $\hat{\rho}$ for any hybrid quantum system in the presence of dissipations and thermal-like noise, has been presented in Ref. [72].

In the interaction picture, this master equation can be written as

$$\dot{\hat{\rho}} = \kappa \mathcal{L}[\hat{A}]\hat{\rho} + \gamma \mathcal{L}[\hat{B}]\hat{\rho},$$  \hspace{1cm} (9)

with $\kappa$ and $\gamma$, respectively, the cavity and mirror damping rates. The dressed photon and phonon lowering operators $\hat{O} = \hat{A}, \hat{B}$ are defined in terms of their corresponding bare operators $\hat{a} = \hat{\alpha}, \hat{b}$ by the relation [20, 54]

$$\hat{O}(\omega) = \sum_{\epsilon - \epsilon' = \omega} \hat{\Pi}(\epsilon)(\hat{\alpha} + \hat{\alpha}^\dagger)\hat{\Pi}(\epsilon')e^{-i\omega t},$$  \hspace{1cm} (10)

where $\epsilon$ are the eigenvalues of $\hat{H}_S$ and $\hat{\Pi}(\epsilon) \equiv |\epsilon\rangle\langle \epsilon|$ indicate the projectors onto the respective eigenspaces. Furthermore, the Liouvillian superoperator $\mathcal{L}[\hat{O}]\hat{\rho}$ can be expressed in the general form:

$$\mathcal{L}[\hat{O}]\hat{\rho} = \sum_{(\omega,\omega') > 0} \frac{1}{2} \left\{ n(\omega',T)[\hat{O}^\dagger(\omega')\hat{\rho}\hat{O}(\omega) - \hat{O}(\omega)\hat{O}^\dagger(\omega')\hat{\rho}] \right. $$

$$+ [n(\omega,T) + 1][\hat{O}(\omega)\hat{\rho}\hat{O}^\dagger(\omega') - \hat{O}^\dagger(\omega')\hat{\rho}\hat{O}(\omega)]$$

$$+ n(\omega',T)[\hat{O}^\dagger(\omega')\hat{\rho}\hat{O}(\omega) - \hat{\rho}\hat{O}^\dagger(\omega')\hat{O}(\omega')]$$

$$+ [n(\omega',T) + 1][\hat{O}(\omega)\hat{\rho}\hat{O}^\dagger(\omega') - \hat{\rho}\hat{O}^\dagger(\omega')\hat{O}(\omega)] \right\}$$  \hspace{1cm} (11)

where $(k_B = 1)$

$$n(\omega,T) = [\exp(\omega/T) - 1]^{-1}$$  \hspace{1cm} (12)

is the thermal noise occupation number of the system reservoir, at real or effective temperature $T$.

When counter-rotating terms are taken into account in the interaction Hamiltonian, the introduction of master equations in the dressed basis is not sufficient. Indeed, a modification of input-output relationships, relating the intracavity field with the external fields [44, 54, 72–74], is also required. According to these modified relationships, the output fields are no more determined by expectation values of the bare photon operators (see, e.g., [75–77]), but by the expectation values of the dressed operators in Eq. (10).

### III. Vacuum Casimir-Rabi Splittings

In order to fully characterize our system, we numerically diagonalize the Hamiltonian $H_S$ in Eq. (1). Figure 2(a) shows the lowest energy levels as a function of

![Figure 2](image-url)

**Figure 2.** (a) Lowest energy eigenvalues of the system as a function of $\omega_c/\omega_m$ for a normalized optomechanical coupling strength $\eta = g/\omega_m = 0.1$. The ground state is not displayed. (b) Enlarged view of the avoided level crossing arising from the coherent coupling between the states $|0,2\rangle$ and $|2,0\rangle$. The energy splitting reaches its minimum at the resonant frequency $\omega_c \simeq \omega_m$. 

the cavity frequency $\omega_c/\omega_m$ considering a normalized optomechanical coupling strength $\eta = 0.1$.

As reported in Ref. [44], when the resonant conditions

$$q \omega_m = 2 \omega_c$$  \hspace{1cm} (13)

are satisfied, the $\tilde{V}_{\text{DCE}}$ term induces a coherent resonant coupling between the bare states $|0,k\rangle$ (i.e., $0$ photons and $k$ phonons) and $|2, (k - q/2)\rangle$ (i.e., $2$ photons and $k-1$ phonons), with $q \in \mathbb{N}^+$, having different number of excitations. Figure 2(b) shows an enlarged view of the avoided level crossing arising for $\omega_m \simeq \omega_c$, involving the states $|0,2\rangle$ and $|2,0_2\rangle$. When the splitting is at its minimum, the two system eigenstates are essentially a symmetric and antisymmetric linear superpositions of these bare states $|\psi_{\pm}\rangle \simeq \frac{1}{\sqrt{2}}(|0,2\rangle \pm |2,0_2\rangle)$. The size of this avoided level crossing (Casimir-Rabi splitting), analytically calculated using first-order perturbation theory, is given by

$$2\Omega^{(2),0}_{0,2} = 2\langle 0,2|\tilde{V}_{\text{DCE}}|2,0_2\rangle = \sqrt{2}g \left[ \sqrt{3}D_{3,0}(2\eta) + \sqrt{2}D_{1,0}(2\eta) \right]^{(14)}$$

where

$$D_{k',k}(2\eta) = \sqrt{k'/k!}(2\eta)^{k'-k}e^{-|2\eta|^2/2}L_{k'}^{k'-k}(|2\eta|^2)$$ \hspace{1cm} (15)

represents the overlap between different displaced mechanical Fock states and $L_{k'}^{k'-k}$ is an associated Laguerre polynomial. It is important to note that the quantity $2\Omega^{(2),0}_{0,2}$ plays a fundamental role in the DCE, since it determines the rate at which a mechanical two-phonon state is able to generate photon pairs. Specifically, for a normalized optomechanical coupling $\eta = 0.1$ we obtain a matrix element $2\Omega^{(2),0}_{0,2} \simeq 0.05$ that ensures that this avoided level crossing is able to produce a detectable rate of Casimir photon pairs.

IV. RESULTS

Here, we present the system dynamics numerically evaluated taking into account a thermal-like pumping of the mechanical components and considering the photonic reservoir both at $T_k = 0$ and at finite temperature. Specifically, we study the time evolution of the mean phonon (photon) number $\langle \hat{B}^\dagger \hat{B} \rangle$ ($\langle \hat{A}^\dagger \hat{A} \rangle$) and the zero-delay phononic (photonic) normalized second-order correlation function, defined as

$$g^{(2)}_O(t,t) = \frac{\langle \hat{O}^\dagger(t)\hat{O}^\dagger(t)\hat{O}(t)\hat{O}(t) \rangle}{\langle \hat{O}^\dagger(t)\hat{O}(t) \rangle^2}$$ \hspace{1cm} (16)

with $\hat{O} \in \{ \hat{A}, \hat{B} \}$.

A. System dynamics in the weak-coupling regime

We start considering the system initially prepared in its ground state and in the weak-coupling regime, which corresponds to the case where the Casimir-Rabi splitting $2\Omega^{(2),k-q}_{0,2}$ is smaller than the total decoherence rate of the system $\Gamma_{\text{tot}} = \gamma + \kappa$.

Specifically, we assume $\gamma/\omega_m = 0.05$ and $\kappa = \gamma/2$ with an optomechanical coupling $\eta = 0.1$. Considering the resonant case $\omega_m \simeq \omega_c$, corresponding to the minimum splitting of the avoided level crossing arising between the states $|0,2\rangle$ and $|2,0_2\rangle$ (see Figure 2(b)). Figures 3(a,b) display the time evolution of the photonic $\langle \hat{A}^\dagger \hat{A} \rangle$ (red solid curve) and phononic $\langle \hat{B}^\dagger \hat{B} \rangle$ (blue dashed curve) populations, together with the time evolution of the respective two-photon and two-phonon correlation
functions $g^{(2)}_{A,B}(t,t)$. All these quantities have been evaluated taking into account the interaction with a zero temperature ($T_{\kappa} = 0$) photonic reservoir and providing an incoherent thermal-like pumping of the mechanical component by means of phononic reservoir with effective temperature $T_{\gamma}/\omega_m = 0.9$. As shown in Figure 3(a), the photonic and phononic populations start from zero and, due to the incoherent thermal-like pumping of the mechanical modes, reach a considerable stationary value. In particular, a steady state intracavity mean photon number $\langle \hat{A}^{\dagger}\hat{A} \rangle_{ss} \approx 0.15$ is obtained. For a cavity mode of frequency $\omega_c/2\pi \approx 6$ GHz, this value corresponds to a steady-state output photon flux $\Phi = \kappa \langle \hat{A}^{\dagger}\hat{A} \rangle_{ss} \approx 1.4 \times 10^8$ photons per second. This output photon flux is remarkable since it is much higher than the detection threshold of the state-of-the-art detectors, despite the quite low quality factor $Q_c = \omega_c/\kappa = 40$ of the cavity considered in the numerical calculations. Furthermore, also the mechanical loss rate $\gamma$ corresponds to a quality factor $Q_m$ one order of magnitude lower than the values which are experimentally measured in ultra-high-frequency mechanical resonators [78, 79]. Moreover, in Fig. 3(b) we observe that the photonic correlation function starts from a value much higher than two, suggesting that a high number of photon pairs is produced. As the time goes on, this value decreases significantly due to the system losses and the corresponding increase of the mean photon number (note that $g_A^{(2)}(t,t)$ is inversely proportional to the square of the mean photon number). On the contrary, the mechanical correlation function sets on a constant value $g_B^{(2)}(t,t) \approx 2$, showing that the mechanical component is in an incoherent state produced by the thermal-like pumping. These results are particularly interesting since they demonstrate that the DCE can also be experimentally observed exciting a movable mirror with an incoherent thermal-like pump as, for example, a white noise generator (made by an ultra-high frequency resonator interacting with a microwave cavity). In real optomechanical systems ground state cooling is never complete and the interaction with a finite-temperature reservoir has to be taken into account.

The time evolution of the photonic and phononic populations together with the respective two-photon and two-phonon zero-delay correlation functions are displayed in Fig. 4. These functions are evaluated in more realistic conditions, taking into account non-zero temperature reservoir for both the subsystems. In these conditions, both the populations start from a non-zero value corresponding to the initial thermal equilibrium density matrix. As expected, a fraction of the observed photons is thermal and does not originate from the mechanical to optical energy conversion mechanism. This picture is confirmed by comparing the dynamics of the two correlation functions shown in Fig. 4(b,d). Specifically, when

Figure 4. System dynamics evaluated considering finite-temperature reservoirs and the system initially prepared in a thermal state at the same temperature $T_{\kappa}$ of the photonic reservoir. Panels (a) and (c) show the time evolution of the cavity mean photon number $\langle \hat{A}^{\dagger}\hat{A} \rangle$ (red solid curves) and the mean phonon number $\langle \hat{B}^{\dagger}\hat{B} \rangle$ (blue dashed curves) for $T_{\gamma}/\omega_m = 0.9$ and $T_{\kappa}/\omega_m = 0.2$ (a), 0.4 (c). Panels (b) and (d) display the time evolution of the zero-delay two-photon (red solid curves) and two-phonon (blue dashed curves) correlation functions, $g_A^{(2)}(t,t)$ and $g_B^{(2)}(t,t)$, for $T_{\gamma}/\omega_m = 0.9$ and $T_{\kappa}/\omega_m = 0.2$ (b), 0.4 (d).
Fourier transform (arb. unit) 

Figure 5. (a) Scheme of the first energy levels of the optomechanical system. Solid arrows represent the possible one-photon decay channels when the effective temperature of the mechanical reservoir is high enough to populate the state $|5\rangle$. Panels (b) and (c) display, respectively, the cavity emission spectra for the system in the weak and strong light-matter coupling regime and at zero detuning. In both cases, the cavity reservoir is at $T_\kappa/\omega_m = 0$, while the mechanical oscillator is coupled to a reservoir with effective temperature $T_\gamma/\omega_m = 0.9$. Parameters are: $\omega_m = 1$, $\eta = 0.1$. The total loss rate $\Gamma_{tot} = \kappa + \gamma$ of the system is: (b) $7.5 \times 10^{-2}\omega_m$ and (c) $7.5 \times 10^{-3}\omega_m$.

Figure 6. Cavity emission spectra for the system in the strong coupling regime for different values of the detuning $\Delta = (\omega_c - \omega_r)/\omega_m$, where $\omega_r \approx 1.017\omega_m$ is the frequency corresponding to the minimum value of the splitting in Fig. 2(b). Specifically, we considered the cases: (a) $\Delta = 0.028$, (b) $\Delta = 0.01$ and (c) $\Delta = -0.028$. Main contributions are indicated by dashed lines. Parameters are the same of Fig. 5(c).

In the cavity temperature increases, we observe a strong decrease of the $g_A^{(2)}(t,t)$ peak value, indicating that less photons are emitted in pairs. However, as expected, the phonon-phonon correlation functions remain constant at the thermal value $g_B^{(2)}(t,t) \approx 2$. These results demonstrate that, when the presence of a cavity thermal noise is taken into account, the number of the produced Casimir photon pairs decrease. However, the output photon flux is still above the detection threshold of the photodetector and the peak value of the $g_A^{(2)}(t,t)$ indicates that photon pairs are produced.

B. Emission spectra in the weak and strong coupling regimes

In order to obtain more information on the ongoing physics, here we present the cavity emission spectra derived via a quantum regression approach. Considering a normalized optomechanical coupling $\eta = 0.1$, we present results for the system both in the weak and in
the strong light-matter coupling regime for different values of $\omega_\text{c}/\omega_m$. We consider the cavity at $T_\text{c} = 0$, while the mechanical oscillator is coupled to a reservoir with effective temperature $T_\text{r}/\omega_m = 0.9$. For the sake of simplicity, we indicate the energy eigenvalues and eigenstates as $\omega_l$ and $|l\rangle$ ($l = 0, 1, \ldots$) and the transition frequencies as $\omega_{jk} \equiv \omega_j - \omega_k$, choosing the labeling of the states such that $\omega_j > \omega_k$, for $j > k$ [see Fig. 5(a)]. If the effective temperature of the mechanical reservoir is high enough to populate the state $|5\rangle$, the system decays toward the ground state via two different one-photon decay channels: $|5\rangle \rightarrow |2\rangle \rightarrow |0\rangle$ and $|3\rangle \rightarrow |2\rangle \rightarrow |0\rangle$. Since the states $|5\rangle$ and $|3\rangle$ do not couple with the state $|4\rangle$, the other possible one-photon transition $|4\rangle \rightarrow |0\rangle$ can occur only by decays from higher energy levels.

We start considering the zero detuning case $\Delta \equiv (\omega_\text{c} - \omega_r)/\omega_m = 0$, where $\omega_r \simeq 1.017 \omega_m$ is the frequency corresponding to the minimum value of the splitting in Fig. 2(b). In this case the states $|3\rangle$ and $|5\rangle$ are well approximated, respectively, by the superpositions $|\psi_\pm\rangle = (|0\rangle \pm |2\rangle)/\sqrt{2}$.

Figure 5(b) displays the emission spectra for the system in the weak coupling regime, e.g., $2\Omega_{0,2}^2 \ll \Gamma_\text{tot}$. Due to the high value of $\Gamma_\text{tot}$, we observe a low-resolution emission spectrum that only displays a wide band constituted by a single peak at frequency $\omega/\omega_m \simeq 0.98$. On the contrary, when the system is in the strong coupling regime ($2\Omega_{0,2}^2 > \Gamma_\text{tot}$), the spectrum becomes well-resolved. As shown in Fig. 5(b), for $2\Omega_{0,2}^2/\Gamma_\text{tot} \simeq 6.7$ the cavity emission spectrum displays two main peaks. Indeed, in the resonant case the accidentally quasi-degenerate transitions $|5\rangle \rightarrow |2\rangle$ and $|2\rangle \rightarrow |0\rangle$ give rise to a single high-frequency peak at $\omega \simeq \omega_m$, whereas the lower-frequency peak at $\omega/\omega_m \simeq 0.98$ corresponds to the transition $|3\rangle \rightarrow |2\rangle$. It is important to notice that, in the presence of a $T_\text{c} = 0$ cavity reservoir, these peaks are observable only if the $V_{\text{DCE}}$ term is included in the Hamiltonian. Indeed, without this term the states $|2, 0\rangle$ and $|0, 2\rangle$ are not coupled anymore and since the mechanical incoherent pumping only populates phononic states, the one-phonon decay peaks cannot be observed in the cavity emission spectra. We now turn to the numerical analysis of the detuning effects on the cavity emission spectra. Figure 6(a) displays the emission spectrum calculated for $\Delta = 0.028$. As the transitions $|5\rangle \rightarrow |2\rangle$ and $|2\rangle \rightarrow |0\rangle$ are no more quasi-degenerate, the peaks at frequencies $\omega_{32}$ and $\omega_{20}$ become well resolved, while the peak corresponding to $|3\rangle \rightarrow |2\rangle$ shifts towards a slightly lower frequency. As expected, if we reduce the detuning and approach the resonance point $\Delta = 0$, the spectrum essentially presents the same main features of Fig. 5(c). Specifically, Fig. 6(b) shows that for $\Delta = 0.014$ the two peaks at $\omega_{32}$ and $\omega_{20}$ merge, and the emission spectrum presents only a main contribution at $\omega/\omega_m \simeq 1.015$, while the transition frequency $\omega_{32}$ does not change significantly. Finally, in Fig. 6(c) we study the emission spectrum in the presence of a negative detuning $\Delta = -0.028$. Also in this case, the spectrum displays three distinct peaks placed at lower frequencies with respect to Fig. 6(a). This shift arises from the energy-level crossing between the states $|1\rangle$ and $|2\rangle$ shown in Fig. 2(a). Although the highest peak still corresponds to the one-photon decay toward the ground state, the emission spectrum is not symmetric respect to the one in Fig. 6(a). In particular, we observe that the intensity of the peak associated to the transition $|3\rangle \rightarrow |1\rangle$ increases, whereas the $|5\rangle \rightarrow |1\rangle$ transition peak displays a much lower intensity. This effect can be explained considering that, differently from the positive-detuning cases studied above, for $\Delta < 0$ the state $|3\rangle \simeq |2, 0\rangle$ has more photonic character than $|5\rangle \simeq |0, 2\rangle$, which has more phononic character. Thus, while the photonic character of the polaron state $|3\rangle$ leads to an enhancement of the peak intensity at $\omega_{31}$ in the cavity emission spectrum, on the other hand the phononic character of the state $|5\rangle$ is responsible for the intensity decrease of the peak at $\omega_{51}$. This study provides useful information on the emission process. Moreover, the presence of these features in the experimental spectra would represent a signature of the production of DCE photons.

V. CONCLUSIONS

In conclusion, we have studied the dynamical Casimir effect in cavity optomechanics achieved only under incoherent mechanical excitation. We employed a fully quantum-mechanical description of both the cavity field and the oscillating mirror. The system dynamics is evaluated under incoherent pumping of the mechanical component, provided by a thermal-like excitation. Using a master equation approach in order to take into account losses, thermal effects and decoherence in the presence of a quasi-harmonic spectrum, we showed that a measurable flux of Casimir photons can be obtained also without a coherent pumping, suggesting another way for experimental observation of the DCE. The energy transfer of incoherent mechanical excitations to phonon pairs can be also observed in parametrically amplified optomechanical systems [80]. In Ref. [44], it has been shown that a vibrating mirror is affected by spontaneous emission in analogy with ordinary atoms. However, it decays emitting photon pairs. Here, we show that an incoherently excited vibrating mirror can emit light, in analogy to atomic fluorescence or electroluminescence in semiconductor devices.

By applying the quantum regression theorem, we have calculated numerically the steady-state cavity emission spectra under incoherent mechanical excitation, for different detunings and loss rates. When the loss rates are lower than the effective coupling rate, the emission spectra allow to identify the different emission channels.
