Astrocytes are important mediators of Aβ-induced neurotoxicity and tau phosphorylation in primary culture

CJ Garwood¹, AM Pooler¹, J Atherton¹, DP Hanger¹ and W Noble*,¹

Alzheimer’s disease (AD) is pathologically characterised by the age-dependent deposition of β-amyloid (Aβ) in senile plaques, intraneuronal accumulation of tau as neurofibrillary tangles, synaptic dysfunction and neuronal death. Neuroinflammation, typified by the accumulation of activated microglia and reactive astrocytes, is believed to modulate the development and/or progression of AD. We have used primary rat neuronal, astrocytic and mixed cortical cultures to investigate the contribution of astrocyte-mediated inflammatory responses during Aβ-induced neuronal loss. We report that the presence of small numbers of astrocytes exacerbate Aβ-induced neuronal death, caspase-3 activation and the production of caspase-3-cleaved tau. Furthermore, we show that astrocytes are essential for the Aβ-induced tau phosphorylation observed in primary neurons. The release of soluble inflammatory factor(s) from astrocytes accompanies these events, and inhibition of astrocyte activation with the anti-inflammatory agent, minocycline, reduces astrocytic inflammatory responses and the associated neuronal loss. Aβ-induced increases in caspase-3 activation and the production of caspase-3-truncated tau species in neurons were reduced when the astrocytic response was attenuated with minocycline. Taken together, these results show that astrocytes are important mediators of the neurotoxic events downstream of elevated Aβ in models of AD, and suggest that mechanisms underlying pro-inflammatory cytokine release might be an important target for therapy.

Subject Category: Neuroscience

Alzheimer’s disease (AD) is a neurodegenerative disorder pathologically characterised by deposits of β-amyloid (Aβ) in senile plaques, intracellular neurofibrillary tangles comprising hyperphosphorylated tau, synaptic dysfunction and neuronal death, some or all of which are believed to cause the cognitive and behavioural deficits that typify this disease. It is now widely recognised that neuroinflammation is a prominent feature of AD brain, with inflammatory responses playing a significant role in modulating disease progression.¹

Prolonged and widespread activation of microglia and astrocytes are apparent in AD brain, in which the severity of glial activation correlates with the extent of brain atrophy² and cognitive decline.³ The majority of transgenic rodent models of AD also exhibit substantial reactive gliosis and accumulation of activated astrocytes in affected brain regions.⁴⁻⁵ These features are often observed before the appearance of plaque and tangle pathology,⁶⁻⁷ and the degree of inflammatory cell activation correlates with pathology development and neuronal death in mouse models of AD.⁶⁻⁸

The role of microglia in the development and/or progression of AD is somewhat controversial. Phagocytosis of Aβ by microglia is believed to be a protective mechanism,⁹ at least in younger animals;¹⁰ however, neuronal loss also results from increased pro-inflammatory cytokine production by microglia in models of AD.¹⁰ In addition to the influence of microglia, an important role of astrocytes in regulating Aβ-induced neuronal death has recently been illustrated.¹¹

Both astrocytes and microglia release a myriad of pro- and anti-inflammatory cytokines, including interleukins (ILs), interferons (IFNs) and tumour necrosis factors (TNFs), as well as chemokines, a family of small pro-inflammatory cytokines that includes macrophage inflammatory proteins and monocyte chemoattractant proteins.¹² Receptor binding of cytokines stimulates a variety of intracellular signalling pathways that have been implicated in AD, including the activation of protein kinase C, c-Jun N-terminal kinase (JNK), p38 mitogen-activated protein kinase (p38/MAPK), PI3 kinase, extracellular signalling-related kinase (ERK), as well as activation of caspase-1 and -3.¹³⁻¹⁴

Caspases are closely associated with induction of the apoptotic cascade, and activation of caspase-3 is both necessary and sufficient to trigger apoptotic cell death in response to elevated Aβ in AD.¹⁵ In addition, Aβ-induced caspase-3 activation causes abnormal processing of the microtubule-associated protein tau in models of AD.¹⁶,¹⁷ Cleavage of tau by caspase-3 at Asp421 generates a

truncated form that aggregates more rapidly, and to a greater extent, than full-length tau, and caspase-cleaved tau fragments directly reduce neuronal viability. Aberrant tau phosphorylation in response to elevated Aβ also contributes to tau aggregation and fibrillisation in AD. Putative tau kinases that phosphorylate tau in response to Aβ include cyclin-dependent kinase-5, glycogen synthase kinase-3β, p38/MAPK, JNK-1 and ERK, several of which are activated by increased production or release of cytokines.

We have shown previously that the neuroprotective agent, minocycline, reduces tau phosphorylation and proteolysis in both Aβ-treated primary cortical cultures and also in htau mice, which progressively accumulate hyperphosphorylated aggregated tau and show significant neuronal loss in the cortex and hippocampus in the absence of elevated Aβ. In htau mice, the impact of minocycline on tau pathology was not associated with tau kinase inhibition, but correlated with reductions in astrocytosis and in the CNS burden of pro-inflammatory factors. Indeed, the cortical amounts of individual inflammatory cytokines correlated strongly with phosphorylated tau load. Here, we have investigated the role of astrocytes in Aβ-induced tau phosphorylation and cleavage, as well as determining the influence of astrocytes in mediating Aβ-induced neuronal death.

**Results**

**Astrocytes accelerate Aβ-induced neurotoxicity.** We first compared primary cortical cultures in which neurons were either cultured alone (neuronal cultures) or were in co-culture with astrocytes (mixed cultures). Immunolabelling with cell-type-specific antibodies identified constituent cells in the cultures and revealed an absence of glia in neuronal cultures. Mixed cultures were predominantly neuronal, containing 4.4 ± 0.4% astrocytes and a negligible amount of microglia (<0.01%) after 7 days in vitro (DIV).

To determine whether or not astrocytes influence Aβ-induced neurotoxicity, mixed and neuronal cultures were treated with 10μM soluble oligomeric Aβ and lactate dehydrogenase (LDH) release was used to measure cell viability. Aβ treatment of mixed cultures, but not neuronal cultures, resulted in a statistically significant increase in LDH release at both 48 and 72 h (Figures 1a and b; P<0.001). In contrast, significantly increased LDH release was only observed in neuronal cultures following a 72 h treatment with Aβ (Figure 1b; P<0.01). Aβ treatment did not cause increased release of LDH from cultured astrocytes (Figure 1c), indicating that the presence of astrocytes significantly accelerates Aβ-induced neuronal death.

**Figure 1** Astrocytes accelerate Aβ-amyloid (Aβ)-induced neurotoxicity. Bar charts show LDH release from rat primary mixed (black bars) and neuronal (white bars) cultures exposed to 10μM Aβ for (a) 48 or (b) 72 h, with and without a 24 h pretreatment with 20μM minocycline (Min). (c) LDH release from rat primary astrocyte cultures exposed to 10μM Aβ for 72 h, with and without a 24 h pretreatment with 20 μM Min. Values represent LDH release from cells into the medium as a percentage of total LDH, shown as mean ± S.E.M. Experiments were performed in triplicate (N=9–15). *P<0.05; **P<0.01; ***P<0.001. (d) Representative images from mixed cortical cultures treated for 48 h with Aβ, labelled with a dead cell dye (red), and then fixed and immunostained with an antibody against glial fibrillary acidic protein (GFAP) (green). Bisbenzimide was used to stain nuclei (blue). The red dye labels dead cells. Arrows indicate astrocytes that are unaffected by Aβ. Scale bar: 50 μm. N = 3.
Astrocytes mediate the neurotoxic effects of Aβ

CJ Garwood et al

To confirm that neurons, and not astrocytes, are susceptible to Aβ toxicity in mixed culture, a fixable dead cell staining kit was used in conjunction with immunolabelling of astrocytes (Figure 1d). As expected, this method revealed a proportion of dead cells following Aβ treatment. However, glial fibrillary acidic protein (GFAP)-immunoreactive astrocytes were not labelled by the dead cell dye. Furthermore, the nuclei of astrocytes were not fragmented or condensed, unlike many of the surrounding neurons (Figure 2d, white arrows). In further support of this finding, no alteration in the abundance of astrocytes was apparent in mixed cultures following Aβ treatment (Supplementary Figure 1). These results support those from the LDH assays and conclusively show that in mixed cell cultures, only neurons are susceptible to Aβ-induced toxicity.

To determine if astrocytic inflammatory responses are involved in the acceleration of Aβ-induced neurotoxicity, cultures were pretreated with the anti-inflammatory agent minocycline. LDH release was not significantly affected by minocycline alone in any of the cultures. Pretreatment of mixed, but not neuronal cultures with minocycline resulted in reduced LDH release from cultures treated with Aβ for 48 or 72 h (Figures 1a and b; P < 0.05 and P < 0.001, respectively). This finding suggests that minocycline may reduce Aβ-induced neuronal death by suppressing the inflammatory response of astrocytes.

Aβ induces morphological changes in astrocytes. Astrocytes are highly dynamic cells that exhibit morphological changes depending on their cellular environment. In primary culture, the morphology of astrocytes is considered a reliable marker of their activation state. Therefore, we next examined astrocyte morphology in response to Aβ and minocycline in mixed cultures. Under control conditions, and following treatment with minocycline alone, astrocytes appeared as stellate process-bearing cells (Figures 2a and b), in line with previous reports. Following exposure to Aβ, there were clear and robust alterations in astrocyte morphology with the appearance of convoluted processes and terminal swellings (Figure 2c, single arrows). Such changes are believed to represent characteristics of astrocyte activation in culture. These alterations are not indicative of dystrophic astrocytes as Aβ-treated astrocytes do not label with the dead cell dye (Figure 1d). Pretreatment with minocycline before Aβ prevented these Aβ-induced morphological changes in mixed cultures (Figure 2d).

In contrast, following Aβ treatment, neurons displayed condensed and fragmented neuronal nuclei (double arrows, Figure 2c) and a disrupted tubulin cytoskeleton (Figure 2c). These results add further support to our finding that neurons, rather than astrocytes, are susceptible to Aβ toxicity in mixed culture. Pretreatment of mixed cultures with minocycline before the addition of Aβ reduced these markers of neuronal death (Figure 2d).

These results suggest that astrocytes are activated in response to Aβ, which is an event closely associated with Aβ-induced neuronal death. Furthermore, minocycline-mediated neuroprotection from Aβ toxicity appears to be associated with the inhibition of astrocyte activation.

A soluble factor secreted from astrocytes mediates Aβ-induced neuronal death. Astrocytes may mediate neuronal responses both by direct membrane interactions and by the release of factors that bind to neuronal receptors. To investigate the mechanism underlying the astrocyte-mediated acceleration of Aβ-induced neuronal death, we treated primary cortical astrocyte-enriched cultures with Aβ for 48 h, a treatment that is not toxic to these cells (Figure 1c). Addition of conditioned medium from Aβ-treated astrocytes to cultured neurons resulted in increased LDH release (Figure 3a). As a control, Aβ was incubated in astrocyte culture medium, in the absence of cells, for 48 h, and application of this medium to neurons did not affect cell viability (Figure 3b). These results show that a component of the astrocyte-conditioned medium mediates neuronal death. ELISA measurement of Aβ in conditioned medium revealed that the amount of Aβ reduced from 10 to 1.08 ± 0.06 pM after 48 h incubation with primary astrocyte cultures. As 1 μM Aβ is insufficient to induce neuronal death in these cultures, we conclude that a soluble factor released from astrocytes is important for Aβ-induced neurotoxicity.
Astrocytes increase Aβ-induced caspase-3 activity. The finding that astrocytes accelerate Aβ-induced neuronal toxicity led us to investigate whether caspase-3 activity was influenced by astrocytes, as increased caspase-3 activity is associated with Aβ-induced neurotoxicity.15–17 Furthermore, we have shown that minocycline inhibits caspase-3 activation in both primary cortical cultures and in htau mice,17 the former closely associated with protection from Aβ-induced neurotoxicity. To investigate if astrocytes influence caspase-3 activity, we analysed cell lysates from Aβ- and/or minocycline-treated mixed and neuronal cultures on western blots (Figure 4).

Caspase-3 is activated by cleavage, generating fragments of approximately 17 and 19 kDa from the full-length (35 kDa) protein. We therefore measured caspase-3 activity using an antibody against cleaved caspase-3 (Figure 4a). Treatment of both mixed and neuronal cultures with Aβ for 48 h significantly increased the amount of cleaved caspase-3 present in cell lysates, when compared with those from vehicle-treated cells (P<0.001 and P<0.01, respectively). The activation of caspase-3 by Aβ was significantly enhanced in mixed cultures when compared with neuronal cultures (P<0.05), indicating that astrocytes exacerbate Aβ-induced caspase-3 activation, and this is likely related to the impact of astrocytes in mediating Aβ-induced neuronal death. Pretreatment of both mixed and neuronal cultures with minocycline reduced the Aβ-induced accumulation of cleaved caspase-3 (Figure 4b; P<0.01 and P<0.05, respectively). This suggests that while astrocytic inflammatory responses may exacerbate caspase-3 activation in response to Aβ, both neurons and astrocytes are targeted by minocycline to reduce caspase-3 activation.

Astrocytes mediate the neurotoxic effects of Aβ. Astrocytes derive soluble factor(s) released in response to Aβ. Pretreatment of astrocyte-enriched cultures with minocycline before Aβ application significantly reduced neuronal death in this model system (Figure 3b), suggesting that the neurotoxic astrocyte-derived soluble factor(s) released in response to Aβ may be an inflammatory mediator.

Astrocytes exacerbate Aβ-mediated tau truncation. The truncation of tau by caspase-3 is believed to be an important event during the development of tau pathology in AD, with caspase-3-cleaved tau more prone to aggregation than full-length tau.16,18 Aβ has previously been shown to induce the generation of caspase-3-cleaved tau species in primary cortical cultures,17 an event associated with neuronal death.19,28 Therefore, cell lysates from mixed and neuronal cultures were assessed for caspase-cleaved tau by western blotting using an antibody that specifically detects tau that has been cleaved at Asp421 (Figures 5a and b). In both types of control cultures, small amounts of caspase-3-cleaved tau were detected at approximately 50 kDa, in line with our previous findings.17 Aβ treatment significantly increased the amount of cleaved tau present in both mixed and neuronal cultures (Figure 5b; P<0.001 and P<0.01, respectively); however, significantly more caspase-3-cleaved tau was apparent following Aβ treatment of mixed cultures when compared with neuronal cultures (P<0.05). Cultured astrocytes contain only trace amounts of tau (Figure 5c), suggesting that the tau measured in the mixed cultures is of neuronal origin, and that the presence of astrocytes significantly potentiates the generation of caspase-cleaved tau in neurons in response to Aβ (Figures 5a and b). Pretreatment of mixed, but not neuronal, cultures with minocycline significantly reduced the amount of caspase-3-cleaved tau species generated in response to Aβ treatment (P<0.01), again suggesting that astrocytic inflammatory responses may have a role in the Aβ-induced cell signalling that leads to caspase activation and tau cleavage.

Astrocytes are necessary for Aβ-induced tau phosphorylation. Truncation of tau is closely associated
performed in triplicate \((N)\) and from primary neuron, astrocyte and mixed cultures, probed with antibodies against \(m\) cultures. Cultures were exposed to 10 \(\mu\)M \(A\beta\) for 48 h with and without pretreatment with 20 \(\mu\)M minocycline for 24 h. Representative western blots probed with an antibody against caspase-3-cleaved tau (50 kDa) are shown. Blots were also probed with \(\beta\)-actin (42 kDa) as a loading control. Molecular weight markers are indicated (kDa). (b) Bar chart showing the amount of caspase-3-cleaved tau as a proportion of \(\beta\)-actin in each sample. (c) Representative western blots of cell lysates from primary neuron, astrocyte and mixed cultures, probed with antibodies against total tau (55 kDa) and \(\beta\)-actin (42 kDa). Data are mean \(\pm\) S.E.M. Experiments were performed in triplicate \((N = 12)\). *\(P < 0.05\); **\(P < 0.01\); ***\(P < 0.001\)

Figure 5 Astrocytes exacerbate \(\beta\)-amyloid (\(A\beta\))-induced tau truncation by caspase-3. (a) Western blots of cell lysates from rat primary mixed (M) and neuronal (N) cultures. Cultures were exposed to 10 \(\mu\)M \(A\beta\) for 48 h with and without pretreatment with 20 \(\mu\)M minocycline for 24 h. Representative western blots probed with antibodies against \(m\) cultures. Pretreatment of mixed cultures with minocycline significantly reduced tau phosphorylation at Ser396/404 and Ser202 \((P < 0.05\) for both). Thus, astrocytic inflammatory responses likely have a role in \(A\beta\)-induced tau phosphorylation. Furthermore, both astrocyte-mediated tau phosphorylation and the generation of caspase-cleaved tau are closely associated with \(A\beta\)-induced neurotoxicity.

The increased release of inflammatory mediators from astrocytes is associated with \(A\beta\)-induced neurotoxicity. We and others have previously shown that the amounts of specific inflammatory cytokines correlate strongly with pathology development in transgenic mouse models of AD.\(^6,8\) Therefore, the release of inflammatory mediators from \(A\beta\)- and minocycline-treated astrocyte-enriched cultures was measured using cytokine arrays. These arrays were chosen as they allow the unbiased and simultaneous measurement of 29 rat cytokines. \(A\beta\) treatment of astrocyte-enriched cultures had a significant overall effect on the release of inflammatory cytokines (Figure 3a; \(P < 0.01\)), appearing to elevate the medium amounts of the majority of cytokines studied, including
IL-1β, IL-6 and IFN-γ, each of which has been reported to be increased in response to Aβ. Moreover, additional cytokines, not previously identified, were elevated by Aβ, including IL-13, IL-17 and IP-10. Statistical analysis revealed that cytokine-induced neutrophil chemoattractant (CINC) 2α/β, IFN-γ, IL-1β, IL-1ra, IL-6, IL-13, IL-17, IP-10 and monokine induced by IFN-γ (MIG) were significantly increased in response to Aβ treatment (Figures 7a and b; P < 0.05 for all). Minocycline pretreatment had a significant overall influence on the Aβ-induced increases in cytokine media amounts (Figure 3a; P < 0.001), with the Aβ-induced increases in the nine aforementioned cytokines being significantly reduced by minocycline pretreatment (Figures 7a and b; P < 0.05 for all). These findings indicate a close association between cytokine release and the neurotoxic events that occur downstream of Aβ, and suggest that suppression of these inflammatory responses may represent a valid therapeutic strategy for the treatment of AD and related neurodegenerative disorders.

Discussion

Here we have used cultured neurons and astrocytes to show that astrocytes have an important role in neurodegenerative events occurring downstream of Aβ. We found that astrocytes exacerbate Aβ-induced neurotoxicity, caspase-3 activation and the generation of caspase-3-cleaved tau fragments, and are necessary for Aβ-induced tau phosphorylation. A soluble factor secreted from astrocytes appears to have an important role in these processes, and we have identified a panel of inflammatory mediators as candidates whose secretion is increased in response to Aβ. Inhibiting astrocytic inflammatory responses with minocycline reduced or abolished these effects of Aβ, suggesting that the soluble factor that has an important role in Aβ-induced toxicity and abnormal tau processing may be an inflammatory cytokine.

Increased LDH release was observed 48 h after Aβ treatment in mixed, but not neuronal cultures, suggesting that astrocytes accelerate the neurotoxic effects of Aβ. These findings are in agreement with those of Paradisi et al., who previously reported that Aβ-treated astrocytes have deleterious effects on neuronal cultures when co-cultured with neurons. In addition, we found that the morphology of astrocytes was altered upon treatment with Aβ, with astrocytes developing convoluted processes and terminal swellings. Specific labelling of dead cells showed that these morphological alterations are not indicative of atrophic...
cells. Indeed, previous findings indicate that this altered morphological state occurs when astrocytes enter an active, cytokine-secreting state. Furthermore, similar alterations to astrocytic morphology have been reported in 3 × Tg-AD mice in which astrocytes located in close proximity to senile plaques were shown to be hypertrophic, rather than atrophic or dystrophic.

We found that Aβ-induced neurotoxicity was associated with increased activity of caspase-3, and that this was exacerbated in the presence of astrocytes. Activated forms of caspase-3 are found in AD brain, and we have previously shown that activation of caspase-3 precedes Aβ-induced neuronal death in primary cortical cultures. The mechanism underlying astrocyte-mediated increased caspase-3 activation in response to Aβ might, therefore, be attributed to factors that are secreted from astrocytes, or direct neuron–astrocyte interactions. Previous evidence suggests that soluble factors released by astrocytes bind to neuronal plasma membrane receptors inducing various cell signalling pathways. For example, when secreted from astrocytes, TNF-α binds to neuronal Cd120a/b receptors triggering caspase activation through death effector domains.

Astrocytes could potentially influence Aβ-induced neurotoxicity through direct membrane-associated interactions, as described previously. However, by treating neurons with the medium from Aβ-treated astrocyte cultures, we established that a soluble factor(s) secreted from astrocytes accelerates Aβ-induced neuronal toxicity. It is well recognised that the activation of astrocytes is accompanied by increased production of potentially neurotoxic factors, including cytokines, nitric oxide (NO) and reactive oxygen species, and Aβ can induce the production and secretion of IL-1β, NO and other inflammatory cytokines in cultured astrocytes and microglia. Here, we took an unbiased approach to show that Aβ treatment significantly increases the secretion of several inflammatory cytokines and chemokines from primary astrocytes, and that minocycline-mediated protection from Aβ-induced neurotoxicity was associated with the decreased secretion of inflammatory mediators from astrocytes. We found that the amounts of CINC2α/β, IFN-γ, IL-1β, IL-1ra, IL-6, IL-13, IL-17, IP-10 and MIG in culture medium were significantly increased by Aβ, and these increases were significantly inhibited by the anti-inflammatory agent, minocycline. This suggests that these cytokines, in particular, may have an important role in the neurotoxic events downstream of Aβ.

IL-17 belongs to the same cytokine subfamily as IL-6, acting to induce IL-6 expression in astrocytes. Thus, this finding is in agreement with those of Jana et al., who recently reported that astrocytes induce neuronal death by sphingomyelinase-mediated induction of IL-1β and IL-6, together with TNFα. Indeed, substantial evidence now indicates that IL-1β and IL-6/IL-17 have important roles in the development and/or progression of AD, with these cytokines found in affected brain regions in association with plaques and tangles in AD brain, and transgenic mouse models of AD. We also found that increased IP-10 secretion from astrocytes was associated with Aβ-induced neurotoxicity. IP-10 is markedly increased in reactive astrocytes in AD brains, and astrocytes positive for IP-10 are associated with senile plaques. To our knowledge, the findings presented here provide the first evidence for a direct effect of Aβ on IP-10 production and thus may implicate IP-10 in AD pathogenesis.

In addition to Aβ-induced neurotoxicity, we have examined the role of astrocytes in Aβ-induced abnormal tau processing. We found that astrocytes augment Aβ-induced caspase-3 cleavage of tau, in keeping with our previous results. We also describe, for the first time, that astrocytes are required for Aβ-induced tau phosphorylation, at least in this model system. Receptor binding of various cytokines and chemokines leads to the activation of protein kinase C, p38, ERK and JNK mitogen-activated protein kinases and PI3 kinase. Thus, it is possible that astrocyte-derived cytokines bind to neuronal plasma membrane receptors, inducing specific signalling pathways that result in the activation of tau kinases implicated in aberrant tau phosphorylation and cleavage in AD and the tauopathies. For example, binding of secreted IL-1 to neuronal IL-1 receptors leads to the activation of p38 MAPK and tau hyperphosphorylation in vivo. Activation of caspase-3 also occurs downstream of IL-1 receptors, which conceivably results in the C-terminal cleavage of tau to generate neurotoxic tau fragments. Our results indicate that it is predominantly the caspase-3-cleaved tau fragments that are more heavily phosphorylated following Aβ treatment of primary cortical cultures, and thus uncovering the mechanism by which astrocytes influence neuronal caspase-3 activity is likely to elucidate the mechanism by which Aβ increases aberrant tau processing, at least in this model system. The mechanism underlying the influence of astrocytes during Aβ-induced tau phosphorylation is currently under investigation in our laboratory.

It is interesting to note, however, that individual cytokines have been reported to have opposing effects on the development of tau and amyloid pathology in transgenic mouse models of AD. Indeed, we have shown previously that several of the cytokines identified here, including IL-17, as being associated with Aβ-associated neurotoxicity, negatively correlated with the amount of tau phosphorylation in htau mice. Thus, further investigation is warranted into the roles of specific inflammatory cytokines in models of AD. Furthermore, it will be important to investigate the findings presented here in intact brain in which the potential influences of microglia–astrocyte signalling and complex neurotransmitter interactions can be investigated in an environment comprising approximately equivalent glia and neurons.

In summary, the results presented here indicate that astrocytes have an important role in mediating the effects of Aβ on cultured neurons. The influence of astrocytes in this system is closely related to the increased secretion of various inflammatory factors, including IL-1β, IL-17 and IP-10. Although we cannot rule out the possibility that additional astrocyte-derived soluble factors may have a role in the effects on neurons reported here, these results provide further support for the investigation of anti-inflammatory strategies, or the specific inhibition of selected inflammatory cytokines, as potential therapies for the treatment of AD and related neurodegenerative diseases.
Materials and Methods
All materials were obtained from Sigma (Poole, Dorset, UK), unless otherwise stated.

Primary cell culture and cell treatments. Primary mixed cortical cultures were prepared from embryonic day 18 (E18) rat embryos and cultured as described previously.17 To establish neuronal cultures, the proliferation of glial cells in mixed cultures was prevented by the addition of 2 μM cytokine arabinoside to three DIV cultures for 48 h. Primary astrocytes were obtained from postnatal day 2 (P2) rats and cultured as described previously.41 At 2 days before treatment, astrocytes were re-plated into six-well dishes and subsequently maintained in serum-free medium. Cultures were treated with 10 μM soluble oligomeric Aβ1–42 (California Peptide Co., Napa, CA, USA) or 20 μM minocycline for 24 h before the addition of Aβ1–42 or vehicle (H2O). Soluble Aβ1–42 was prepared according to the method described in Town et al.,21 which we confirmed generates predominantly soluble oligomeric forms of Aβ.

Toxicity assays. Cytotoxicity was evaluated by measuring LDH in culture medium using Cytotox 96 assay kits (Promega, Madison, WI, USA) according to the manufacturer’s directions. After collection of medium, the remaining cells were lysed in 0.9% (w/v) Triton X-100, and LDH content in medium and lysed cells was measured to determine total LDH content. Optical density was measured at 492 nm (Wallac 1420 Victor3 plate reader, Perkin-Elmer, Waltham, MA, USA). LDH release from cells was calculated as a percentage of total LDH in each sample.

Dead cells in culture were identified by a live/dead fixable cell stain (Invitrogen, Paisley, UK) according to the manufacturer’s instructions. Following uptake of the amine-reactive fluorescent dye provided, cells were washed, fixed and immunolabelled with an antibody against GFAP, as described below.

Aβ1–42 ELISA. Semiquantitative ELISAs were performed as described previously,42 using the 6E10 antibody (Eurogentec, Southampton, UK) to detect Aβ1–42 in culture medium. Aβ1–42 standards of known concentration were plated to generate a standard curve from which Aβ1–42 content was measured in the medium of primary cortical cultures.

Immunocytochemistry. Cultured cells were fixed in 4% (w/v) paraformaldehyde in phosphate-buffered saline (PBS) for 5 min at 37 °C. Following fixation, cells were permeabilised (0.3% (v/v) Triton X-100 in PBS) and blocked with 1% (w/v) bovine serum albumin before incubation with monoclonal antibodies against GFAP (Dako, Ely, UK) or Jiffi-tubulin (Cell Signalling, Beverly, MA, USA). Cells were incubated with the appropriate species of secondary antibody and cell nuclei were stained with the Hoechst 33342 (5 μg/ml bisbenzimide in PBS).

Neurons were examined using a Zeiss Axioskop microscope (Carl Zeiss Inc., Welwyn Garden City, UK). For cell counts, five separate non-overlapping images were taken using the x 20 objective. Cell counts were made using the ImageJ software (National Institutes of Health, Bethesda, MD, USA).

Preparation of neuronal lysates. After treatments, the medium was removed and cells were washed in ice-cold PBS, followed by lysis in extra strong lysis buffer (100 mM Tris-HCl (pH 7.5), 0.3% (v/v) sodium dodecyl sulphate (SDS), 0.5% (w/v) sodium deoxycholate, 1% (v/v) Triton X-100, 75 mM sodium chloride, 10 mM ethylenediaminetetraacetic acid, 2 mM sodium orthovanadate, 1.25 mM sodium fluoride and protease inhibitor cocktail for mammalian tissues), and centrifugation at 16,000 × g at 4 °C for 20 min at 4 °C. The protein concentration of supernatants was measured using a BCA protein assay kit (Pierce Endogen, Rockford, IL, USA) and samples were standardised to equal protein concentration before being analysed on SDS-PAGE.

SDS-PAGE and Immunoblotting. In total, 5–20 μg protein was separated on 10 or 12% (w/v) SDS-PAGE gels and electrophoretically transferred to nitrocellulose membrane. After blocking with 5% (w/v) non-fat dried milk for 1 h, membranes were probed with primary antibodies, followed by fluorochrome-coupled secondary antibodies. Detected proteins were visualised and quantified, using an Odyssey infrared imaging system (Li-Cor Biosciences, Cambridge, UK). The following primary antibodies were used for western blotting. Total tau (rabbit polyclonal; Dako); tau-C3 (tau truncated at Asp421, mouse IgG1; Millipore, Billerica, MA, USA); tau (pSer396) (rabbit polyclonal; Invitrogen Biosoce, Carlsbad, CA, USA); cleaved caspase-3 (Asp175, rabbit IgG; Cell Signaling); and β-actin (mouse IgG1, done AC-15; Abcam, Cambridge, UK). The following tau antibodies were kindly gifted by Peter Davies (Albert Einstein College of Medicine, Bronx, NY, USA): CP13 (phospho-Ser-202; mouse IgG1) and PHF-1 (phospho-Ser-396/404; mouse IgG1).

Cytokine antibody arrays. The medium from astrocyte-enriched cultures was collected and stored at −20 °C pending analysis of pro-inflammatory mediator content using Rat Proteome Profiler antibody arrays (R&D Systems, Minneapolis, MN, USA). Before analysis, samples of medium were thawed on ice and centrifuged at 10,000 × g for 1 min at 4 °C. Media from all experiments were processed in parallel to enable comparisons between experiments. Cytokine and chemokine content was measured according to the manufacturer’s instructions. Briefly, array membranes were incubated in blocking buffer for 1 h at ambient temperature. Samples of medium were mixed with a cocktail of biotinylated detection antibodies before incubation at 4 °C with the array membranes. Following washing, membranes were incubated with streptavidin–horseradish peroxidase for 30 min at ambient temperature. Immunoreactive species were visualised using enhanced chemoluminescence. Positive and negative controls included in each membrane allowed quantitative analysis by densitometry, with results expressed as percentage change from control cultures.

Statistics. Data were analysed using either Student’s unpaired t-test or one-way analysis of variance (Graphpad Prism 5.0. Software, Graphpad Software Inc., La Jolla, CA, USA), followed by Bonferroni (for grouped) and Newman–Keuls (for all other analyses) post hoc tests. Differences were considered statistically significant when P < 0.05.

Conflict of Interest
The authors declare no conflict of interest.

Acknowledgements. Work in the authors’ laboratories is supported by funding from the Alzheimer’s Society, Medical Research Council, the Henry Smith Charity and the Wellcome Trust.
