We report a new measurement of the exclusive electroproduction reaction $\gamma^*_p \rightarrow \pi^0 p$ to explore the evolution from soft non-perturbative physics to hard processes via the $Q^2$ dependence of the magnetic ($M_{1+}$), electric ($E_{1+}$) and scalar ($S_{1+}$) multipoles in the $N \rightarrow \Delta$ transition. 9000 differential cross section data points cover $W$ from threshold to 1.4 GeV/c$^2$, a $\pi$ center-of-mass solid angle, and $Q^2$ from 3 to 6 GeV$^2$/c$^2$, the highest yet achieved. It is found that the magnetic form factor $G_M$ decreases with $Q^2$ more steeply than the proton magnetic form factor, the ratio $E_{1+}/M_{1+}$ is small and negative, indicating strong helicity non-conservation, and the ratio $S_{1+}/M_{1+}$ is negative, while its magnitude increases with $Q^2$.

The $\Delta(1232)$ resonance is the lowest and most prominent baryon excitation, and the $N \rightarrow \Delta$ transition has served as a prototype for testing theoretical models of baryon structure. For electromagnetic excitations in which the $\Delta$ decays into a pion and nucleon, the transition amplitudes are expressed in terms of multipole operators which for the $N \rightarrow \Delta$ transition are the magnetic $M_{1+}$, electric $E_{1+}$, and scalar $S_{1+}$ operators. Alternatively, the $N \rightarrow \Delta$ transition is expressed in terms of form factors $G_M^s, G_E^s$ and $G_C^s$.

The $Q^2$ dependence of the electromagnetic multipoles in the $N \rightarrow \Delta$ transition is sensitive to the evolution from soft non-perturbative physics to hard processes and perturbative QCD. At low $Q^2$, the small quadrupole deformation of the nucleon was long ago understood in the framework of the quark model, assuming the reaction is dominated by a single spin-flip of a constituent quark in a nearly spherical potential where $M_{1+}$ is dominant. The coupling of the pion cloud to the quark core and two body exchange currents may also contribute to the small values of the $E_{1+}$ and scalar $S_{1+}$ multipoles. At high $Q^2$, helicity conservation in pQCD requires $E_{1+} = M_{1+}$.

This Letter presents the results of a Jefferson Lab (JLab) experiment that extends the measurement of the electromagnetic $N \rightarrow \Delta$ transition to the highest momentum transfer yet achieved, in order to explore the transition region between these low and high $Q^2$ regimes. The unpolarized differential cross section for inclusive $\pi^0$ electroproduction has been obtained in the hadronic mass $W$ from threshold to 1.4 GeV/c$^2$, in four-momentum transfer $Q^2$ from 3 to 6 GeV$^2$/c$^2$, and solid angle $4\pi$ in the center-of-mass. The quantities $G_M^s, R_{EM} \equiv Re(E_{1+}/M_{1+})$ and $R_{SM} \equiv Re(S_{1+}/M_{1+})$, have been extracted from the measured cross sections using a unitary isobar model that takes into account all available data for the $\Delta$ and higher $W$ resonances from JLab and other laboratories.

In the one-photon-exchange approximation, the four-fold differential cross section of $\pi^0$ electroproduction can be factorized as

$$\frac{d^4\sigma}{dWdQ^2d\Omega_\pi} = \Gamma_\pi d^2\sigma/d\Omega_\pi^2,$$

where $\Gamma_\pi$ is the virtual photon flux and $d^2\sigma/d\Omega_\pi^2$ is the center-of-mass differential cross section for $\pi$ production by a virtual photon.

For the present experiment, an electron beam of energy of 5.75 GeV was incident on a 5.0-cm-long liquid hydrogen target. The CEBAF Large Acceptance Spectrometer CLAS was used to detect the scattered electrons and final state protons. Electrons were selected by a hardware trigger formed from the coincidence of signals from a threshold gas Čerenkov detector and an electromagnetic calorimeter. Multiwire drift chambers were used to reconstruct momenta by measuring particle tracks in the CLAS toroidal magnetic field. Plastic scintillators were used to record particle time of flight from the interaction point to the scintillators. From their known track length, particle velocities were computed and masses calculated using the measured momenta. Software analysis included geometrical and kinematic cuts to eliminate inefficient areas within the spectrometer. Backgrounds coming from $e^-/e^-$ contamination were suppressed using the energy response in the calorimeter and the sig-
functions are expanded up to $p^{1+}$ or $d^{1+}$ waves in Legendre polynomials, whose coefficients are related to the multipoles $11$. The magnetic dipole transition $|M_{1+}|^2$ is then assumed to dominate the $\pi^0$ production at the $\Delta$ pole, and only the terms interfering with $M_{1+}$ are retained. As the $\Delta$ resonance contribution to the cross section diminishes smoothly with increasing $Q^2$, the TME becomes less accurate because $M_{1+}$ dominance is no longer assured. Therefore, models that isolate the $\Delta$ amplitudes from the underlying backgrounds must be used.

The predominantly used approaches have been based on the effective Lagrangian expansions, which model the reactions in terms of meson and baryon degrees of freedom. MAID $13$, which is commonly used to characterize resonance amplitudes, is an isobar model approach for photo- and electroproduction data. Other elaborations of the effective Lagrangian are the Dynamical $14$, and DMT $15$ models, which couple the baryon core and the pion cloud. SAID $16$ is another approach often used to extract amplitudes from global data.

For the present case, the unitary isobar model (UIM) $7$, developed at JLab, was used. This model incorporates the isobar approach as in Ref. $12$. The non-resonant background consists of the Born term and

![FIG. 1: The Bethe–Heitler rejection. Left: $\phi_p^*$ vs $M_x^2$ for $W = 1.25 \text{ GeV}/c^2$. The cuts defined to reject the BH events are shown as solid curves and depend on $W$. The dotted line shows the $M_x^2$ distribution prior to the cut, the solid line is what remains after the cut, and the dashed line represents the events eliminated by the cut.](image1)

in the Čerenkov detector. The $p\pi^0$ final state was identified using a cut on the reconstructed missing mass ($M_x^2$) of the detected electron and proton. Figure 1 (left) shows the center-of-mass azimuthal angle of the proton $\phi_p^*$ versus $M_x^2$. The most prominent feature is the Bethe–Heitler radiative tail (BH) associated with elastic scattering. Since the BH events peak at $M_x^2 = 0$ and lie primarily in the electron scattering plane, they were suppressed by suitable cuts in the $M_x^2 - \phi_p^*$ plane. Figure 1 (right) shows the effects of the cuts on the $M_x^2$ distribution.

A Monte Carlo simulation based on GEANT3 $2$ was used to determine the acceptance of CLAS and to evaluate the efficiency of the BH cuts. Inelastic radiative losses were corrected for using the program EXCLURAD $10$, which provides a covariant treatment of both hard and soft photon radiation in exclusive electroproduction and does not rely on the peaking approximation.

Differential cross sections were obtained at 9000 kinematic points, binned as follows: 15 bins in $W$, 5 bins in $Q^2$, 10 bins in $\cos(\theta^*_\pi^0)$, and 12 bins in $\phi^*_\pi^0$. Cross sections are quoted at the center of each kinematic bin, and a correction was calculated to take into account non-linear dependencies of the cross section inside each bin. Systematic errors were estimated by varying the kinematic cuts, such as $M_x^2$, detector acceptance, particle identification and vertex reconstruction. Estimated uncertainties in the radiative and bin averaging corrections arising from their model dependence are also included. Figure 2 shows an example of the extracted cross sections as a function of $\phi^*_\pi^0$ for different $\cos(\theta^*_\pi^0)$ bins at $W = 1.25 \text{ GeV}/c^2$ and $Q^2 = 4.2 \text{ GeV}^2/c^2$.

In order to extract the $\Delta$ multipoles $M_{1+}$, $E_{1+}$ and $S_{1+}$, the truncated multipoles expansion (TME) was commonly used at low $Q^2$. In the TME, the structure functions are expanded up to $p$- or $d$-waves in Legendre polynomials, whose coefficients are related to the multipoles $11$. The magnetic dipole transition $|M_{1+}|^2$ is then assumed to dominate the $\pi^0$ production at the $\Delta$ pole, and only the terms interfering with $M_{1+}$ are retained. As the $\Delta$ resonance contribution to the cross section diminishes smoothly with increasing $Q^2$, the TME becomes less accurate because $M_{1+}$ dominance is no longer assured. Therefore, models that isolate the $\Delta$ amplitudes from the underlying backgrounds must be used.

![FIG. 2: The extracted virtual photon cross section as a function of $\phi^*_\pi^0$ for each $\cos(\theta^*_\pi^0)$ bin in the center-of-mass system at $W = 1.25 \text{ GeV}/c^2$ and $Q^2 = 4.2 \text{ GeV}^2/c^2$. The error bars are statistical, and the gray band at the bottom of each panel corresponds to the systematic. The solid curves represent the fit using UIM $7$. The fit was carried out utilizing 9000 such data points. Each $Q^2$ point was fitted separately.](image2)
The form factor $G_M^*/3G_D$. The filled squares are from the current CLAS experiment utilizing the UIM. The errors shown are statistical, while estimated systematic errors are shown as gray bars at the bottom of the graph. Also shown are selected earlier published results. The filled triangles correspond to a recent analysis of previous CLAS data [17, 13], and the filled circles are from an earlier JLab Hall C experiment [16, 11]. The curves are due to the following calculations. Dashed: dynamical model of Ref. [12]. Grey dot-dot-dash: full dynamical model of Ref. [14]. Black dotted: full dynamical model of Ref. [17]. Black dot-dot-dash: Light cone sum rule model of Ref. [20]. Dot-dash: MAID-2003 [13]. Grey solid: GPD model of Ref. [21].

the $t$-channel $\rho$ and $\omega$ contributions. To calculate the Born term the latest available measurements of the nucleon and pion form factors are used. Underlying tails from resonances such as the $P_{11}(1440)$, $D_{15}(1520)$ and $S_{11}(1535)$, which are modeled as Breit–Wigner shapes, are also incorporated. The total amplitude is unitarized using the K-matrix approach. The dependence of the extracted results on uncertainties in non-resonant and higher resonances contribution is included in the systematic errors. The results of the fit are given in Table I.

Figure 4 shows the extracted ratios $R_{EM}$ and $R_{SM}$. $R_{EM}$ is small and negative over the entire $Q^2$ range, indicating strong helicity non-conservation. $R_{SM}$ is negative and its magnitude increases as a function of $Q^2$. Our results suggest that the region of $Q^2$ where pQCD processes would be expected to be valid is higher than currently accessible. Adding to the controversy, Ref. [27] has suggested that pQCD can possibly be invoked without strict helicity conservation if orbital angular momentum flips are included into the perturbative reaction mechanism.

| $Q^2$ (GeV$^2$/c$^2$) | $100 \cdot G_M^*/3G_D$ | $R_{EM}$ (%) | $R_{SM}$ (%) |

![Graph showing the ratios $R_{EM}$ and $R_{SM}$](image)

**FIG. 4**: The ratios $R_{EM}$ (upper panel) and $R_{SM}$ (lower panel). The filled red squares are from the UIM fit to the current CLAS experiment. The errors shown are statistical, while estimated systematic errors are shown as gray bars at the bottom of the graph. The filled triangles at lower $Q^2$ are from an earlier JLab Hall C experiment [15, 19]. The open symbols are from the previously reported CLAS results [17]. The filled circle is from the current CLAS experiment. The errors shown are statistical, while estimated systematic errors are shown as gray bars at the bottom of the graph. The filled red squares are from the UIM fit to the current CLAS experiment. The errors shown are statistical, while estimated systematic errors are shown as gray bars at the bottom of the graph.

In summary, complete angular distributions for single $\pi^0$ electroproduction from protons are reported for a range of $Q^2$ from 3 to 6 GeV$^2$/c$^2$ and a range of $W$ from $\pi^0$ threshold to 1.4 GeV/c$^2$. The quantities $G_M^p$, $R_{EM}$, and $R_{SM}$ were extracted utilizing the isobar model [7]. The results indicate that the form factor $G_M^p$ decreases with $Q^2$ faster than the elastic magnetic form factor. $R_{EM}$ is small and negative, while $R_{SM}$ remains negative and increases in magnitude. These results confirm the absence of pQCD scaling at these kinematics and suggest large helicity non-conservation. They provide strong constraints on isobar-based effective Lagrangian models, or on approaches employing fundamental partonic degrees of freedom.
