The dephasing time of the lowest bright exciton in CdSe/ZnS wurtzite quantum dots is measured from 5 K to 170 K and compared with density dynamics within the exciton fine structure using a sensitive three-beam four-wave-mixing technique unaffected by spectral diffusion. Pure dephasing via acoustic phonons dominates the initial dynamics, followed by an exponential zero-phonon line dephasing of 109 ps at 5 K, much faster than the ∼ 10 ns exciton radiative lifetime. The zero-phonon line dephasing is explained by phonon-assisted spin-flip from the lowest bright state to dark exciton states. This is confirmed by the temperature dependence of the exciton lifetime and by direct measurements of the bright-dark exciton relaxation. Our results give an unambiguous evidence of the physical origin of the exciton dephasing in these nanocrystals.

The optical properties of excitons in colloidal semiconductor quantum dots (CQDs) of size comparable or smaller than the exciton Bohr radius have been the subject of intensive research since many years, also owing to the simplicity of colloidal synthesis and the consequent easiness to practically engineer CQD size, shape, composition and in turn quantum confinement [1]. One of the greatest hopes with these nanostructures is to achieve atom-like absorption/emission spectra and in turn ultra-long exciton coherence, attractive for applications ranging from cavity quantum electronics [2] to laser technology [3]. Among the various material types, CdSe CQDs were studied since early days [1]. Noticeably, their strong and spectrally wide absorption combined with a narrow and size-tuneable emission spectrum in the visible range has promoted their application as biolabels [4], and in photovoltaics, invigorating the interest in CQDs.

The excitonic level structure in CdSe CQDs has been treated theoretically [5] and is non-trivial. Due to the s-like conduction band, p-like valence band and the electron and hole spin, the envelop ground state contains 12 sub-levels. Spin-orbit coupling splits the p-like valence band according to the hole total angular momentum sub-levels. Spin-orbit coupling splits the p-like valence band and hole spin, the envelop ground state contains 12 s-like conduction band, p-like valence band and the electron-hole exchange interaction [5]. Assuming a shape which retains cylindrical symmetry around c, excitons levels are classified by the absolute value of the total angular momentum projection |F| along c. For large sizes and small or oblate ellipticity, the lowest exciton level is of heavy-hole character, two-fold degenerate and dark with |F| = 2 and lies few meV below a two-fold degenerate bright level with |F| = 1. Prolate (i.e. rod-shaped) shape asymmetry counteracts the crystal-field splitting in CdSe, eventually pushing the light-hole states below the heavy-hole states, and resulting in a lower dark F = 0 state, called 0^2, becoming the lowest level below the bright |F| = 1 level |2, 0⟩.

The dephasing time in turn the homogeneous linewidth of the lowest bright ground-state exciton level in wurtzite CdSe CQDs was first addressed experimentally by Schoenlein et al. [6] in 2-4 nm diameter nanocrystals using transient three-beam four-wave mixing (FWM) photon echo. Within the available dynamic range, an ultrafast dephasing of 85–270 fs was found at low temperature and attributed to acoustic phonon interactions. Subsequent spectral-hole burning (SHB) experiments [7] on larger CdSe/ZnS core/shell CQDs with 9 nm core diameter demonstrated a composite homogeneous lineshape with a sharp zero-phonon line (ZPL) of 6 μeV linewidth full-width at half maximum (FWHM) at 2 K, corresponding to 200 ps dephasing time, superimposed on a few meV broad band due to phonon-assisted transitions. Such a composite lineshape and a ZPL of ∼ 10 μeV at low temperature were confirmed by more recent studies on single CdSe/ZnS CQDs [10–12]. On the other hand, the radiative lifetime of the lowest bright ground-state exciton is ∼ 10 ns [12], indicating that even a 200 ps dephasing time is not radiatively limited. Single-dot PL as well as SHB experiments are affected by spectral diffusion, a variation of the CQD transition frequency over time from slow fluctuations of the CQD environment. It was thus speculated in those reports that the measured ∼ 10 μeV linewidth was limited by spectral diffusion and that a coherence lifetime of ∼ 100 ps was only a lower bound.

We previously demonstrated in self-assembled quantum dots that transient resonant FWM overcomes not only the inhomogeneous broadening in ensembles via the photon echo formation, but also spectral diffusion [14]. By combining directional selection with heterodyne detection we achieved shot-noise limited detection sensitivity and a large dynamic range [13]. In this work we have applied this technique to CdSe/ZnS CQD ensembles and, owing to its much greater dynamic range compared to

Ref. [7], resolved the ZPL dephasing of the lowest bright ground-state exciton level, not limited by spectral diffusion.

We investigated high-quality wurtzite CdSe/ZnS CQDs (Qdot655, Invitrogen), nominally identical to those used in Refs. [10, 11], with a room temperature PL peak emission wavelength at 655 nm (see Fig. 1b) and an average core size of 8 nm. High-resolution transmission electron microscopy shows that the dots are typically non-spherical with a rod-shaped core of \( \sim 5 \text{ nm} \) diameter and \( \sim 10 \text{ nm} \) length. The CQDs were dispersed in a polystyrene film and sandwiched between two quartz windows mounted onto a cold-finger cryostat. To preferentially excite the lowest bright ground-state excitonic absorption, the center wavelength of the exciting pulses was tuned below the PL emission at low temperature by an amount of the order of the Stokes shift (\( \sim 40 \text{ meV} \)) in these CQDs. We used a three-beam geometry, as sketched in Fig. 1b, where each beam is a train of 150 fs pulses with 76 MHz repetition rate. The first pulse \( (P_1) \) induces a coherent polarization in the sample, which after a delay \( \tau_{12} \) is converted into a density grating by the second pulse \( (P_2) \). The third pulse \( (P_3) \), delayed by \( \tau_{23} \) from \( P_2 \), is diffracted and frequency-shifted by this density grating which is moving in the heterodyne technique [12], providing the FWM field which is detected by its interference with a reference pulse of adjustable delay. In an inhomogeneously broadened ensemble the FWM signal is a photon echo emitted at \( \tau_{12} \) after \( P_3 \) and the microscopic dephasing is inferred from the decay of the photon echo amplitude versus \( \tau_{12} \). Conversely, the decay of the photon-echo amplitude versus \( \tau_{23} \) probes the exciton density dynamics [10]. We recently applied this technique to compare the dephasing time and exciton density dynamics in PbS CQDs [17]. To minimize selective excitation of linearly polarised transitions in the ensemble of randomly oriented CQDs, all pulses were co-circularly polarised.

The time-integrated FWM (TI-FWM) field amplitude is shown in Fig. 1c as a function of \( \tau_{12} \) for different temperatures. Measurements are taken for non-zero \( \tau_{23} = 1 \text{ ps} \) to avoid non-resonant nonlinearities. The time-averaged excitation intensity of \( \sim 60 \text{ W/cm}^2 \) per beam was well within the third-order nonlinear regime, and also resulted in negligible local heating as we affirmed by power-dependent measurements. Remarkably, the dephasing is initially very fast even at 5 K, but within the dynamic range of 3 orders FWM field corresponding to 6 orders FWM intensity a long mono-exponential dephasing time \( (T_2) \) is resolved at larger \( \tau_{12} \). With increasing temperature the initial dephasing becomes faster and more dominant, while simultaneously \( T_2 \) decreases. This behavior reflects in time domain the composite homogeneous lineshape consisting of a sharp Lorentzian ZPL (corresponding to the long exponential dephasing) superimposed onto a broad acoustic phonon band (the initial fast dephasing), also observed in self-assembled quantum dots [18]. It is due to the excitation of localized carriers, which distorts the lattice equilibrium and thus couples the optical transition with phonon absorption/emission processes similar to roto-vibrational bands in molecules.

With increasing temperature, it is expected that the weight of the ZPL (defined as the area fraction of the ZPL in the linear absorption spectrum) decreases and the width of the phonon band increases [18].

From the dynamics in Fig. 1c we have quantified in Fig. 2a the temperature dependence of the ZPL width \( \gamma_{\text{ZPL}} = 2h/T_2 \), the FWHM of the acoustic phonon band \( \Gamma_{\text{ph}} \), and the ZPL weight \( Z \), using the method discussed in Ref. [18]. \( \Gamma_{\text{ph}} \) is obtained by an exponential fit to the initial FWM decay which is an approximation since the phonon broadband is non-Lorentzian but is in qualitative agreement with what obtained by Fourier transforming the FWM dynamics [14]. Above 80 K the initial dephasing becomes faster than the pulse duration in the experiment hence the reported \( \Gamma_{\text{ph}} \) represents a lower bound. Besides the expected behavior of \( Z \) and the acoustic phonon band, we observe a decrease of \( \gamma_{\text{ZPL}} \)
with decreasing temperature. Importantly, the measured $T_2 = 109 \pm 2\, \text{ps}$ ($\gamma_{\text{ZPL}} = 12\, \mu\text{eV}$) at 5 K not limited by spectral diffusion clearly shows that the ZPL dephasing is far from the $\sim 10\, \text{ns}$ radiative limit, which raises the question of its physical origin.

It was shown in Ref. [13] by temperature dependent time-resolved PL in single wurtzite CdSe/ZnS CQDs that rapid thermalization occurs between the lowest bright and the lowest dark levels, following a three-level model as sketched in the inset of Fig. 2a. Within this model, after photoexcitation into the bright state (B) rapid phonon-assisted relaxation occurs into the dark state (D) with a low-temperature spin-flip rate $\gamma_0 \sim 10\, \text{ns}^{-1}$ which is much larger than the radiative recombination rate of the bright state $\gamma_B \sim 0.1\, \text{ns}^{-1}$. With increasing temperature, not only spontaneous emission but also stimulated emission and absorption of acoustic phonons with energy equal to the bright-dark splitting $\Delta E_D$ occurs with a rate $\gamma_{th} = \gamma_0 N_B$ where $N_B = 1/\{\exp(\Delta E_D/k_B T) - 1\}$ is the phonon occupation number. For $k_B T \ll \Delta E_D$ radiative recombination takes place mainly from the dark state with a long lifetime $(\gamma_D)^{-1} \sim 1\, \mu\text{s}$ [13]. For $k_B T \gg \Delta E_D$ thermalization between bright and dark states results in a higher occupation probability of the bright state. Exciton recombination therefore occurs from both levels and the total decay rate is the thermal average between the two rates. Since $\gamma_0 \gg \gamma_B$, such a spin-flip could be the origin of the non-radiatively limited $\gamma_{\text{ZPL}}$.

To prove this mechanism in our sample, we have first investigated the temperature dependence of the exciton decay rate by measuring FWM versus $\tau_{23}$ (see Fig. 2b). The probed exciton density exhibits a multi-exponential decay which we fit with three time constants in the sub-picosecond, hundreds of picoseconds and few nanosecond range (see inset of Fig. 2b). The first sub-picosecond time constant is attributed to a sub-ensemble of CQDs resonantly excited in the upper bright states, showing a rapid relaxation towards the lower states. This time constant is not temperature dependent up to 80 K, consistently with $\sim 20\, \text{meV}$ crystal field splitting [3] and correspondingly negligible phonon occupation up to 80 K. Such finding however implies that the initial dephasing in Fig. 1 might include this relaxation. To quantify this effect we have plotted in Fig. 2a the homogeneous broadening $\gamma_1$ resulting from the sub-ps relaxation from the upper-bright states. We find that $\Gamma_{th} > \gamma_1$ above 7 K indicating that the initial dephasing is dominated by the acoustic phonon broadening at these temperature. However at 5 K due to this contribution we could be underestimating the ZPL weight by about 10% (as deduced from the $\sim 30\%$ amplitude drop of the sub-ps density dynamics and the cubic relationship between FWM field and $Z$ [13]). The second time constant of $\sim 400\, \text{ps}$ found in the density dynamics is temperature independent and attributed to Auger recombination of charged excitons. The longest time constant, manifesting as pulse to pulse pile-up included in our fit, corresponds to a recombination rate $\gamma_r$ which increases with increasing temperature (see Fig. 2b), consistent with Ref. [13].

The three-level model sketched in the inset of Fig. 2a explains the temperature dependence of both $\gamma_{\text{ZPL}}$ and $\gamma_r$. In this model, the dephasing rate is given by $\gamma_{\text{ZPL}} = \gamma_B + \gamma_0 + \gamma_{th} + \gamma_U$ where $\gamma_0$ is the radiatively limited dephasing of the bright state, $\gamma_0 + \gamma_{th}$ is the spin-flip relaxation into the dark state via spontaneous and stimulated phonon emission, and $\gamma_U$ accounts for phonon absorption into an upper level. $\gamma_r$ is the thermal average of the radiative rates of the bright, the lower dark and the upper level with their occupation probabilities and degeneracy. By performing a combined fit of the measured temperature dependencies of $\gamma_{\text{ZPL}}$ and $\gamma_r$ we find that the dephasing rate is dominated by $\gamma_0 + \gamma_U$ while the stimulated emission term $\gamma_{th}$ is actually negligible up to 20 K (see dotted line in Fig. 2a) considering the bright-dark splitting

![Image](image_url)
\[ \Delta E_D = 2.0 \pm 0.2 \text{ meV} \]

The fit of the \( \gamma_{\text{ZPL}} \) we deduce \( \gamma_0 = 11 \pm 0.5 \text{ meV} \) (corresponding to 17 \( \text{ns}^{-1} \) spontaneous spin-flip rate) and a phonon absorption \( \gamma_\text{phon} \) with amplitude \( 130 \pm 40 \text{ meV} \) and activation energy \( \Delta E_\text{phon} = 2.2 \pm 0.3 \text{ meV} \). In prolate CQDs theory predicts \[ \Delta E_\text{phon} = 2.2 \pm 0.3 \text{ meV} \]

FIG. 3. a) TI-FWM field versus \( \tau_{23} \) for different \( \tau_{12} \) together with fits (dashed lines) to the dynamics. b) The additional time constant \( \tau_s \) (squares) inferred from the dynamics at \( \tau_{12} \neq 0 \) is compared with the measured ZPL dephasing time.

\[ \Delta E_0 = 2.0 \pm 0.2 \text{ meV} \]

The measured temperature dependence of \( \gamma_\tau \) is well described by \[ \gamma_\tau = (2\gamma_B + 2\gamma_D \exp(\Delta E_D/k_B T) + \gamma_D \exp(-\Delta E_U/k_B T))/(2 + 2 \exp(\Delta E_D/k_B T) + \exp(-\Delta E_U/k_B T)) \]

where for simplicity we have assumed the radiative rate of the dark state \( \gamma_D \) to be equal for the lower and upper dark levels. We find that the temperature dependence is dominated by the thermalization into the lowest dark state, hence the fit to the measured \( \gamma_\tau \) is mostly sensitive to the lowest bright-dark splitting \( \Delta E_D = 2.0 \pm 0.2 \text{ meV} \) with \( \gamma_B = 2.4 \pm 0.1 \times 10^{-1} \text{ ns}^{-1} \). Importantly, \( \gamma_B \ll \gamma_0 \), thus the zero-temperature extrapolated \( \gamma_{\text{ZPL}} \) is indeed \( \gamma_0 \) limited by the spin-flip rate.

To further verify this attribution we directly determined the bright-dark relaxation by measuring for \( \tau_{12} > 0 \) the FWM amplitude versus \( \tau_{23} \), which is sensitive to the density dynamics within the fine-structure since a spectrally modulated density grating is created. Specifically for the dark-bright relaxation, one can understand this as follows. At \( \tau_{12} = 0 \) the creation of an exciton by the \( P_1 \) and \( P_2 \) pulses makes the sample transparent to the probe \( P_3 \), since stimulated emission at the ground-state to bright exciton transition (0-B) and absorption at the exciton to biexciton transition (B-XX) compensate (note that the biexciton binding energy \( E_{\text{XX}} \) is smaller that the spectral width of the pulses). The exciton is in the dark state, the sample is also transparent to \( P_3 \) since both absorption and stimulated emission is forbidden. We are thus not sensitive to the dark-bright relaxation for \( \tau_{12} = 0 \). Conversely, for \( \tau_{12} > 0 \) the phase difference between the fields from the 0-B and B-XX transitions at the photon-echo time is \( \pi + E_{\text{XX}} \tau_{12}/\hbar \), resulting in exciton-biexciton beats versus \( \tau_{12} \). We indeed observe weak oscillations in the TI-FWM versus \( \tau_{12} \) with a modulation period in the 3-6 ps range. In particular for \( \tau_{12} \) equal to half the exciton-biexciton beat period, 0-B and B-XX fields interfere constructively, as opposed to the destructive interference at \( \tau_{12} = 0 \). A spin-flip into a dark level instead reduces the field to zero. A bright-dark relaxation thus manifests as a decrease in the FWM signal versus \( \tau_{23} \), most pronounced for \( \tau_{12} \) equal to half the exciton-biexciton beat period. In Fig. 3 the measured FWM amplitude versus \( \tau_{23} \) at 10 K is shown for three different values of \( \tau_{12} \), and the dashed lines are fits using a bi-exponential decay, plus an offset accounting for the long radiative lifetime. The bi-exponential decay consists of a new time-constant (\( \tau_s \)) present only for \( \tau_{12} > 0 \), and the 400 ps time constant previously discussed. We see that the effect of \( \tau_s \) is most pronounced for \( \tau_{12} = 1.5 \text{ ps} \) and we can consistently fit all dynamics for \( \tau_{12} \neq 0 \) with \( \tau_s = 27 \pm 7 \text{ ps} \) at 10 K. This spin-flip time is in very good agreement with the density lifetime \( \tau_{23}/2 \) deduced from the measured ZPL dephasing, as shown in Fig. 3b.

Similar measurements carried out at 15 K confirm this agreement.

In conclusion, we have shown that the intrinsic zero-phonon line dephasing of the ground-state exciton in CdSe/ZnS wurtzite colloidal quantum dots is limited even at low temperatures by the radiative (\( \sim 100 \text{ ps} \)) spin-flip from the lower bright to dark exciton levels. This finding is different from InGaAs self-assembled quantum dots, where the bright-dark exciton relaxation is longer than the radiative lifetime and the exciton dephasing is radiatively limited. Our results conclusively resolve the long standing question of the physical origin of the ZPL broadening in CdSe/ZnS quantum dots.

We acknowledge discussions on the excitonic fine structure with Iwan Moreels at Ghent University (Belgium).
