The large scale anisotropies of WMAP data have attracted a lot of attention and have been a source of controversy, with many of favourite cosmological models being apparently disfavoured by the power spectrum estimates at low $\ell$. All of the existing analyses of theoretical models are based on approximations for the likelihood function, which are likely to be inaccurate on large scales. Here we present exact evaluations of the likelihood of the low multipoles by direct inversion of the theoretical covariance matrix for low resolution WMAP maps. We project out the unwanted galactic contaminants using the WMAP derived maps of these foregrounds. This improves over the template based foreground subtraction used in the original analysis, which can remove some of the cosmological signal and may lead to a suppression of power. As a result we find an increase in power at low multipoles. For the quadrupole the maximum likelihood values are rather uncertain and vary between 140-220$\mu$K$^2$. On the other hand, the probability distribution away from the peak is robust and, assuming a uniform prior between 0 and 2000$\mu$K$^2$, the probability of having the true value above 1200$\mu$K$^2$ (as predicted by the simplest $\Lambda$CDM model) is 10%, a factor of 2.5 higher than predicted by WMAP likelihood code. We do not find the correlation function to be unusual beyond the low quadrupole value. We develop a fast likelihood evaluation routine that can be used instead of WMAP routines for low $\ell$ values. We apply it to the Markov Chain Monte Carlo analysis to compare the cosmological parameters between the two cases. The new analysis of WMAP either alone or jointly with SDSS and VSA reduces the evidence for running to less than 1-$\sigma$, giving $\alpha_s = -0.022 \pm 0.033$ for the combined case. The new analysis prefers about 1-$\sigma$ lower value of $\Omega_m$, a consequence of an increased ISW contribution required by the increase in the spectrum at low $\ell$. These results suggest that the details of foreground removal and full likelihood analysis are important for the parameter estimation from WMAP data. They are robust in the sense that they do not change significantly with frequency, mask or details of foreground template marginalization. The marginalization approach presented here is the most conservative method to remove the foregrounds and should be particularly useful in the analysis of polarization, where foreground contamination may be much more severe.

I. INTRODUCTION

Data analysis of cosmic microwave background maps is a challenging numerical problem. The question that we want to answer is the probability (or likelihood) of a theoretical model given the data. In order to evaluate the exact likelihood of a theoretical power spectrum of CMB fluctuations given a sky map of these fluctuations it is necessary to invert the theoretical covariance matrix. This operation scales as $O(N^3)$, where $N$ is the length of the data vector and is currently limited by practically available computer technology to $N \lesssim 10^4$. One is hence forced to use approximate estimators when inferring the power spectrum from data such as WMAP satellite \cite{WMAP}, which have 1-2 orders of magnitude more independent measurements. The most popular methods are the pseudo-Cl (PCL) method (see e.g. \cite{PCL}) and the Quadratic Maximum Likelihood (QML) estimator (see e.g. \cite{QML}). Both of these methods produce as an intermediate step estimates of multipole moments $C_\ell$ and approximate methods have been developed to describe their probability distributions as accurately as possible \cite{APPQML}. These perform satisfactorily for high $\ell$ values, where the central limit theorem guarantees a Gaussian distribution (in offset lognormal transformed variables) will be a good approximation. Unfortunately, these methods are much less reliable at low multipoles, where the distributions are not Gaussian. The situation is complicated further by the masks applied to the data to remove the galactic foreground contamination and by the marginalization of unwanted components, all of which makes analytic approach unreliable. In \cite{APPQML} it was suggested to use a hybrid approach using QML on degraded maps at low $\ell$ and PCL at higher multipoles.

The issue of the exact values of multipole moments in WMAP data has attracted much attention since the original analysis by WMAP team \cite{WMAP}. Several unusual features have been pointed out already in the original analysis. One of these was the correlation function, which appears to almost vanish above 60$^\circ$. Another was the low value of the quadrupole. With the PCL analysis the value of the quadrupole was found to be $\sim 123\mu$K$^2$, com-
pared to the expected value of $\sim 1200\mu K^2$ for the simplest $\Lambda CDM$ model. The probability for this low value was estimated to be below 1%, depending on the parameter space of models. The discussion of the statistical significance of the low values of quadrupole and octopole in the WMAP data [16] has sparked a renewed interest into the so called estimator induced variance [12] - the error in the likelihood evaluation arising due to the use of an estimator rather than the exact expression. In [12] it has been argued that QML estimator performs significantly better than the PCL estimator and that the true value of the quadrupole probably lies in the range around $170-250\mu K^2$. However, only the maximum likelihood value was computed and not the full likelihood distributions so the statistical significance of this result and its effect on the parameter estimation remained unclear. In addition, the role of foregrounds and monopole/dipole removal has not been explored in detail.

In this paper we take a different approach. We argue that the actual value of the best fitted quadrupole (and other multipoles) is not of the main interest, since it can be quite sensitive to the details of the foreground subtraction procedure, type of mask used and numerical details of the analysis (in fact, the various values proposed so far may even be statistically indistinguishable if the likelihood function at the peak is very broad). What is more important is the probability or likelihood of a model given the data, compared to another model that may, for example, fit the data better. This is encapsulated in the likelihood ratio between models and within the Bayesian context is the only information we really need to assess the viability of cosmological models that belong to a certain class. In this paper we perform the exact likelihood calculation by a direct inversion of the covariance matrix for the low resolution maps, thus eliminating all the uncertainties related to estimator variance approximations. Since we use low resolution maps with less than 3000 pixels we can do the inversions with a brute force linear algebra routines. This means we cannot do the analysis on all of the multipole moments, so we analyse low multipoles with the exact method and use PCL analysis for the higher multipoles, where the two methods agree with each other and where the approximate variance estimates developed for PCL analysis are likely to be valid.

Second issue we wish to address in this paper is the question of foreground subtraction. This is done in two steps. First, pixels with high degree of contamination are completely removed from the data. This results in the so called KP2 (less aggressive, 85% of the sky) and KP0 (more aggressive, 75% of the sky) masks [10]. There remains contamination even outside these masks in individual frequency channels. This contamination can be further reduced using templates and/or frequency information [10]. In WMAP analysis the templates were fitted for and subtracted out of WMAP data. Even with a perfect template there is a danger that this procedure can oversubtract the foregrounds, since one is essentially subtracting out the maximum amplitude consistent with the template which could include some of the signal. Instead, here we do not subtract out the templates, but marginalise over them by not using any information in the data that correlates with a given template. This procedure has not been applied to WMAP data in previous analyses. It guarantees that there is no statistical bias caused by the foreground removal.

Some of the templates that were subtracted in WMAP analysis, particularly 408MHz Haslam synchrotron radiation map [14], are of poor quality. WMAP produced a better set of templates applying Maximum Entropy Method (MEM) to WMAP maps in several frequency channels using templates as priors only [13]. In addition to the Haslam synchrotron map, they used [12] H-α map as a tracer of free-free emission and the SFD dust template based on [16]. This process resulted in three MEM derived foreground maps. These, however, were not used to infer the power spectrum. Instead, the official power spectrum was determined from the integrated single frequency maps and the same templates that were used as priors for the MEM map making procedure, ignoring the MEM derived maps.

The MEM derived maps are likely to be the most faithful representation of the foregrounds. When used in power spectrum inference, however, they must be used with care due to complicated nature of their signal and noise correlations [13]. Nevertheless, on the largest scales, where receiver noise is negligible, they are probably the best available option. We therefore use the integrated single channel maps and the MEM derived foreground templates as a basis of our work. Note that in foreground marginalization procedure no template is actually removed from the data and there is no danger of introducing noise correlations that could significantly affect the power spectrum estimates. We perform this process on foreground unsubtracted maps of the V and W channels of the WMAP satellite. We use both KP2 and KP0 masks and project out the remaining galactic contamination using MEM inferred maps of dust, synchrotron and free-free foregrounds. We use the likelihood evaluated in this way to assess the statistical significance of departure from the concordant model at low multipoles and to perform the statistical analysis of cosmological models given the data.

WMAP team also produced the so called Internal Linear Combination (ILC) map of the CMB emission, by using internal maps at various frequencies to decompose them into CMB and foreground components. This approach is not based on any templates and so uses less information than in principle available. While visually these maps appear to be relatively free of contamination outside the galactic plane, there are still artifacts within the plane. This means that one must be careful when projecting out monopole and dipole: one should not simply remove them from the all-sky map, since they could be contaminated by galactic emission at the cantor and this would leave a residual offset outside the galactic plane, which could contaminate all of low multipoles.
One must again apply the marginalisation over monopole and quadrupole on the masked map to eliminate any contamination in the final result. A similar approach has been taken by [17] and [18], who produced their own versions of ILC maps. Since we argue that the best method is to use single frequency maps together with correct templates and we use ILC map for illustration and cross-check purposes only, we do not consider these alternative ILC solutions further.

II. METHOD

A. Likelihood evaluation

Given noise-less and independent measurements of the CMB sky \( \mathbf{d} \), the theoretical covariance matrix for these measurements is given by [19]

\[
C_{ij} = \sum_{\ell=2}^{\infty} \frac{2\ell+1}{4\pi} C_{\ell} P_\ell(\cos \theta_{i,j}),
\]

(1)

where \( C_{\ell} \) is the power spectrum, \( P_\ell \) is the Legendre Polynomial of order \( \ell \) and \( \theta_{i,j} \) is the angle between \( i \)th and \( j \)th point on the sky. We also define

\[
C_{\ell} = \frac{C_\ell(\ell+1)}{2\pi},
\]

(2)

which is the quantity that is conventionally plotted (and often referred to) as the power spectrum.

In addition to the covariance matrix in equation (1) we want to project out linear components of the data vector that correspond to known contaminants in our data. Fortunately, there exist a standard procedure for this [20]: the covariance matrix of the contaminant is calculated and added to the theoretical covariance matrix with a very large variance. Here the covariance matrix of the template is given by \( C = \left\langle LL^T \right\rangle \), where \( L \) is the template vector. Using this method, we project out the map’s monopole, dipole and the known galactic contaminants, namely dust, synchrotron and the free-free emission. For completeness we add the diagonal noise component \( N_{ii} = \sigma_i^2 \), although this is not strictly required for this analysis, because the noise power spectrum is less than \( 10 \mu \text{K}^2 \) on scales of our interest.

Hence, the total covariance matrix can be written as

\[
C_{\text{total}} = C + N + \lambda (C_{\text{dust}} + C_{\text{synch}} + C_{\text{free-free}} + C_{\ell=0} + C_{\ell=1}).
\]

(3)

The value of \( \lambda \) in the above equation must be large enough so that unwanted components are projected out. If it is too large, however, the numerical errors start to affect the results.

The logarithm of likelihood of given \( C_{\text{dust}} \)s can then be written as

\[
\log L = -\frac{1}{2} \mathbf{d}^T (C_{\text{total}})^{-1} \mathbf{d} - \frac{1}{2} \log |C| + N \log 2\pi,
\]

(4)

where \( \mathbf{d} \) is the data vector. To evaluate the likelihood of a given theoretical model we simply evaluate this expression, computing the covariance matrix using the theoretical model spectrum \( C_\ell \) in equation (1).

B. Choice and preparation of maps

As mentioned in the introduction the procedure described above can realistically be performed only on modestly sized maps. We decrease the resolution of a given map using the following procedure: Firstly, the full resolution source map is multiplied by the mask, whereby every masked pixel is zeroed, while unmasked remains the same. The map is then smoothed by the 5° FWHM Gaussian beam and resampled at a lower Healpix resolution (\text{nside}=16), giving 3072 roughly independent pixels on a full-sky map. The mask itself is smoothed in the same manner and this gives us information by how much the smoothed pixels that were affected by the mask need to be up-scaled. We do not use pixels whose smoothed mask value drops below 0.7. We use this information to reduce the effective scale of smoothing beam (by square root of this correction) in the calculation of covariance matrix, although we verified that this does not affect any of the final results.

We have also attempted an exact calculation of the window function treating each subpixel of a low resolution Healpix map separately. Unfortunately, this is computationally prohibitively expensive. Instead, we have performed weighted averaging within each low-resolution Healpix pixel using the effective Healpix window function with the package and get compatible results. We chose not to adopt this approach for the main analysis since the individual Healpix pixel windows are anisotropic, depend on the mask and are very slowly dropping off with \( \ell \). For our resolution level the effective windows (which are only valid for full sky coverage) are only given up to \( \ell = 64 \) and there is still a lot of power beyond that.

The gaussian smoothing procedure is used on WMAP integrated maps for V and W channels and for the MEM maps for the three major foregrounds: Dust, Synchrotron and Free-Free emission. In all cases, the low resolution maps were produced for the KP2 mask and for the more conservative KP0 mask. We also applied the same procedure to the ILC map, except that in this case we smooth over the whole map and so do not need to upscale the pixel values by the effect of the mask. By changing various parameters of the inversion process we get consistent likelihoods and we estimate the uncertainty in likelihood evaluation to be about 0.2 in logarithm of the likelihood.
III. MULTIPOLE MOMENTS AND THEIR STATISTICAL SIGNIFICANCE

In figure 1, we show the maximum likelihood (ML) values of the multipoles up to \( \ell = 18 \) for several of our basic cases. One can see from this figure that most of the estimates up to \( \ell \sim 10 \) are above the PCL values given by WMAP team, while at higher multipoles the two agree well (\( \ell = 11 \) appears anomalous and PCL gives a much higher value than the exact likelihood analysis). Some of the differences are due to random fluctuations: KP2 mask contains 85% of the sky compared to 75% for KP0 and this can lead to differences in the two estimates. Similarly, projecting out the foreground templates reduces the amount of information, so there can be statistical differences between our analysis and the one without marginalization. While the differences between KP0 and KP2 masks are likely to be within the allowed range of statistical fluctuations, this is less likely for the differences between WMAP-PCL and our analysis of V with KP2 mask, since the same mask and channel have been used by WMAP. The difference is partly due to the use of the exact likelihood analysis and partly due to the foreground marginalization. While WMAP team marginalized over monopole and dipole, they subtract out the foregrounds with the maximal amplitude, which may have removed some of the true cosmological signal and pushed the values lower. To eliminate the bias that can arise from this procedure it is best to exclude the information in the signal that correlates with templates and with monopole/dipole. This reduces the statistical power, but is guaranteed to be unbiased.

To investigate further the robustness of our results figure 2 shows the most likely values of power spectra (up to multipole \( \ell = 10 \)) for various combinations of template choice for W channel data and for the ILC map. This realistically indicates potential systematic differences arising due to choice of templates. On the same graphs we also show the reduction performed with Healpix window functions (where pixels of the low-resolution map were only weighted averages of all corresponding pixels in the high-resolution map), indicating that our results are robust with respect to choice of window function and smoothing procedure. The differences between the various cases are small compared to the difference between exact evaluations and WMAP values. We emphasize that ML values are the least robust part of the analysis and it is much more important that the probability distributions away from the peak are consistent. For quadrupole we discuss this below, while the overall impact on the cosmological parameter estimation is discussed in next section.

Marginalisation procedure is guaranteed to give unbiased results independent of the form of the template or its nongaussian properties. The only assumption is that the template is not correlated with the true CMB, which could happen if the templates are produced from the CMB data itself and were affected by noise, calibration or beam uncertainties. It is unlikely that this would happen on large scales. We have tested this hypothesis by using the external templates instead of MEM templates, without finding much differences in the result (figure 3).

Figure 3 shows the probability distribution for the value of \( C_2 \) for several cases, assuming best fit \( \Lambda \)CDM model for other \( C_i \)s. Particular choice of other \( C_i \)s affects the inferred curves, although at a level below the variance between various curves. It has several interesting features. Firstly, when all marginalizations are used, the V channel, W (not shown) and ILC give very consistent results. In the absence of marginalization and foreground subtraction the V and W channel maps are very affected by foregrounds and ML values reach up to 500\( \mu \)K\(^2\). The ILC map could be affected by the foreground marginalization: its value drops from \( \sim 220\mu \)K\(^2\) (consistent with [12]) to \( \sim 170\mu \)K\(^2\) when projection is included in analysis. The ILC map may suffer even more from the residual monopole / dipole contamination, which pushes the quadrupole value up.

While our procedure of marginalising over 3 templates is the most conservative, one may worry that it is unnecessary. Some of the channels are not really strongly contaminated by all 3 components and if frequency scaling is known then multi-frequency information can be used to constrain a given component in a given channel. While there is nothing wrong with our procedure one could argue that it reduces the amount of information. The number of eliminated modes is roughly given by the number of templates used, but since the templates are correlated (being all dominated by our galaxy) the information loss from large scale modes is likely to be less than 3. It is also not clear how the templates couple to different multipoles. To test these effects we perform the analysis in W channel, where foreground contamination is dominated by dust. We use marginalization only over SFD dust template (subtracting out the free-free component and doing nothing for synchrotron). We find this has very little effect on the maximum likelihood values of multipoles, as shown in figure 2. For \( \ell = 2 \) we find ML value at 220\( \mu \)K\(^2\), slightly higher than in other cases (figure 4), but the overall probability distribution is very similar to other cases. The effect of this procedure on the parameter estimation is explored in the next section.

It is interesting to assess the statistical significance of the departure of the lowest multipoles from the concordant model. Our focus is not on the actual statistical procedure of assessing this departure (see e.g. [8]), but on the effect of estimator induced variance. We consider 5 cases: all possible combinations of the choice of mask (KP2 or KP0) and frequency (V channel or W channel) and the official WMAP likelihood code [22]. The inferred maximum likelihood values (figure 4) lie in the range 140\( \mu \)K\(^2\) - 220\( \mu \)K\(^2\), but the likelihood function is broad at the peak and the exact value of the maximum likelihood estimate is driven by small details in the analysis: in all of our basic cases the likelihood is within 10-20% of the peak value over the range (120-250)\( \mu \)K\(^2\).
FIG. 1: This figure shows the maximum likelihood power spectrum for several combinations of frequencies and masks. Note that all spectra agree reasonably well beyond $\ell = 11$.

FIG. 2: This figure shows the maximum likelihood power spectrum up to $\ell = 10$ for several test cases. The derived features in the most likely values of power spectrum are robust with respect to choice of window function (gaussian versus healpix), templates (MEM versus external, dust only versus standard 3 templates in W) and maps (W versus ILC).

Thus our results are consistent both with the original WMAP value (123$\mu$K$^2$) and the values in [12] and there is no “correct” value given the level of foreground contamination.

As we argued in introduction, the precise value of maximum likelihood estimator is not of primary interest, given that it can be strongly affected by the details of the analysis. Much more important for the question of parameter estimation is the shape of the likelihood function. Figures 3-4 shows that while the maximum likelihood value of the quadrupole is quite uncertain, all of our cases give very similar shapes of the likelihood function. This likelihood distribution is not consistent with the likelihood provided by WMAP team, which appears to underestimate the errors associated with the galactic cut and marginalizations. The WMAP likelihood of the concordant model $C_2 (\sim 1200 \mu K^2)$ is roughly 2.5 times too low with respect to the most likely point when compared to our likelihood values. This change in the shape of the likelihood function affects the parameter estimation, particularly the running of the spectral index, as shown in section IV. We note here that not performing the marginalization over foregrounds and/or monopole/dipole would lead to an even higher probability of concordance model compared to low $C_2$ models (see the corresponding probability distributions in figure 3), but these are more likely to be contaminated and should not be used in the likelihood analysis.

Figure 5 shows the integrated probability as a function of the true value of the quadrupole (integrated from large values downward), under the assumption that the prior distribution of quadrupole values is uniform between 0 and 2000$\mu$K$^2$. This prior is adopted due to the fact that the concordance value of quadrupole is $\sim 1000 \mu K^2$ (see e.g. [8]). This gives the probability of the true value exceeding $C_2$ assuming this prior. We find that this probability is around 10%, as opposed to 4% by the WMAP likelihood analysis. Thus with uniform prior on values of $C_2$ the probability of the true quadrupole to be above that predicted by the concordance model is not particularly small. It becomes even larger if the upper limit at 2000$\mu$K$^2$ is removed, in which case we find 18% probability of the true value exceeding the concordance value.

Note that WMAP team chose to give the statistical significance of the low quadrupole in terms of number of random realizations of theoretical models in Monte Carlo Markov Chains (MCMC) for which the extracted
quadrupole is lower than the observed value of 123\(\mu K^2\). This is a frequentist statistic which cannot be directly compared to the one we defined here in the context of Bayesian statistics. The frequentist approach leads to lower numbers (less than 1%, compared to 4% above) for the specific value of the quadrupole obtained by WMAP, but the probability is likely to be higher if our analysis procedure was applied to the data given our broader likelihoods and higher values of the best fitted quadrupole. The WMAP analysis does not include the uncertainties in the foreground subtractions, which should have an important effect given the skewed nature of the probability distributions: if an error estimate of 50\(\mu K^2\) on \(C_2\) were added to the measured value it would lead to an increased probability of concordance model. In order to truly decouple the cosmic variance uncertainty for the errors arising from the galactic cut and foregrounds one would need to infer the probability distribution for a particular realisation of \(a_{lm}\)'s. For a full-sky CMB observation with no galactic contamination, this would be a delta function; galactic cut and large scale contamination would spread the probability over a finite region. This distribution, marginalised to produce \(p\left(\langle a_{lm}^2\rangle_m\right)\) would be the correct quantity that must be compared to the concordant value and the corresponding cosmic variance. Work on this front is currently in progress.

While the frequentist approach does allow one to test a model (or a class of models) independent of other models, it is still not free of assumptions. Testing the quadrupole on its own only makes sense if we believe that there is something special about it, for example because it is sensitive to the physics on the largest scales, which may not be probed by lower multipoles. If it is not viewed as special, but only one of the many estimated multipoles, then the probability of one of them being this low is significantly higher. This is tested in the frequentist approach with the goodness of fit (\(\chi^2\)), which for WMAP does not reveal any particular anomalies. Unfortunately there is no hope to resolve these statistical questions completely with only one observed sky.

In figure 6 we plot the contour plots of parameters on the \(C_2-C_3\) plane for the considered models. This shows that the likelihoods between \(C_2\) and \(C_3\) are only weakly correlated, both for exact likelihood evaluation as well as for the PCL approximation. In original analysis there was some evidence for both \(C_2\) and \(C_3\) being low, so that the overall significance was between 2 – 3\(\sigma\) (figure 6). The evidence for discrepancy weakens below 2\(\sigma\) with our analysis and is consistent among the four cases.

WMAP team presented further evidence of unusual nature of large scale correlations using the correlation function, which appears to vanish on angles above 60° [7]. Correlation functions are notoriously difficult to interpret due to the correlated nature of the values at different angles, so one must be careful not to over-interpret such results. In figure 7 we show the correlation function analysis for these cases, compared to the original WMAP analysis and to theoretical predictions of \(\Lambda CDM\) model.

FIG. 4: This figure shows the probability distributions for the value of \(C_2\) as inferred for the various combinations of the selected channel and mask and the official WMAP likelihood code. The upper panel shows the normalised probability distribution, while the lower panel shows the probability relative to the most likely point. Note that the lower panel’s vertical axis is logarithmic. Values of other \(C_\ell\)s were set to those of the best fit \(\Lambda CDM\) model.

FIG. 5: Cumulative probability as a function of the true value of the quadrupole (integrated from large values downwards assuming \(0 < C_2 < 2000\mu K^2\)).
FIG. 6: In this figure we show the probability distribution function on the $C_2$-$C_3$ plane for all considered possibilities and the original WMAP likelihood code. Contours correspond to the one, two, three and four sigma assuming top-hat priors on the plotted limits ($0 < C_2 < 1500\mu K^2, 300 < C_3 < 1800\mu K^2$). The dashed circles correspond to the approximate values of the concordant model.

We also show the result for the $\Lambda CDM$ model where $C_2$ has been lowered to $150\mu K^2$, keeping the other multipoles unchanged. Several features are apparent from this figure. First, theoretical predictions for large scale correlation function are largely driven by the quadrupole and lowering its value to $150\mu K^2$ brings the correlation function into a significantly better agreement with the observations than the unmodified $\Lambda CDM$ model. Second, our results significantly modify the predicted correlation function and the deviations from zero on large angles are now much more evident, both in the positive direction and in the negative direction at very large angles. To investigate it further WMAP team introduced a statistic $S = \int_{1}^{0.5}[C(\theta)]^2d\cos \theta$. This is a posteriori statistic that was designed to maximise the effect, so its statistical significance is difficult to evaluate. We find that its value increases from 1691 for WMAP analysis to 4197 (W KP0), 5423 (V KP0), 9086 (V KP2), 7698 (W KP2) and 5832 (W KP2, dust marginalization only). While its value for standard $\Lambda CDM$ model is 49625, reducing the quadrupole to $150\mu K^2$ changes this to 8178, below the value we find in the case of V KP2. We conclude that there is no obvious anomaly in the correlation function beyond the fact that the quadrupole is low and there is no evidence of the correlation function vanishing on large angles.

IV. PARAMETER ESTIMATION

In order to assess the effect of the exact likelihood evaluations on the inferred cosmological parameters we have run the Markov Chain Monte Carlo parameter estimations using the original WMAP likelihood code and the code modified to use the exact calculations at lowest multipoles. The total likelihood was calculated by evaluating the likelihood for the $\ell \leq 12$ multipoles using the exact matrix inversion and adding the likelihood evaluated from the remaining multipoles using the WMAP likelihood code. The power spectrum values for the multipoles $\ell > 12$ in the exact likelihood code were kept at the WMAP PCL most likely model when calculating the covariance matrix: this ensures that the likelihood is not “accounted for” twice. We also neglect the anti-correlation between $\ell = 12$ and $\ell = 13$ modes at the boundary. The evaluation of the exact likelihood typically takes around a few seconds on a modern workstation and this is less than the time it takes to evaluate a theoretical CMB power spectrum with CMB-FAST [23]. Therefore, using the exact likelihood code
does not slow down the MCMC parameter estimation significantly. Each of the chains described below contains 100,000-200,000 chain elements, the success rate was of order 30-60%, correlation length 10-30 and the effective chain length of order 5,000-15,000. We use 8-24 chains and in terms of Gelman and Rubin $R$-statistics we find the chains are sufficiently converged and mixed, with $R < 1.01$, compared to recommended value $R < 1.2$ or more conservative value $R < 1.1$ adopted by MCMC team.

The likelihood also uses the information contained in the polarization-temperature (TE) cross-correlation power spectrum using the official WMAP likelihood code, which uses similar approximations as temperature power spectrum and completely ignores correlations between TT and TE power spectra. We cannot yet use the exact evaluations since the polarization maps are not publicly available at this time.

We ran several MCMCs using a custom developed software described in. We consider only flat models. We begin with the simplest 5-parameter models

$$p = (\tau, \omega_b, \omega_{cdm}, R, \Omega_m),$$

(5)

where $\tau$ is the optical depth, $\omega_b = \Omega_b h^2$ is proportional to the baryon to photon density ratio, $\omega_{cdm} = \Omega_{cdm} h^2$ is proportional to the cold dark matter to photon density ratio, $\Omega_m = \Omega_{cdm} + \Omega_b = 1 - \Omega_\Lambda$ is the matter density today and $R$ is the amplitude of curvature perturbations at $k = 0.05$/Mpc (we replace this parameter with $\sigma_8$ in table 1). To reduce the degeneracies we use $\omega_b$, $\omega_{cdm}$, angular diameter distance $\theta_A$, $\ln R$ and $\ln (R - \tau - 0.5 \log(\omega_b + \omega_{cdm})$ instead of parameters in equation (5) adopting broad flat priors on them. Most of these priors are not important because the parameters are well determined. The exception is optical depth, for which we additionally apply $\tau < 0.3$ on some of MCMCs following WMAP team.

The simple 5-parameter model is sufficient to obtain a good fit to the WMAP data. We add CBI+ACBAR to the WMAP data and follow WMAP team in denoting this dataset as WMAPext. Second set of MCMCs we ran was also based on WMAPext data, but with an expanded set of parameters which include primordial slope $n_s$, its running $\alpha_s = dn_s/d\ln k$ and tensors (parametrised with $r = T/S$), adopting flat priors on these parameters. Adding these 3 parameters only improves $\chi^2$ by 5, so they are not really needed to improve the fit to the data. Because of this we find significant degeneracies among many of the parameters. The best fitted values are not necessarily very meaningful and they could be significantly influenced by the assumed priors, but we can still compare the changes between the new and original analysis. Third set of MCMCs was based on the combined WMAPext+SDSS analysis which breaks some of these degeneracies. Last set of MCMCs was based on WMAP+VSA, both with and without SDSS. We remove $\tau < 0.3$ constraint for this case. The results are shown in tables 1-2.

A. Matter density

In 5-parameter chains $\Omega_m$ is the parameter that changes most by the new analysis. Its probability distribution from various MCMCs is shown in figure 8. This parameter is not well determined from the CMB data, since it only weakly affects the positions of acoustic peaks in a flat universe. This leaves the integrated Sachs-Wolfe effect on large scales as an important way to constrain $\Omega_m$: reducing $\Omega_m$ leads to a decay in the gravitational potential, which increases the contribution to the large scale anisotropies from the line of sight integration of the time derivative of gravitational potential. Increase of the low multipoles by our analysis (figure 8) thus requires a lower value of $\Omega_m$ to fit the data. This is more prominent for KP2, where the best fit value is $\Omega_m = 0.24^{+0.07}_{-0.05}$, than KP0 which gives $\Omega_m = 0.26^{+0.07}_{-0.06}$, but the latter contains less area and its error distribution is slightly broader. Lower $\Omega_m$ values are also preferred in the joint WMAPext+SDSS analysis, but here the SDSS data tend to push the overall up to $\Omega_m = 0.27^{+0.05}_{-0.03}$. In these 8 parameter chains the WMAP $\chi^2$ is higher by about 5 compared to the WMAP without SDSS. Thus there is a bit of a tension between the SDSS data, favouring high $\Omega_m$ and the WMAP data favouring low values of this parameter, although the statistical significance of this tension is low. For low $\Omega_m = 0.24$ the Hubble parameter is $h = 0.75$, still in agreement with the HST key project value of $h = 0.72 \pm 0.08$. If we eliminate tensors from the analysis then we find $\Omega_m = 0.30^{+0.06}_{-0.05}$ for WMAP+SDSS+VSA combination of the data. The overall conclusion is that values of $\Omega_m$ between 0.2 to 0.4 remain acceptable by the data and that the actual value depends strongly on the choice of parameter space.

B. Running

Running has attracted a lot of attention ever since WMAP team argued for a 2-$\sigma$ evidence of negative running. When analyzing CMB data alone one finds that running is strongly correlated with the optical depth $\tau$.

Figure 11 shows an example of this in WMAP+VSA MCMCs. We see that this particular combination of data prefers $\tau > 0.3$ and that such a high value of optical depth requires large negative running. A similar effect has been noticed in WMAP+CBI analysis and WMAP+VSA analysis. We find that the statistical significance of running is strongly affected by the adopted prior on $\tau$. In fact, when prior on $\tau$ is relaxed, the one-dimensional marginalised probability distribution seem to prefer models with high values of $\tau$ and large negative running. However, we note that this is the result of the large posterior probability volume in this region, rather than a better fit to the data. Moreover, such high values of optical depth are difficult to reconcile with the hierarchical models of structure formation and would require a lot of small scale power, contrary to the effect of a
negative running. Even more importantly, a high optical depth would lead to a large signal in WMAP EE polarization spectrum. To eliminate this region of parameter space WMAP team adopted a prior \( \tau < 0.3 \) and we follow that for most of our MCMCs. However, one can also eliminate this region of parameter space by adding the SDSS data, which do not favor the high optical depth values (figure 10) and we give an example of this in table 2.

In this paper we are more interested in how running changes if we use the exact likelihood routine as opposed to the approximate one. The resulting values of the running for various cases are given in tables 1-2. They are significantly affected by the exact likelihood calculations. This is expected from the analysis presented in previous section, where we have shown that the exact likelihood analysis with foreground marginalization leads to an enhancement of low \( \ell \) multipoles and broadens the shape of the likelihood distribution for quadrupole to allow a higher likelihood for models with less negative running. Figure 9 shows the MCMC generated probability distributions for running \( \alpha_s \) using WMAPext+SDSS in 8-parameter models. Note that there is a strong correlation between running and tensors in such a way that for no tensors there is less evidence for running \[25\]. So some of the evidence for running in the 8-parameter analysis (and in \[33\]) is driven simply by the large parameter space of \( r > 0 \) models and should not be taken as an evidence of running on its own. Even so we find that the evidence for running, marginally suggested by the old analysis, largely goes away in the new analysis and the value of running changes from -0.060 to -0.015 (V KP2, full marginalization) or -0.032 (W KP2, dust marginalization only), with an error of 0.035. This confirms that the suggested evidence for running relies crucially on low quadrupole and octupole \[34\], for which the statistical analysis and foreground removal are least reliable.

This point was also noted in the recent analysis of WMAP+VSA data \[32\], where the WMAP likelihood code was used and evidence in excess of 2-\( \sigma \) for running was found, while removing \( \ell < 10 \) information reduced this evidence to less than 1-\( \sigma \). While one should not simply remove the entire \( \ell < 10 \) information one should use the exact calculations instead of approximate ones if the answer depends on it. Our results for WMAP+SDSS+VSA analysis for 7-parameter models without tensors given in table 2 show that running is strongly suppressed with the new analysis, \( \alpha_s = -0.022^{+0.034}_{-0.032} \), even without adopting any prior on the optical depth.
As shown in table 1 the best fitted value of the primordial slope \( n_s \) increases appreciably as well, although this is mostly a consequence of the change in running. This is clarified in figure 11 which shows old and new contours in \((n_s, \alpha_s)\) plane. There is some degeneracy between the two parameters, so that models with low values of running also require low slope. Since low values of running are excluded by the new analysis this implies that low values of the primordial slope are also excluded, pushing the average slope up.

V. CONCLUSIONS

In this paper we have developed routines to calculate the exact likelihood of the low resolution WMAP data. We have projected out unwanted foreground components by adding the foreground templates to our covariance matrix with large variance. Both of these methods have not been applied to WMAP data before and should improve upon the existing analyses. We have tested the robustness of our results by applying the method to many different combinations of observing frequency, mask, smoothing and templates and found consistent results among these various cases. In particular, we find consistent results if we marginalize only over dust in W channel as opposed to all 3 foreground templates, if we use templates external to WMAP instead of WMAP MEM templates, if we use KP0 instead of KP2 mask, if we use ILC maps instead of individual V or W frequencies or if we use Healpix windows instead of gaussian smoothing. The two most important features of our procedure are thus marginalization over dust and exact likelihood analysis.

Important differences exist between our results and previous work. We find higher values of the lowest multipoles, which is partly a consequence of template subtraction method used in WMAP analysis. This procedure would certainly remove some of the real power, although it is difficult to estimate how much and the differences could also be just a statistical fluctuation. For the maximum likelihood value of the quadrupole we find values between the original WMAP analysis and subsequent reanalysis by [12]. The differences are within the estimated error of the foreground contamination and we argue that the actual value is not very reliable given how broad the likelihood is at the peak. More important is the shape of the likelihood function, which we find to be broader than in the WMAP team provided likelihood evaluation, which underestimates the errors compared to our analysis. This lowers the statistical significance of the departure of the data from the concordant model. Within a Bayesian context and assuming a flat prior on the distribution of quadrupoles we find the probability that a model exceeds the concordance model predicted quadrupole to be 10%. We also do not find anything particularly unusual in the correlation function and in the joint quadrupole-octopole analysis.

We combine the full likelihood calculation with foreground marginalization at low \( \ell \) with the original WMAP PCL analysis at high \( \ell \) to generate Monte Carlo Markov Chains, whose distribution converges to the probability distribution of theoretical models given the data and assumed priors. The main effect of the new analysis is on the running of the spectral index, for which the marginal 2 sigma evidence for \( \alpha_s < 0 \) present in the original analysis and in the recent analysis of WMAP+VSA [22] (see also [31]) is reduced to below 1 sigma. Using the exact WMAP likelihood analysis will be essential for attempts to determine the running of the spectral index by combining WMAP with either the small scale CMB data or with the upcoming Ly-\( \alpha \) forest analysis from SDSS. In all of these cases the exact method increases the value of the running by pushing up the CMB spectrum at large scales. Another parameter which is significantly affected is the matter density \( \Omega_m \) or, equivalently, the dark energy density \( \Omega_\Lambda \). We find \( \Omega_m \) to be reduced by the new analysis because of the added power at low multipoles, which is most easily accounted for by an increase in ISW contribution.

We have shown that the effects of the improved likelihood analysis presented here can be significant for the determination of cosmological parameters. We expect the methods applied here will be equally important for the analysis of polarization data in WMAP, where the foregrounds play a much more important role and where a full likelihood analysis of joint temperature and polarization data is necessary to extract the maximum amount of information. Current analysis of temperature-polarization data is rather unsatisfactory, since it is based on the cross-spectrum information alone. Without having access to the full polarization maps we cannot improve upon it here. Thus the results shown in tables 1-2 should still be viewed as preliminary regarding the optical depth, which is essentially determined by the polarization data. Upcoming WMAP 2-year analysis/release
of polarization data should elucidate the current situation. The code developed here will be made available to the community at cosmas.org.

ACKNOWLEDGEMENTS

We thank WMAP for the wonderful data they produced and made available through the LAMDBA web site. Our MCMC simulations were run on a Beowulf cluster at Princeton University, supported in part by NSF grant AST-0216105. US thanks O. Dore, C. Hirata, P. McDonald and D. Spergel for useful discussions. US is supported by Packard Foundation, Sloan Foundation, NASA NAG5-1993 and NSF CAREER-0132953.
