ABSTRACT

Let $G = (V, E)$ be a connected graph, where $V$ and $E$ represent, respectively, the node-set and the edge-set. Besides, let $Q \subseteq V$ be a set of terminal nodes, and $r \in Q$ be the root node of the graph. Given a weight $c_{ij} \in \mathbb{N}$ associated to each edge $(i, j) \in E$, the Steiner Tree Problem in graphs (STP) consists in finding a minimum-weight subgraph of $G$ that spans all nodes in $Q$. In this paper, we consider the Min-max Regret Steiner Tree Problem with Interval Costs (MMR-STP), a robust variant of STP. In this variant, the weight of the edges are not known in advance, but are assumed to vary in the interval $[l_{ij}, u_{ij}]$. We develop an ILP formulation, an exact algorithm, and three heuristics for this
problem. Computational experiments, performed on generalizations of the classical STP instances, evaluate the efficiency and the limits of the proposed methods.

KEYWORDS. Steiner tree problem. Min-max regret. Interval uncertainty.

Combinatorial optimization, Mathematical programming

1. Introduction

Let $G = (V, E)$ be a connected graph, where $V$ is the set of nodes and $E$ is the set of edges, where each edge $(i, j) \in E$ is associated with a cost $c_{ij} \in \mathbb{N}_+$. Given a set $Q \subset V$ of terminal nodes, a Steiner tree is defined as a tree in $G$ that spans all nodes in $Q$ and may contain additional nodes from $V \setminus Q$. The Steiner Tree Problem in graphs (STP) [Dreyfus and Wagner, 1971] consists in finding a minimum cost Steiner tree of $G$.

STP is a well known NP-Hard problem [Karp, 1972]. This problem finds practical applications in areas such as telecommunication networks design, computational biology, VLSI design, among others [Prömel and Steger, 2012]. In most of these applications, the cost associated with each edge is not precisely known. In this paper, we investigate how Robust Optimization (RO) [Kouvelis and Yu, 1997] can be applied to this context.

RO is an approach to deal with uncertain parameters in decision making, where the data variability is represented by deterministic values [Kasperski and Zieliński, 2016; Kouvelis and Yu, 1997]. We focus on RO models where the uncertain data is modelled by an interval of possible values. We refer to the book by Kouvelis and Yu [1997] for other robust optimization models. In this approach, any realization of a single value for each parameter is considered as a scenario that can happen. The objective is to find a solution that is efficient for all scenarios, usually referred to as a robust solution. The RO criterion used in this work to classify a solution as robust or not is the min-max regret. It was proposed by Wald [1939] in the context of game theory and was adapted to RO by Kouvelis and Yu [1997].

In this paper, we introduce a variant of STP where the value of $c_i$ is uncertain. However, it is assumed that this value is in the range $[l_{ij}, u_{ij}]$. This problem is refereed to
as the Min-max Regret Steiner Tree Problem with with Interval Costs (MMR-STP) and is
defined as follows.

**Definition 1.** A scenario $S$ is an assignment of a single value $c^S_{ij} \in [l_{ij}, u_{ij}]$ for each edge
$(i, j) \in E$.

It is worth noting that there are infinitely many scenarios, as $c^S_{ij}$ can assume any
real value in $[l_{ij}, u_{ij}]$. Let $\Gamma$ be the set of all scenarios and $\Phi$ be the set of all Steiner trees
in $G$.

**Definition 2.** The cost of a solution $x \in \Phi$ in a scenario $S \in \Gamma$ is given by

$$F(x, S) = \sum_{(i,j) \in E} c^S_{ij} x_{ij}.$$

**Definition 3.** The cost of the optimal SPT solution $z^S$ in the scenario $S$ is denoted by

$$F(z^S, S) = \min_{z \in \Phi} F(z, S) = \min_{z \in \Phi} \sum_{(i,j) \in E} c^S_{ij} z_{ij}.$$

**Definition 4 (Kouvelis e Yu [1997]).** The regret of a solution $x \in \Phi$ in a scenario $S \in \Gamma$ is
the difference between the cost of $x$ in the scenario $S$ and the cost of $z^S$ in $S$.

**Definition 5.** The worst-case scenario scenario of $x$, i.e., the one where the regret of $x$ is
the maximum is denoted by

$$S^x = \arg \max_{S \in \Gamma} \{ F(x, S) - F(z^S, S) \}.$$ 

**Lemma 1 (Averbakh [2001]).** Although $|\Gamma| = \infty$, for any min-max regret optimization
problem, $S^x$ is such that $c^{S^x}_{ij} = u_{ij}$ if $x_{ij} = 1$, and $c^{S^x}_{ij} = l_{ij}$ otherwise. That is, $c^{S^x}_{ij} = l_{ij} + (u_{ij} - l_{ij}) x_{ij}$, for all $x \in \Phi$ and $(i, j) \in E$.

**Definition 6.** The robust cost of a solution $x \in \Phi$ is defined as

$$Z(x) = F(x, S^x) - F(z^{S^x}, S^x),$$

i.e. $Z(x)$ is the maximum regret of $x$. It is worth noting that one has to solve an STP in
$S^x$ in order to compute $z^{S^x}$. That is, it is NP-Hard to compute the robust cost of a single
solution for MMR-STP.
Definition 7. MMR-STP consists in finding the Steiner tree \( x^* \in \Phi \) with the smallest robust cost \( Z(x^*) \).

MMR-STP is clearly NP-Hard, as for \( l_{ij} = u_{ij} = c_{ij} \) it reduces to SPT. Therefore, in this paper we propose heuristics and exact algorithms for this problem. We evaluate how good are the solutions provided by the state of the art exact and heuristic algorithms designed for min-max regret optimization problems these problems for the case of MMR-SPT.

The remainder of this work is organized as follows. Related works are presented in Section 2. Section 3 shows the proposed ILP formulation for MMR-STP. Then, an exact algorithm for MMR-STP are described in Section 4, while three heuristics are proposed for this same problem in Section 5. Computation experiments, which evaluates the proposed exact and heuristic algorithms, are reported in Section 6. Finally, concluding remarks are drawn in the last section.

2. Related work

The Steiner Tree Problem in graphs was proposed in Dreyfus e Wagner [1971], and was proven NP-Hard in Karp [1972]. Several mathematical formulations [Chopra e Rao 1994; Goemans e Myung 1993; Polzin e Daneshmand 2001], as well as exact algorithms [Lucena e Beasley 1998], and heuristics [Duin e Vöß 1994, 1999], were proposed and evaluated for this problem. A comparison among several mathematical formulations for STP was shown in Polzin e Daneshmand [2001]. A compendium of STP formulations can be found in Goemans e Myung [1993]. Furthermore, the state-of-the-art algorithms and other recent advances regarding this problem can be found in Du et al. [2013]; Prömel e Steger [2012].

Many robust counterparts of classical optimization problems have been studied in the literature, such as the Robust Shortest Path Problem [Karaşan et al. 2001; Catanzaro et al. 2011; Pérez-Galarce et al. 2018] and the Robust Minimum Spanning Tree Problem [Montemanni 2006; Godinho e Paquete 2019], and the Robust Shortest Path Tree Problem [Catanzaro et al. 2011; Carvalho et al. 2016a, 2018]. These problems are NP-hard [Aissi et al. 2009], despite the fact that their deterministic counterparts can be solved
in polynomial time. RO problems whose deterministic counterparts are already NP-hard have also been studied, such as the Robust Restricted Shortest Path Problem [Assunção et al., 2017], the Robust Traveling Salesman Problem [Montemanni et al., 2007], and the Robust Set Covering Problem [Pereira e Averbakh, 2013; Coco et al., 2015, 2016], and the Robust Knapsack Problem [Deineko e Woeginger, 2010; Furini et al., 2015]. As is the case of MMR-STP, these problems are particularly harder to solve than other NP-Hard problems, because the complexity of computing the cost of a single solution is at least that of solving the deterministic counterpart, which is itself NP-Hard.

Some works in the literature also consider robust variations of STP. A Robust Prize-Collecting Steiner Tree Problem in which both edge weights and node prizes are subject to uncertainty was proposed in ´Alvarez-Miranda et al. [2013]. Moreover, a Two-stage Robust Steiner tree was presented in Khandekar et al. [2008]. In the initial stage, a small subset of terminal nodes is given. In the second stage, the edge weights are increased by a factor $\lambda$ and several scenarios can occur, each one with a new set of terminal nodes. The objective is to minimize the maximum overall cost over all scenarios.

Other variations of Steiner problems with data uncertainty were handled by means of stochastic programming. The most studied of these problems is the Two-stage Stochastic Steiner Tree in graphs with recourse [Bomze et al., 2010; Fleischer et al., 2006; Gupta e Pål, 2005]. In the initial stage, a known probability distribution $\pi$ is set on subsets of nodes and a cost is assigned to each edge of the graph. In the second stage, a subset of nodes materializes, given their prior known distribution, and the cost of each edge is increased by a factor $\lambda$. Then, an additional set of edges can be bought to build a tree that spans all materialized nodes. The objective is to minimize the expected cost of the two-stage solution. A mathematical formulation and an exact algorithm for this problem were presented in Bomze et al. [2010]. Approximation algorithms were presented in Fleischer et al. [2006]; Gupta e Pål [2005].

To the best our knowledge, the min-max regret Robust Steiner Tree Problem in graphs has not been studied in the literature. Therefore, we propose an Integer Linear Programming (ILP) formulation for MMR-SPT, based on STP’s bi-directed multi-commodity
flow formulation presented in Chopra and Rao [1994]. As this formulation has an exponentially large number of constraints, we extend the Benders-like Decomposition framework of Montemanni and Gambardella [2005] for MMR-SPT. Furthermore, we propose three heuristics based on the framework of Kasperski and Ziełański [2006]: (i) the Algorithm Mean (AM); (ii) the Algorithm Upper (AU); and (iii) the Algorithm Mean Upper.

3. An ILP formulation for MMR-STP

Our ILP formulation for MMR-STP is based on the multi-commodity flow formulation for STP proposed in Chopra and Rao [1994]. Let \( G' = (V, A) \) be a directed graph, obtained by bi-directing the edges in \( E \). Furthermore, let \( r \in Q \) be an arbitrary terminal node, which is referred to as the root node. From this data, STP is formulated by means of binary variables \( x_{ij} \in \{0, 1\} \), such that \( x_{ij} = 1 \) if arc \((i, j)\) belongs to the Steiner tree, and \( x_{ij} = 0 \) otherwise. Besides, we make use of auxiliary binary variables \( y_{ij} \in \{0, 1\} \times Q \), such that \( y_{ij}^k = 1 \) if arc \((i, j)\) is used to send an unit of flow from the root \( r \) to the terminal \( k \in Q \), and \( y_{ij}^k = 0 \) otherwise. The resulting formulation consists of the objective function (1) and the constraints in (2)–(5).

\[
\begin{align*}
\min & \sum_{(i,j)\in A} c_{ij}x_{ij} \\
\text{s.t.} & \sum_{(j,i)\in A} y_{ji}^k - \sum_{(i,j)\in A} y_{ij}^k = \begin{cases} 
1, & \text{if } j = r \\
-1, & \text{if } j = k \\
0, & \text{otherwise}
\end{cases}, \forall j \in N, k \in Q \\
y_{ij}^k + y_{ij}^k \leq x_{ij}, & \forall (i, j) \in A, k \in Q \\
x_{ij} \in \{0, 1\}, & \forall (i, j) \in A \\
y_{ij}^k \in \{0, 1\}, & \forall (i, j) \in A, k \in Q
\end{align*}
\]

The objective function (1) minimizes the cost of the arcs in the Steiner tree. The constraints in (2) are the classic flow conservation constraints that enforce a path from the root \( r \) to every other terminal \( k \in Q \). The inequalities in (3) project the variables \( y \) into the
variables \( x \). Besides, together with (2), they enforce that \( x \) induce a spanning tree of the terminals in \( Q \). The domain of the variables \( x \) and \( y \) are defined by (4) and (5), respectively.

From the STP formulation described above, we have that the polytope that describes the set \( \Phi \) of Steiner trees of \( G \) can be formulated by (2)–(5). We have that MMR-STP can be written as

\[
\min_{x \in \Phi} Z(x) = \min_{x \in \Phi} F(x, S^x) - F(z^{S^x}, S^x).
\]

Besides, from definition 1.2, we have that

\[
F(x, S^x) = \sum_{(i,j) \in e} u_{ij} x_{ij},
\]

and from definition 1.3 and lemma 1.6, we have that

\[
F(z^{S^x}, S^x) = \min_{z \in \Phi} \sum_{(i,j) \in A} c_{ij}^{S^x} z_{ij} = \min_{z \in \Phi} \sum_{(i,j) \in A} (l_{ij} + (u_{ij} - l_{ij}) x_{ij}) z_{ij}.
\]

Therefore, MMR-SPT can be formulated by the 0-1 Bilevel Integer Linear Program defined by the objective function (6) and the constraints (2)–(5). We note that (6) is indeed linear as \( x \) is constant in the inner optimization problem.

\[
\min_{x \in \Phi} \left\{ \sum_{(i,j) \in A} u_{ij} x_{ij} - \min_{z \in \Phi} \sum_{(i,j) \in A} (l_{ij} + (u_{ij} - l_{ij}) x_{ij}) z_{ij} \right\}
\]

We can then obtain a MIP formulation by linearizing \( F(y^{S^x}, S^x) \), as explained in Aissi et al. [2009]. Let \( y_{ij}^{S^x} \) and \( x_{ij} \) be the binary variables defined in the STP formulation (1)–(4). Besides, let variable \( \theta \in \mathbb{R} \) be the cost of the Steiner tree in the worst-case scenario defined by variables \( z_{ij} \). The resulting formulation is defined by the objective function (7) and constraints (8)–(13).
\begin{equation}
\min \sum_{(i,j) \in A} u_{ij} x_{ij} - \theta \tag{7}
\end{equation}

s.t.
\begin{equation}
\theta \leq \sum_{(i,j) \in A} (l_{ij} + (u_{ij} - l_{ij}) x_{ij}) z_{ij}, \quad \forall z \in \Gamma \tag{8}
\end{equation}

\begin{equation}
\sum_{(j,i) \in A} y_{ji}^k - \sum_{(i,j) \in A} y_{ij}^k = \begin{cases}
1, & \text{if } j = r \\
-1, & \text{if } j = k \\
0, & \text{otherwise}
\end{cases}, \quad \forall j \in N, k \in Q \tag{9}
\end{equation}

\begin{equation}
y_{ij}^k + y_{ij}^k \leq x_{ij}, \quad \forall (i,j) \in A, k \in Q \tag{10}
\end{equation}

\begin{equation}
x_{ij} \in \{0, 1\}, \quad \forall (i,j) \in A \tag{11}
\end{equation}

\begin{equation}
y_{ij}^k \in \{0, 1\}, \quad \forall (i,j) \in A, k \in Q \tag{12}
\end{equation}

\begin{equation}
\theta \in \mathbb{R} \tag{13}
\end{equation}

The objective function (7) aims at minimizing the maximum regret. The constraints in (9)–(12) are as previously defined for the STP. The inequalities in (8) computes the cost of each solution \(z \in \Gamma\) in the worst-case scenario. One can see that we have an inequality (8) for each possible solution. Therefore, the number of these inequalities is exponential. In order to satisfy these inequalities, the value of \(\theta\) should not be greater than the cost of any solution \(z \in \Gamma\). Finally, the constraint in (13) defines the domain of variable \(\theta\).

4. A Benders-like Decomposition for MMR-STP

The Benders-like Decomposition (Benders) for MMR-STP is inspired by the Benders Decomposition and based on the approaches used to solve other interval data min-max robust optimization problems, as the Robust Set Covering Problem \textit{Pereira e Averbakh} [2013] and the Robust Minimal Spanning Tree Problem \textit{Montemanni} [2006]. Benders is based on formulation (7)–(13). As the number of constraints (8) grows exponentially with the number of nodes, they are relaxed in the master problem. At each iteration, one of these constraints is separated and added to the master problem. Benders stops when the lower
bound obtained by solving the master problem is equal to the cost of the best (in this case optimal) solution.

Let $\Gamma^h \subseteq \Gamma$ be the subset of constraints (8) that are known in the master problem at iteration $h$ of Benders, and $X^h$ be the optimal solution of this problem. The value of $\theta$ may not be equal to the cost of the optimal solution $Y^h \in \Gamma$ of scenario $s(X^h)$, as constraints (8) are relaxed. Therefore, a new constraint (8), generated from $Y^h$, must be added to $\Gamma^{h+1}$ in order to update the value of $\theta$ for $X^h$. $Y^h$ can be obtained by solving a STP subproblem in $s(X^h)$.

In the first iteration, in order to avoid an unbounded master problem, $\Gamma^1$ is initialized with two solutions obtained by the Algorithm Mean and Algorithm Upper heuristics proposed in Section 5, as suggested in Pereira e Averbakh [2013]. At each iteration, the master problem and the corresponding STP subproblem (Equations (1)–(5)) are solved. Given the lower bound $z^h$ obtained by solving the master problem at iteration $h$, if $z^h < \min_{i \in \{1, \ldots, h\}} \rho^i(X^h)(X^h)$, $\Gamma^{h+1} = \Gamma^h \cup \{Y^h\}$ and a new iteration starts. Otherwise, Benders stops since an optimal solution was found.

5. Heuristics for MMR-STP

A framework for building heuristics that can be applied to any interval data min-max robust optimization problem was introduced in Kasperski e Zieliński [2006]. The complexity of the algorithms developed through this framework are the same of solving the classical counterpart of the robust optimization problem studied. In this work, we applied this framework to develop three heuristics for MMR-STP.

The first heuristic, called Algorithm Mean (AM), uses a branch-and-bound algorithm based on the flow formulation presented in Polzin e Daneshmand [2001] to solve a STP at the midpoint scenario $s^\pm$. In $s^\pm$, the weight of each edge is set to its mean value, i.e. $c^\pm_{ij} = (u_{ij} + l_{ij}) / 2$, for all edges $(i, j) \in E$. Next, the maximum regret of the computed solution is evaluated and returned. The cost of the solution obtained through AM is bounded by a factor of 2 from the optimal solution, as proved in Kasperski e Zieliński [2006].

The second heuristic, called Algorithm Upper (AU), is similar to AM. However, instead of solving a STP for scenario $s^\pm$, AU solves the STP for the upper scenario $s^\pm$,
where the weight of each edge is set to its upper value, i.e. $c_{ij}^+ = u_{ij}$, for all edges $(i, j) \in E$. Unlike AM, the cost of the solution obtained by AU is not bounded.

The last heuristic, called Algorithm Mean Upper (AMU), combines AM and AU. Next, it returns the smallest computed maximum regret. As AMU runs AM, it is also a 2-approximation algorithm for any interval data min-max robust optimization problem.

6. Computational experiments

Computational experiments have been performed on an Intel Xeon CPU E5645 with 2.4 GHz clock and 32 GB of RAM memory, running under Linux operating system. The branch-and-bound implementation of the ILOG CPLEX version 12.6 with default parameter settings was used to solve the mixed integer linear programs. The algorithms were implemented in C++ using the ILOG Concert Technology and compiled with GNU g++ 5.4.0. The running time of all algorithms has been limited to 10800 seconds (3 hours).

The instances used in the experiments are generalizations of classical STP instances. The 5 first instances (WRP3-11 to WRP3-15) from the SteinLib\footnote{http://elib.zib.de/steinlib} WRP3 set were used. Their sizes range from 128 nodes, 227 edges, and 11 terminal nodes (WRP3-11) to 138 nodes, 257 edges, and 15 terminal nodes (WRP3-15). Next, three different methods, namely Beasley (BE), Montemanni (MO) and Kasperski-Zielinski (KZ), are used to generate the edge weights interval as in Pereira e Averbakh [2013]. A parameter $\beta = \{0.1, 0.3, 0.5\}$ is used in BE, while $M = \{750, 1000, 1250\}$ is used as parameter in MO and KZ. For each method, the higher the parameter value, the larger the edge weight interval. These methods are applied to the selected WRP3 instances. Therefore, nine sets of 5 instances were generated by using different interval sizes. They are used in the experiment described below.

The performance of Benders, AM, AU, and AMU for these sets is displayed in Table\footnote{http://elib.zib.de/steinlib}. The name of each instance set is shown in Column 1. The average relative optimality gap of Benders, as well as the average computation time of these runs are reported in columns 2 and 3, respectively. Then, columns 4 and 5 present respectively (i) the average percent relative deviation to the Bender’s upper bound and (ii) the average computational
time of AM for each set. The same information is given for AU and for AMU.

| Instance set | Benders gap% | AM %dev | AU %dev | AMU %dev |
|--------------|--------------|---------|---------|---------|
| WRP3-BE-0.1  | 15.48        | 3.70    | 1.83    | 1.46    |
| WRP3-BE-0.3  | 14.80        | 3.12    | 1.03    | 0.91    |
| WRP3-BE-0.5  | 6.25         | 0.85    | 1.65    | 0.14    |
| WRP3-MO-750  | 6.32         | 4.33    | 2.29    | 1.21    |
| WRP3-MO-1000 | 12.60        | 4.22    | 2.80    | 1.96    |
| WRP3-MO-1250 | 23.64        | 5.93    | 2.79    | 2.79    |
| WRP3-KZ-750  | 28.37        | 3.94    | 3.78    | 2.02    |
| WRP3-KZ-1000 | 27.88        | 1.25    | 4.10    | 0.91    |
| WRP3-KZ-1250 | 27.92        | 1.83    | 3.12    | 0.93    |

Tabela 1: Evaluation of Benders, AM, AU, and AMU

One can see from Table 1 that Benders achieves a smaller relative optimality gap and running times in BE and MO instances than in KZ. It indicates that the KZ instances are the most difficult ones among the three proposed sets. Regarding the interval sizes, we obtained different results for each instance set. For the BE instances, the smaller is the interval size, the greater is the average optimality gap. On the other hand, for the MO instances, the greater is the interval size, the smaller is the average optimality gap. However, the Bender’s algorithm average optimality gap was almost the same for all of the KZ instances.

Regarding the heuristics, one can see from this same table that, for BE instances, AM, AU and AMU average running times never exceed 4 seconds, but grow quickly for MO and KZ instances. The maximum average relative deviations for AM, AU, and AMU are respectively 5.93%, 4.10%, and 2.79%. These results indicate that the Bender’s algorithm did not greatly improved its initial solution (which is given by AMU, as explained in
Section 7.

7. Conclusions

This paper considers a new combinatorial optimization problem that arises from the uncertain nature of Steiner tree problem applications. We propose a mathematical formulation based on the robust optimization framework presented in Kouvelis and Yu [1997] and an exact and three heuristic algorithms to solve it. Computational experiments show that Benders-like decomposition did not solve all proposed instances to optimality. However, the heuristics achieve good results in a small running time. Future works should focus on the development of new exact and heuristic methods for the studied problem. Moreover, other mathematical formulations for the Steiner tree problem in graphs presented in Polzin and Daneshmand [2001] can be extended to handle the uncertain data for this problem.
