ABSTRACT

One of the most robust observations of the stellar initial mass function (IMF) is its near-universality in the Milky Way and neighboring galaxies. But recent observations of early-type galaxies can be interpreted to imply a "bottom-heavy" IMF, while others of ultra-faint dwarfs could imply a "top-heavy" IMF. This would impose powerful constraints on star formation models. We explore what sort of "cloud-scale" IMF models could possibly satisfy these constraints. We utilize simulated galaxies which reproduce (broadly) the observed galaxy properties, while they also provide the detailed star formation history and properties of each progenitor star-forming cloud. We then consider generic models where the characteristic mass of the IMF is some arbitrary power-law function of progenitor cloud properties, along with well-known literature IMF models which scale with Jeans mass, "turbulent Bonnor-Ebert mass", temperature, the opacity limit, metallicity, or the "protostellar heating mass". We show that no IMF models currently in the literature – nor any model where the turnover mass is an arbitrary power-law function of a combination of cloud temperature/density/size/metallicity/velocity dispersion/magnetic field – can reproduce the claimed IMF variation in ellipticals or dwarfs without severely violating observational constraints in the Milky Way. Specifically, they predict too much variation in the "extreme" environments of the Galaxy, compared to that observed. Either the IMF varies in a more complicated manner, or alternative interpretations of the extragalactic observations must be explored.

Key words: stars: formation – turbulence – galaxies: star formation – cosmology: theory

1 INTRODUCTION

The mass distribution of stars at formation (often called the initial mass function or IMF) is a key part of cosmic evolution as it affects essentially all astrophysical scales. A key finding regarding the IMF is its apparent universality in the Milky Way and its satellite galaxies (see the reviews of Chabrier 2003; Bastian et al. 2010; Offner et al. 2014; Krumholz 2014), regardless of the locations and ages of the observed population with a few possible outliers (e.g. Espinoza et al. 2009). While the IMF appears to be universal in the Galaxy, recent observations of the extragalactic IMF have been extrapolated to imply significant variations. Recent studies have looked at the centers of massive early type galaxies (ETGs) and have seen an apparent excess of low mass stars, a "bottom-heavy IMF" (see van Dokkum & Conroy 2010, 2011; Conroy & van Dokkum 2012; Treu et al. 2010; Sonnenfeld et al. 2015; Cappellari et al. 2012; Posacki et al. 2015; Martín-Navarro et al. 2015b,c). One must be cautious as these measurements use fundamentally different methods (e.g. Stellar Population Synthesis, SPS) than those used for IMF measurement in the Milky Way (e.g. star counting). For more details see the recent review of Hopkins 2018. This means that various interpretation of these extragalactic results can lead to different implied IMFs. Furthermore, several other studies conflict with the claimed variations (e.g. Smith 2014; Smith et al. 2015, 2017; Collier et al. 2018a). Meanwhile observations relying on star counts in Ultra Faint Dwarf Galaxies imply an overabundance of high mass stars, a “top-heavy IMF” (see Geha et al. 2013; Gennaro et al. 2018a). Note, that due to large uncertainties in the results, MW-like IMFs are not entirely ruled out by many of these observations (e.g. Offner 2016), and some UFD galaxies have IMFs consistent with a MW IMF, which means that the previously observed variations could be due to observational artefacts (El-Badry et al. 2017; Gennaro et al. 2018b).

Nonetheless, several theoretical models have been proposed to explain the claimed IMF variations. In fact, analytic sonic mass/turbulent Bonnor-Ebert mass models¹ (e.g. Hennebelle & Chabrier 2008, 2013; Hopkins 2012) provide a

¹ In these models the IMF is regulated by isothermal turbulence,
2 Model and Methods

2.1 IMF slope and characteristic mass

Observations relying on the integrated spectra of galaxies (SPS modeling) are currently unable to probe the IMF in its entire mass range. Instead they constrain the relative number for a few select types of stars, effectively calculating the “slope” of the IMF in relatively small mass ranges. As different measurements probe slightly different regions of the

the higher the turbulent velocity dispersion the more the clouds fragment, which leads to more low mass stars.

2 Note that the observed IMF variations in ETGs correlate not only with metallicity but with the galactic scale velocity dispersion as well, see Zhou et al. (2019).

Figure 1. Effects of different characteristic masses $\mu$ in the one-parameter IMF model we adopt in this paper. The characteristic scale $\mu$ essentially sets the mass scale where the PDF deviates from the high-mass power-law behavior.

In this paper we use a simplified version of the $L_3$ parametric IMF model of Maschberger (2013). In the $L_3$ model the IMF has the following form:

$$
\frac{dN}{dM} = L_3(M, \alpha, \beta) \equiv A \left(\frac{M}{\mu}\right)^{-\alpha} \left[1 + \left(\frac{M}{\mu}\right)^{1-\alpha}\right]^{-\beta}
$$

In the low and high mass limits this simplifies to power laws with $-\alpha$ and $-\alpha - \beta(1-\alpha)$ slopes respectively. The characteristic mass scale is $\mu$, this is where the function transitions between the two limits. Note that $A$ is just a normalization constant that depends on $\alpha, \beta$ and $\mu$, as well as $m_1$ and $m_u$, the low and high mass cut-offs of the IMF for which we use $m_1 = 0.01 M_\odot$ and $m_u = 150 M_\odot$.

Since most observations only measure a single slope of the IMF, it is necessary to reduce the number of parameters for our IMF model. In this paper we adopt $\alpha = 2.3$ and $\beta = 1.4$, which are the canonical fit values for the MW IMF. The adoption of these “fixed” slopes is further motivated by the fact that most scale-free structure formation processes naturally produce a $-2$ slope in the mass function (Guszejnov et al. 2018). These parameters lead to the one parameter IMF model that we adopt for the rest of the paper, where

$$
\frac{dN}{dM} \propto \left(\frac{M}{\mu}\right)^{-2.3} \left[1 + \left(\frac{M}{\mu}\right)^{-1.3}\right]^{-1.4}
$$

This leaves the characteristic mass scale $\mu$ as the only free parameter, so our model essentially assumes that the IMF has a universal shape that can only be shifted to lower or higher masses (see Figure 1). As observations only constrain the IMF slope in a small dynamic range, such a one-parameter IMF can fit the observations.

Armed with this simple, one-parameter model we can create a one-to-one mapping between the slopes measured in different mass ranges and the characteristic mass (the “peak”/“turnover mass”) of the IMF. Figure 2 shows that the inferred characteristic mass is sensitive to the probed mass range, so one should be cautious when trying to compare different observations.

One of the aims of this paper is to explore the space of...
### 2.3 Simulations

We utilize several simulated galaxies from the Feedback in Realistic Environments (FIRE) project (Hopkins et al. 2014)\(^4\). These galaxies have been presented in detail in Hopkins et al. (2018), Anglés-Alcázar et al. (2017) and Graus et al. (2019) with one exception (\(z5m12c\)) that we will later discuss in § 2.3.1 (also, see § 2.3.2 on how we choose our UFD proxy). These are cosmological “zoom-in” simulations, which means that the simulation starts from a large cosmological box that is later rerun with increased resolution in areas of matter concentration (“zooms-in” on galaxies). The simulations proceed from \(z > 100\) to present day (except \(z5m12c\) and \(h29\_HR\), see § 2.3.1). They are run using the GIZMO code Hopkins (2015)\(^5\), with the mesh-free Godunov “MFM” method for the hydrodynamics (Hopkins 2015). Self-gravity is included with fully-adaptive force resolution and hydrodynamic resolution. The simulations include detailed metallicity-dependent cooling physics from \(T = 10 - 10^{10}\)K, including photo-ionization/recombination, thermal bremsstrahlung, Compton, photoelectric, metal line (following Wiersma et al. 2009), molecular, fine structure (following Geha et al. 2013; Gennaro et al. 2018a,b) but there is no consensus in the field about these claims (e.g. Öfner 2016). As Fig 3 shows, these results do not rule out a MW-like IMF with high confidence but are plausibly consistent with having a factor of 2 higher \(\mu\) than in the MW. Due to this uncertainty, we explore the constraints arising from either having a top-heavy IMF or MW-like UFD IMF.

(i) **Universal IMF in the MW**: It has been fairly well established in the literature that the IMF in the MW is close to universal, regardless of the age and location of the stellar population (see reviews of Bastian et al. 2010; Öfner et al. 2014; Hopkins 2018). Slight variation is possible in the characteristic mass on which we impose the conservative estimate of 0.2 dex based on Figure 3 of Bastian et al. 2010. Furthermore, based on resolved star counts the IMFs of old stellar populations have a similar or slightly more massive peak (see Figure 5 and the references in the caption), still within the 0.2 dex limit\(^3\)\(^3\).

(ii) **MW-like IMF in dwarfs**: Dwarf galaxies like the LMC and SMC appear to have the same IMF as the MW despite different galactic metallicity, stellar mass and turbulent properties (see review Öfner et al. 2014). Note that the completeness limit of these studies is \(> 0.3M_\odot\) (see Da Rio et al. 2009; Gouliermis 2012) so the peak of the IMF is not actually resolved, thus some variation is possible.

(iii) **Top-heavy IMF in ultra-faint dwarf galaxies**: Several recent observations have been extrapolated to imply top-heavy IMFs in ultra faint dwarf (UFD) galaxies (see Geha et al. 2013; Gennaro et al. 2018a,b) but there is no consensus in the field about these claims (e.g. Öfner 2016). As Fig 3 shows, these results do not rule out a MW-like IMF with high confidence but are plausibly consistent with having a factor of 2 higher \(\mu\) than in the MW. Due to this uncertainty, we explore the constraints arising from either having a top-heavy IMF or MW-like UFD IMF.

(iv) **Bottom-heavy IMF in early-type galaxies**: There is growing indirect evidence suggesting that centers of early-type galaxies (ETGs) may have IMFs that are significantly more bottom heavy than the MW IMF (e.g. van Dokkum & Conroy 2010, 2011; Conroy & van Dokkum 2012; Treu et al. 2010; Sonnenfeld et al. 2015; Cappellari et al. 2012). A recent study by Conroy et al. (2017) put the characteristic mass for one such galaxy below \(0.1M_\odot\), about a factor of 3 smaller than the MW value.

(v) **MW-like IMF in early-type galaxies**: Several recent studies using gravitational lensing have found ETGs to have mass-to-light ratios consistent with a MW-like IMF (see Collier et al. 2018a,b). This contradicts the results from studies using stellar population synthesis models. In this paper we will investigate the effects of both constraints.

---

\(^{3}\) Note that dynamical evolution significantly alter the mass function of globular clusters leading to an apparent shift of the IMF peak to higher masses in studies that do not account for these

---

**Figure 2.** IMF slope and characteristic mass, based on where the slope is calculated using the one-parameter IMF model of Eq. 2. Since most observations of the extragalactic IMF measure the “slope” in different mass ranges, it is necessary to calculate the appropriate characteristic mass \(\mu\) to interpret them (see Figure 1 for the effects of \(\mu\) on the IMF).

---

**Table 3:**

| Characteristic mass (\(\mu/M_\odot\)) | IMF slope within mass range |
|--------------------------------------|---------------------------|
| 0.1–0.5 \(M_\odot\)                | Salpeter slope            |
| 0.1–1.5 \(M_\odot\)                |                           |
| 0.5–0.8 \(M_\odot\)                |                           |

A major caveat of our analysis is that the feedback processes (Kroupa 2002) with inputs taken directly from stellar evolution models (OB & AGB mass-loss, SNe Ia & II, metallicity etc.) and thus the same IMF. A characteristic mass that is roughly a factor of 2 higher than the MW value would be within 1σ for all galaxies, so we adopt that value as the average IMF shift for UFD galaxies.

Figure 3. IMF slopes (between $0.5 - 0.8 M_\odot$) and characteristic masses of UFD galaxies based on the data of Gennaro et al. (2018a). The errorbars correspond to 1σ (thicker line) and 2σ (thinner line) confidence intervals. The dashed line shows the mapping between the IMF slope and the $\mu$ characteristic mass from Fig. 2. The shaded region shows the possible values of the IMF characteristic mass in the MW. Of the 6 UFD galaxies, 3 have characteristic masses that are within 1σ of the MW values and all of them are within 2σ. A characteristic mass that is 3 times smaller than the MW value would be within 1σ for all galaxies, so we adopt that value as the average IMF shift for UFD galaxies.

Ferland et al. (2013), dust collisional and cosmic ray processes, including both a meta-galactic UV background and each star in the simulation as a local source. The mass resolution for individual simulations is fixed and varies between $M_{\text{star}} = 250 - 56000 M_\odot$ among our simulated galaxies (see Table 1).

The resolution of these cosmological simulations is not high enough to resolve the formation of individual stars ($M_{\text{star}} \gg 0.01 M_\odot$), instead star formation is approximated from resolved scales using a sink particle method. Gas is transformed into a sink particle if it:

(i) Is locally self-gravitating
(ii) Is self-shielding
(iii) Is Jeans-unstable
(iv) Exceeds a minimum density threshold ($n > n_{\text{crit}}$, see Table 1)

Such a sink particle is transformed into a “star cluster sink particle” on its dynamical time. Each of these represent a stellar population with the same formation properties (age, metallicity etc.) and thus the same IMF.

These “star cluster sink particles” provide feedback to the simulation via OB & AGB mass-loss, SNe Ia & HII, and multi-wavelength photo-heating and radiation pressure; with inputs taken directly from stellar evolution models (Leitherer et al. 1999), assuming (in-code) a universal IMF (Kroupa 2002)\(^6\).

In this work, similar to Guszejnov et al. (2017), we use cosmological simulations instead of present-day observations because they give us access to the entire star formation history of a galaxy. In a simulation we know the properties of star forming progenitor clouds at all times, allowing us to predict the IMF variation for the entire stellar population in a galaxy.

2.3.1 Finding a Proper Proxy for Massive Elliptical Galaxies

For our analysis we utilize simulated present-day galaxies where the at-formation properties of all sink particles (star clusters) are available. We use these galaxies as proxies for the Milky Way (m12i), LMC and SMC (m11q) and UFDs (m10q). For early type galaxies we currently don’t have access to such simulations so in this study we use three different proxies:

(i) **h29_HR**: This is a simulated FIRE galaxy with additional black hole physics which lead to extreme starburst behavior, similar to what we expect in early type galaxies (see simulation A2 in Anglés-Alcázar et al. 2017, for details). Unfortunately for these runs the at-formation properties of sinks were not saved. Re-running the simulation would have been very expensive, so instead we post-processed the about 150 snapshot files of the simulation, taking actively star-forming gas from each to approximate the distribution of progenitor cloud properties over cosmic time. In our previous study (Guszejnov et al. 2017) we found that this approach provides a good approximation of the actual distribution. A major caveat with this proxy is that AGN feedback is poorly understood and thus it is not implemented in these simulations, despite the fact that it is believed to be one of the main mechanisms shutting off star formation.

(ii) **z5m12c**: This run was originally conceived to study galaxy scaling relation in the era of reionization (see Ma et al. 2018, for details of the simulation setup). It utilizes the same FIRE physics suite and the progenitor cloud properties are saved for all sink particles. Although this galaxy was simulated only to $z = 5$, it is the progenitor of massive elliptical galaxy. The reason the simulation was not run further is due to the uncertainties in the physics that would quench star formation in such a galaxy. The stellar mass of $z5m12c$ is only $3 \times 10^{10} M_\odot$ at $z = 5$, which is only a few percent of the mass it would attain by $z \sim 2$, the time from which most ETG IMF measurements are from. Nevertheless we can still use this simulated galaxy to look at the oldest population of stars in a ETGs.

(iii) **Both previous proxies have important caveats, so as a complementary approach we will approximate the properties of the progenitor clouds in ETGs using typical values for galaxies with extreme star formation (e.g. an Ultra Luminous Infrared Galaxy - ULIRG), see Table 2.**

Our 3 proxies essentially cover three possible ways to deal with the uncertain physics related to the quenching of star-formation in early type galaxies. With **h29_HR** we neglect

\(^6\) A major caveat of our analysis is that the feedback processes in the simulations assume a Kroupa IMF, so our post-processing neglects the potential feedback from a varying IMF and how it could enhance or suppress further IMF variation in a galaxy.
Early type

Table 1. Properties of simulated galaxies from the FIRE project, including stellar mass $M_*$, target dark matter halo virial mass $M_{DM}$ (at $z = 0$), half-mass radius $R_{1/2}$, gas element mass resolution $M_{\text{min}}$, critical density for sink particle creation $\rho_{\text{crit}}$ and the galactic average temperature $T$, metallicity $Z$ and $B$ magnetic field (when available) for progenitor clouds. See Figure 4 for further details.

Table 2. ULIRG-like values assumed for the star-forming clouds in early-type galaxies that we use for testing IMF constraints.

| Property                          | Value          |
|-----------------------------------|----------------|
| Density                           | $2 \times 10^7$ cm$^{-3}$ |
| Temperature                       | 75 K           |
| Turbulent dispersion ($\sigma_T$) | 10 km/s        |
| Metallicity ($\log(Z/Z_\odot)$)  | 0.5            |
| Magnetic field                    | 100 µG         |

2.3.2 Finding a Proxy for Ultra Faint Dwarf Galaxies

To find an appropriate proxy for a UFD galaxy we use the simulations of Graus et al. (2019). With a combination of the Rockstar halo finder (Behroozi et al. 2013), and the Amiga Halo Finder (Knollmann & Knebe 2009, AHF) we identify halos and then select for galaxies with a low stellar mass ($< 10^8 M_\odot$). In m10xf there are over 150 such low-mass, from these we restrict our study to those whose stellar population is well-resolved ($> 25$ “star” sink particles), which essentially sets the lower bound to our galaxy masses as $10^7 M_\odot$. This leaves 8 galaxies, for our study we choose m10xf_14706, the one with the lowest stellar mass ($1.5 \times 10^7 M_\odot$). Note that picking a different galaxy from this group does not change the qualitative results of this study.

2.4 From Parent Cloud to IMF Properties

Because the simulations resolve down to cloud scales, but no further, we treat each star-forming gas element as an independent “parent cloud”, which sets the initial conditions for its own detailed IMF model (in accordance with the IMF models we investigate). Specifically, whenever a sink particle is spawned, we record all properties of the parent gas element from which it formed, and use these in post-processing to predict the IMF for the stellar population it spawns. From this point we infer the IMF characteristic mass $\mu$ from the initial conditions of the parent clouds that form stars in the simulations (see Guszejnov et al. 2016, for an example of how GMC properties could be mapped to the IMF). While we investigate the entire model space described by Eq. 3 we give special attention to the following classes of models that are common in the literature (summarized in Table 4):

- Jeans mass models: Gas clouds collapse primarily through the Jeans instability. This model assumes that the initial Jeans mass of the progenitor cloud sets the characteristic mass of the stars it spawns (e.g. Bate & Bonnell 2005),

![Figure 4. Galaxy-average properties of progenitor clouds (Top: turbulent Mach number vs temperature, Bottom: metallicity vs cloud size) in the simulated galaxies (see Table 1 for more details on the individual runs). The mean values are galaxy-scale averages of the logarithmic quantity weighted by stellar mass, while the errorbars show the corresponding 1σ scatter. There is significant variation not only between the different galaxies but also within individual galaxies. The average properties of star-forming clouds evolve significantly during a galaxy’s lifetime, this is why this scatter is much larger than the observed scatter in present-day star-forming clouds.](image-url)
so

\[
\mu_{\text{Jeans}} \propto M_{\text{Jeans}} = \frac{\pi c_s^3}{6G\Sigma_{\text{crit}}}.
\]

Note that the models may still assume sub-fragmentation to smaller scales, but the key assumption (for our purposes) is simply that the turnover mass is proportional to the parent cloud Jeans mass.

- **Opacity limited equation of state (EOS) models:** As clouds become denser they reach the point where they become opaque to their own cooling radiation, leading to a transition from isothermal to adiabatic behavior, suppressing fragmentation at the Jeans mass corresponding to this critical volume density \( \rho_{\text{crit}} \) (Globus 1976; Whitworth et al. 1998; Larson 2005; Glover & Mac Low 2007; Jappsen et al. 2005; Masunaga & Inutsuka 2000). Motivated by radiation transfer simulations like Bate (2009) we also investigated the case where the transition occurs at a critical surface density \( \Sigma_{\text{crit}} \). The resulting characteristic masses are:

\[
\rho_{\text{EOS,}\rho} \sim \frac{\pi c_s^3}{6G\Sigma_{\text{crit}}}, \quad \rho_{\text{EOS,}\Sigma} \sim \frac{c_s^4}{G^2\Sigma_{\text{crit}}},
\]

where \( \rho_{\text{crit}} \) and \( \Sigma_{\text{crit}} \) are the critical densities for the isothermal-adiabatic transition.

- **Turbulent/sonic mass models:** Several analytical theories derive the core mass function (CMF) and IMF from the properties of the turbulent medium, in which they form (e.g. Padoan & Nordlund 2002; Hennebelle & Chabrier 2008; Hopkins 2012; Hennebelle & Chabrier 2013). In these models, both the CMF and IMF peaks are set by the “sonic mass” \( M_{\text{sonic}} \), namely the turbulent Jeans or Bonnor-Ebert mass at the sonic scale (\( R_{\text{sonic}} \)) below which the turbulence becomes sub-sonic and therefore fails to generate large density fluctuations (which seed fragmentation). The various theories give slightly different answers to this critical mass, in this paper we will use the definitions of Hopkins (2012) and Hennebelle & Chabrier (2013), which give:

\[
\mu_{\text{sonic}} \sim M_{\text{sonic}} \sim \frac{2c_s^2R_{\text{sonic}}}{G} \sim M_{\text{Jeans}}/M
\]

\[
\mu_{\text{H2013}} \sim M_{\text{Jeans}}/M^2 \sim M_{\text{sonic}}/M,
\]

where \( R_{\text{sonic}} \) is defined through the linewidth-size relation

\[
\sigma_{\text{turb}}^2(d) = \frac{c_s^2}{R_{\text{sonic}}}.\]

In our simulations \( \sigma_{\text{turb}}^2 \) is estimated for a progenitor cloud (sink particle) by measuring the velocity dispersion (after subtracting the mean shear) between neighboring gas particles in a sphere of radius \( d \) (taken to be that which encloses the nearest \( \sim 32 \) gas neighbours).

- **Protostellar feedback models:** Although there are a number of ways newly-formed stars can regulate star formation, most studies have concluded that at the scale of the IMF peak (early protostellar collapse of \( \sim 0.1M_\odot \) clouds) the most important self-regulation mechanism is radiative feedback from protostellar accretion (Bate 2009; Krumholz 2011; Guszejnov et al. 2016). This sets a unique mass and spatial scale within which the protostellar heating has raised the temperature to make the core Jeans-stable, suppressing fragmentation. The resulting critical mass is

\[
\theta_{\text{K11}} \sim 0.15 \left( \frac{P/k_B}{10^8 \text{K/cm}^3} \right)^{-1/18} M_\odot
\]

where \( P \) is the pressure of the gas. There are several other formulas in the literature (e.g. Bate 2009); the differences are due to the detailed uncertainties in the treatment of radiation. However, for our purposes, they give nearly identical results, so we will focus on the model from Krumholz (2011).

- **Metallicity dependent IMF models:** Some SPS analyses of early-type galaxies have been empirically fit by assuming a trend of increasing shallow IMF slopes with decreasing metallicity (see Martín-Navarro et al. 2015c and Figure 5). This phenomenological model sets the slope of the IMF (in the \( > 0.6M_\odot \) range) as:

\[
\text{Slope} [0.6M_\odot < M] = -2.2 - 3.1 \times \log[M/H],
\]

where \( \log[M/H] \) is the logarithm of the metallicity relative to the solar value. Note that the actual measurements are only sensitive to the IMF in the \( 0.1M_\odot - 2.0M_\odot \) regime and the above relation was derived in Martin-Navarro et al. 2015c by assuming a two-part IMF with fixed parameters below \( 0.6M_\odot \). To preserve generality, we use instead the single-power-law IMF fit from work which yields:

\[
\text{Slope} [0.1M_\odot < M < 1.5M_\odot] = -1.5 - 2.1 \times \log[M/H].
\]

Using the one-parameter model from Eq. 2, we can convert the metallicity-slope relation into the \( \mu \)-metallicity relation of

\[
\log(\mu/M_\odot) = -1.3 - 2.4 \times \log[M/H] + O\left(\frac{[M/H]^2}{M_\odot}\right).
\]

As shown in Figure 5 this phenomenological model provides a good fit for the inferred extragalactic IMFs but drastically

---

Table 3. Summary of observations constraints on the IMF in various environments as well as the proxies (mostly simulated galaxies from FIRE project) we use to estimate the constraints they put on IMF models. Here \( \Delta\mu = \log(\mu/M_\odot) \) is the amount (in dex) the IMF characteristic mass is shifted in different environments, while \( \sigma_{\mu,M_\odot} \) is the standard variation of \( \log \mu \) in the Milky Way.

| Environment       | Constraint | Reference                  | Proxy |
|-------------------|------------|----------------------------|-------|
| Milky Way         | Universal IMF | \( \sigma_{\mu,M_\odot} < 0.2 \) | Offner et al. (2014) | m12i |
|                   | Universal IMF | \( \Delta\mu_{MW} > 0.2 \) | Bastian et al. (2010) and Figure 5 | m11q |
| Dwarf Galaxies    | MW-like IMF  | \( \Delta\mu_{DG} < 0.2 \) | Offner et al. (2014) | m11q |
|                   | Top-heavy IMF | \( \Delta\mu_{TH} < 0.2 \) | Gennaro et al. (2018a) | m10x,14706 |
|                   | MW-like IMF  | \( \Delta\mu_{MW} < 0.2 \) | Offner (2016) | m10x,14706 |
| UFD Galaxies      | MW-like IMF  | \( \Delta\mu_{UFD} < 0.2 \) | Collier et al. (2018b) | m10x,14706 |
| Early Type Galaxies | Bottom-heavy IMF | \( \Delta\mu_{ETG} > 0.2 \) | Colley et al. (2017) | z5m12c |
|                   | MW-like IMF  | \( \Delta\mu_{ETG} < 0.2 \) | Conroy et al. (2017) | z5m12c |
|                   | MW-like IMF  | \( \Delta\mu_{HR} < 0.2 \) | Colley et al. (2018b) | z5m12c |
overpredic the variations for old stellar populations within the MW.

3 RESULTS AND DISCUSSION

Using our simulation proxies we can calculate the shifts and variations of the IMF for the previously mentioned models. Table 4 shows although some models can come close to reproducing the claimed UFD and ETG IMF variations (e.g. Hennelbe & Chabrier 2013), these drastically violate IMF universality within the MW. We find that none of the current models in the literature can satisfy all constraints, so we extend our search to generic models following Equation 3.

Using the variations in progenitor cloud properties in the MW-like galaxy of m12i we can identify the IMF models (the exponents for Eq. 3) that would satisfy IMF universality in the MW (this exercise is worked out in detail by Guszejnov et al. (2017)). With our additional constraints for old MW populations, dwarf galaxies, UFDs and ETGs from § 2.2 we can further restrict the model space, see Appendix A. We investigate both models from the literature (see Table 4 for results) and generic models following Equation 3 (see Figure 6 for an example). In general, we can draw the following conclusion:

• The large difference in average cloud metallicity in the older (\(z > 3\)) stellar population in our MW-like galaxies (m12i, see Figure 4) compared to average and the significant scatter in metallicity in the latter, only allows the IMF characteristic mass to have a weak metallicity dependence (see Figure 6).

• There is little-to-no overlap between the regions that satisfy local IMF universality and those that reproduce the observed IMF shifts in ETGs (see Figure 6 and Figure A2).

• MW universality strongly rules out most IMF models in the literature, including the turbulent/sonic mass models (see Guszejnov et al. 2017, for a detailed analysis).

• There exists a significant region of the model space that satisfies the assumption that the IMF is near universal in all types of galaxies (< 0.2 dex scatter in the galactic mean \(\mu\)). An example of such “weakly varying IMF” models is the protostellar heating model of Krumholz 2011 (Heating-K11).

None of the models detailed in § 2.4 can reproduce the IMF variations which have been claimed for either ETGs or UFDs without grossly violating constraints from the local measurements with resolved star counts. Meanwhile the only model that reproduces the MW observations (the Protostellar Heating model) predicts essentially zero IMF variations in almost all environments. It is therefore natural to ask whether there even exists a model that can reproduce both the claimed variations and the near-universality in the MW. Progenitor clouds have essentially 6 (nearly) independent properties: size, density, temperature, Mach number, magnetic field strength and metallicity\(^9\). We are looking for the exponents corresponding to these quantities in Eq. 3. If these quantities are independent then MW universality allows us to restrict the space we search to a 6D rectangle whose sides are described by: \(|y_{X} \Delta \log X_{\text{MW}}| < \Delta \log \mu_{\text{MW}}\), where \(\Delta \log X_{\text{MW}}\) is how many orders of magnitude of scatter quantity \(X\) has in our proxy for the MW (m12i), while \(\Delta \log \mu_{\text{MW}}\) is the maximum allowed scatter in the MW IMF peak (0.2 dex, see § 2.2). Within this region we use a Monte-Carlo search to find a set of exponents that would satisfy all criteria. We find the following:

(i) There is a significant volume in the model space that satisfies local IMF universality and produces a top-heavy IMF UFD galaxies.

(ii) In case of our ETG proxy where we followed the galaxy evolution to \(z \sim 2.5\) without AGN effects we find that there is no IMF model in the shape of Equation 3 that can satisfy local IMF universality and produce the claimed bottom-heavy IMF.

(iii) There exist a small volume in the model space that seems to satisfy local IMF universality and reproduce the observed IMF variations in both UFDs and ETGs (either \(z\text{m12c}\) or ULIRG values, not both). These models however do not correspond to any known physical mechanism (e.g. \(\mu \propto R^{-3/2}\)). Furthermore they all utilize the fact that the cloud sizes in \(z\text{m12c}\) and in the ULIRG values are significantly different from the values in m12i. Note that the mass resolution and the critical density of the simulations (see Table 1) set a size scale that appears in the sink particle sizes and thus in the progenitor cloud sizes (essentially the size scale where the simulation replaces gas clouds with sink particles). To verify these models we use a lower mass resolution version of m12i (\(\Delta m = 56000 M_\odot\), like in Guszejnov et al. 2017), which clearly rules out all of these models. This means that there is no generic model that satisfies all constraints.

(iv) If we relax the claimed variations in early-type galaxies (e.g. a factor 2 shift instead of 3) we find that a significant volume of the model space can produce appropriate bottom-heavy IMFs for both simulation proxies (\(z\text{m12c}\) and \(h29\_HR\)) as well as satisfying local IMF universality and producing a top-heavy IMF for UFDs. Still, these models correspond to no known physical mechanism (e.g. \(T^{-1/4}R^{-1/4}\)).

4 CONCLUSIONS

In this paper we used different types of simulated galaxies to infer what constraints different observational claims impose on theoretical IMF models. We mainly focused on three common claims from the literature: 1) that the IMF in the MW and nearby dwarf galaxies is nearly universal, 2) that the IMF in early-type galaxies is “bottom-heavy” and 3) that the IMF in ultra-faint dwarf galaxies is “top-heavy”.

We found that the current models in the literature either

---

\(^9\) The measurements of Martín-Navarro et al. 2015a,b,c are sensitive to the \(F_G\) dwarf-to-giant ratio in the \(0.1M_\odot \sim 2.0M_\odot\) range. The IMF slope is inferred by assuming that it is well-described by a single power-law in this regime.

\(^9\) In the simulations we used there is some correlation between these quantities, but we neglect them here for simplicity. Taking them into account does not change the result significantly.
fail to reproduce the observed IMF variations or violate IMFs universality in the MW.

We also investigated generic IMF models where the IMF characteristic mass is a power-law of progenitor cloud properties. Despite the high dimensionality of the model space, we find that no model where the turnover mass is an arbitrary power-law function of a combination of cloud temperature/density/size/metallicity/velocity dispersion/magnetic field can reproduce the claimed IMF variations in ellipticals or dwarfs without severely violating observational constraints in the Milky Way.

One possibility is that the characteristic mass of the IMF is set by a yet unknown physical mechanism. Another, more likely scenario is that the magnitude of IMF variations in ETGs are overestimated in stellar population synthesis models. This would further explain why non-SPS based methods (e.g. gravitational lensing, see Collier et al. 2018a) appear to contradict SPS-based observations. There are a several possible reasons for such a bias, most of them coming from the inherent uncertainties of extrapolating stellar atmosphere models to extreme metallicities. We find that relaxing the claimed variations greatly increases the number of possible models.
**ACKNOWLEDGMENTS**

Support for DG and PFH was provided by an Alfred P. Sloan Research Fellowship, NSF Collaborative Research Grant #1715847 and CAREER grant #1455342, and NASA grants NNX15AT06G, JPL 1589742, 17-ATP17-0214. Numerical calculations were run on the Caltech compute cluster “Wheeler,” allocations from XSEDE TG-AST130039 and PRAC NSF.1713353 supported by the NSF, and NASA HEC SMD-16-7592. This work used computational resources of the University of Texas at Austin and the Texas Advanced Computing Center (TACC; http://www.tacc.utexas.edu), the NASA Advanced Supercomputing (NAS) Division and the NASA Center for Climate Simulation (NCCS). DG and ASG were supported by the Harlan J. Smith McDonald Observatory Postdoctoral Fellowship. We would like to thank Stella Offner, Daniel Anglés-Alcázar and Alexa Villaume for their help and comments.

APPENDIX A: EFFECTS OF INDIVIDUAL CONSTRAINTS ON THE ALLOWED IMF EXPONENTS

In this appendix we show how the individual constraints affect the available parameter space for the IMF models defined by Equation 3. Figure A1 show that the requirement for low galactic scatter in the $\mu$ characteristic IMF mass drastically reduce the available exponents. Requiring that old stellar populations have similar or slightly more massive $\mu$ further restricts this space, especially in the case of the metallicity exponent $\gamma_Z$. Meanwhile, Figure A2 show that although a large volume of parameter space would reproduce the inferred bottom-heavy IMF in early type galaxies, few models in the literature can do so and only in case of using canonical ULIRG values instead of simulated galaxies.
Figure A1. Power-law exponents for the density, temperature, metallicity, Mach-number, size and magnetic field in Equation 3 that satisfy IMF universality in the MW and nearby dwarf galaxies (see Table 3 for details on constraints and Table 1 for the simulated galaxies). The shaded regions show the exponents that satisfy the different constraints, while symbols represent models from the literature (Table 4). From these we can infer that there is a fairly limited volume in the model space of Equation 3 that satisfies MW universality, the constraints are especially stringent on the $\gamma_Z$ metallicity exponent.
Figure A2. Power-law exponents for Equation 3 that reproduce the inferred bottom-heavy IMF for early type galaxies (top 2 rows) and the inferred top-heavy IMF for ultra faint dwarf galaxies (bottom 2 rows), similar to Figure A1. Note that UFD proxy (m10xf14706) as well as one of our simulated early type galaxies (z5m12c) did not include magnetic fields, hence they provide no constraints on the $\gamma_B$ exponent. It is clear that the models in the literature fail to reproduce the bottom-heavy IMF for simulated galaxies, but some can satisfy the constraints when using canonical ULIRG values.
