Pre-test characteristics of unstable angina patients with obstructive coronary artery disease confirmed by coronary angiography

Kristina Fladseth,1,2 Andreas Kristensen,2 Jan Mannsverk,2 Thor Trovik,2 Henrik Schirmer3,4

ABSTRACT

Objective Patients referred for acute coronary angiography (CAG) with unstable angina (UA) have low mortality and low rate of obstructive coronary artery disease (CAD). Better pre-test selection criteria are warranted. We aimed to assess the current guidelines against other clinical variables as predictors of obstructive CAD in patients with UA referred for acute CAG.

Methods From 2005 to 2012, all CAGs performed at the University Hospital of North Norway, the sole provider of CAG in the region, were recorded in a registry. We included 979 admissions of UA and retrospectively collected data regarding presenting clinical parameters from patient hospital records. Obstructive CAD was defined as ≥50% stenosis and considered prognostically significant if found in the left main stem, proximal LAD or all three main coronary arteries. Characteristics were analysed by logistic regression analysis. A score was developed using ORs from significant factors in a multivariable model.

Results The overall rate of obstructive CAD was 45%, and the rate of prognostically significant CAD was 11%. The risk criteria recommended in American College of Cardiology/American Heart Association and European Society of Cardiology guidelines had an area under the curve (AUC) of 0.58. Adding clinical information increased the AUC to 0.77 (95% CI 0.74 to 0.80). Applying the derived score, we found that 56% (n=546) of patients had a score of <13, which was associated with a negative predictive value of 95% for prognostic significant CAD.

Conclusions The current results suggest that CAG may be postponed or cancelled in more than half of patients with UA by improving pre-test selection criteria with the addition of clinical parameters to current guidelines.

INTRODUCTION

Acute chest pain is one of the most common presenting symptoms in emergency departments.1 It poses a challenge to healthcare systems as critical conditions require prompt diagnosis and treatment, whereas benign disorders need to be identified early to prevent unnecessary and potentially harmful procedures. Suspected acute coronary syndrome refers to patients with chest pain presumably caused by acute myocardial ischaemia and encompasses myocardial infarction (MI) and unstable angina (UA). Patients with UA have no evidence of myocardial injury.2 3 New, high-sensitive cardiac troponin (hs-cTn) assays detect myocardial injury in a group of patients previously diagnosed as UA, thus changing the diagnosis to MI.4–6 Consequently, the present UA population have lower mortality and are less likely to have obstructive coronary artery disease (CAD).7 8

Despite this, the fear of missing an impending MI results in a liberal referral practice of patients with presumed UA to acute coronary angiography (CAG). European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of acute coronary syndrome in
patients without ST elevation recommend performing CAG within 72 hours if there is either an intermediate Global Registry of Acute Coronary Events (GRACE) risk score (109–140), relevant comorbidity, recurrence of symptoms or a positive ECG or stress test.4,9 GRACE risk score predicts the risk of MI and death and is included in the guidelines as a tool to risk stratify these patients.10

A better pre-test selection is warranted. We aimed to assess the GRACE risk score, guidelines risk criteria and other clinical factors capability of predicting obstructive CAD in patients referred for acute CAG on the indication of UA.

METHODS
Study population
Between 1 January 2005 and 31 December 2012, all coronary angiographies (CAG) performed at the University Hospital of North Norway were recorded in a clinical registry. The University Hospital is the sole provider of CAG in Northern Norway, serving a local population of 127 000 and a total regional population of 481 000. We included the 1936 CAGs performed in patients with presumed UA from the local catchment area to facilitate further retrospective data collection from patient hospital records. Patients with more than one procedure per admission were only included once (n=35), and patients with a peak troponin level above the 99th percentile (n=813) were excluded.2 We also excluded patients mislabelled as UA (n=46) and patients with other primary local hospitals (n=30), incorrectly registered as local patients. Patients who had undergone percutaneous coronary intervention (PCI) within the last 30 days (n=33) were excluded because 91% of these patients had obstructive CAD, warranting acute CAG. Subsequently, the final cohort included 979 UA patient admissions.

Data collection
The registry contains data from all consecutive CAGs, recorded by the operator at the time of the procedure. Linkage to troponin levels from the Department of Clinical Chemistry at the University Hospital of North Norway and to patient hospital records was done by the national 11-digit identification number. From patient hospital records, we retrospectively collected data on symptoms and clinical findings at presentation, preceding symptoms, stress tests, risk factors, comorbidities and medication. The extent of CAD was evaluated by the interventional cardiologist. In patients with prior coronary artery bypass grafting, only those with new obstructive CAD were labelled with obstructive CAD. From July 2009, hs-cTnT replaced standard troponin assay. A standard troponin value of 10 ng/L corresponds to 30 ng/L hs-cTnT. To adjust for this, the troponin values measured up to July 2009 were multiplied by a factor of three.11 12 In addition, we performed sensitivity analyses on the subpopulation with measured hs-cTnT.

Patients were referred as UA if chest pain at rest, new-onset angina or rapidly worsening angina. We registered the threshold of angina prior to admission by the Canadian Cardiovascular Society grading of angina pectoris. A variation in the threshold of angina of two or more grades was defined as a variable threshold. A declining threshold of angina was not included as a variable threshold. Refractory angina was recorded if intravenous nitroglycerine was given. We defined a history of typical angina as (1) substernal chest pain or discomfort, (2) provoked by physical exertion or emotional stress and (3) relieved by rest within minutes. Atypical angina was defined as one of these characteristics, and patients with one of these characteristics were defined as having non-anginal chest pain.13 A positive stress ECG was defined as ≥1 mm of ST-segment depression or elevation, or stress-induced chest pain. The guideline criterion of acute heart failure was defined as Killip class II–IV. We calculated the GRACE risk score according to the Fox model for death between hospital admission and 6 months (http://www.outcomes-unmassmed.org/grace/files/GRACE_RiskModel_Coefficients.pdf). Family history of CAD was defined as first-degree relatives with premature CAD stated in the patient hospital record. Diabetes mellitus was defined if the diagnosis occurred in the patient hospital records or HbA1c≥6.5%. Hypercholesterolaemia was defined by the use of lipid-lowering drugs or serum cholesterol level of ≥6.5 mmol/L.

Endpoint
As the mortality is very low in patients with UA in the hs-cTnT era, we chose obstructive CAD as the primary endpoint of our analyses. To ensure high sensitivity, obstructive CAD was defined as ≥50% angiographic diameter stenosis or fraction flow reserve <0.8 in any epicaudal coronary artery.14 We defined obstructive CAD in the main stem, proximal left anterior descending artery or in all three main coronary vessels (three-vessel disease) as prognostically significant CAD.14 15 UA resembles stable angina, both having negative hs-cTn and low mortality compared with MI, and an unsure prognostic benefit of revascularisation. Therefore, we assumed no immediate yield of acute revascularisation in the hs-cTnT-negative UA patients without prognostically significant CAD.

Statistical analysis
Patient characteristics were reported as counts, percentages or means±SD. Logistic regression analysis was used to investigate predictors of obstructive CAD. In the final multivariable model, we included the predictors with clinical significance and p<0.05. We included interaction terms significantly improving the model by receiver operating characteristics (ROC) and the Net Reclassification Improvement. The Hosmer-Lemeshow goodness-of-fit test was not significant for the final model. To investigate the main contributing variables of the GRACE risk score and guidelines risk criteria, we used a forward selection logistic regression analysis, with inclusion at p<0.05.
We found that an increasing number of variables with missing information was significantly associated with no obstructive CAD (odds ratio (OR) 0.77, 95% confidence interval (CI) 0.71 to 0.83). We tested this assumption for all variables included in the final model; it was found to be true for all variables except symptom characteristics. Therefore, missing information was combined in the reference group for the other variables, but classified as an independent predictive category for symptom characteristics.

We created a score based on the final multivariable model, weighting the variables with the OR rounded off to the nearest integer. Applying the score, we estimated the proportion of patients with a high negative predictive value (NPV) for prognostically significant CAD, assuming these patients could have been safely discharged without a CAG or referred for elective CAG. The discriminative performance of the GRACE risk score, the ESC and ACC/AHA guidelines risk criteria, and the derived model and its score were tested by ROC analysis. Statistical analyses were performed with Stata V.14.0. All reported differences had two-sided p values<0.05.

RESULTS

Patient characteristics

Of the 979 patients with UA, the overall rate of obstructive CAD was 45% (n=443), falling from 56% (n=70) in 2005 to 29% (n=33) in 2012 (p for trend<0.001). Obstructive CAD of prognostic significance was prevalent in 11% (n=103) of the patients. Patient characteristics are shown in table 1. Patients with obstructive CAD were older, more often male, smoked more, had more hypertension and hypercholesterolaemia, a higher GRACE risk score and a higher rate of established CAD.

Performance of GRACE risk score and risk criteria from guidelines

We found that both patients with and without obstructive CAD had low GRACE risk scores, 83 versus 76, respectively. In total, <1% (n=7) of the patients with UA had a high GRACE risk score (>140) and 11% (n=104) had an intermediate GRACE risk score (109–140). In patients with a high GRACE score, five out of seven patients had obstructive CAD versus half of the patients with an intermediate GRACE score. According to the ESC guidelines, 21% (n=202) of the patients in our study were candidates for a selective invasive strategy based on the results of a non-invasive stress test. However, 26% (n=52) of these patients had obstructive CAD and 5.5% (n=11) had prognostic significant CAD. ACC/AHA guidelines would allocate conservative treatment to 31% (n=299) of the patients, of which 32% (n=96) had obstructive CAD and 4.3% (n=13) prognostic significant CAD. High-risk criteria from ESC and ACC/AHA guidelines were present in 25% (n=242) and 22% (n=216) of the patients, respectively.

Table 1 Patient characteristics

|                         | Obstructive CAD (n=443) | No obstructive CAD (n=536) | P values |
|-------------------------|-------------------------|---------------------------|----------|
| Age (years)             | 65±11                   | 60±12                     | <0.001   |
| Male gender (%; n)      | 67% (297)               | 52% (281)                 | <0.001   |
| BMI (kg/m²)             | 28±5                    | 28±6                      | 0.543    |
| Heart rate (beats/min)  | 68±14                   | 71±16                     | 0.014    |
| Systolic blood pressure (mm Hg) | 145±22               | 140±21                    | <0.001   |
| Diastolic blood pressure (mm Hg) | 81±12                 | 80±13                     | 0.223    |
| Use of antihypertensive drugs (%; n) | 77% (339)         | 63% (339)                 | <0.001   |
| Hypercholesterolaemia (%; n) | 74% (326)           | 66% (352)                 | 0.008    |
| Diabetes mellitus (%; n) | 18% (79)               | 15% (82)                  | 0.287    |
| Established coronary artery disease (%; n) | 59% (263)       | 39% (209)                 | <0.001   |
| Previous MI (%; n)      | 36% (158)               | 21% (113)                 | <0.001   |
| Previous PCI (%; n)     | 46% (205)               | 33% (177)                 | <0.001   |
| Previous CABG (%; n)    | 18% (80)                | 14% (74)                  | 0.069    |
| Family history of CAD (%; n) | 50% (220)          | 53% (285)                 | 0.274    |
| Smoking status          |                         |                           | 0.008    |
| Current smoker (%; n)   | 29% (130)               | 27% (143)                 |          |
| Former smoker (%; n)    | 44% (195)               | 38% (201)                 |          |
| GRACE risk score        | 83±22                   | 76±24                     | <0.001   |

Values are % (n) or mean±SD. BMI, body mass index; CABG, coronary artery bypass grafting; CAD, coronary artery disease; GRACE, Global Registry of Acute Coronary Events; MI, myocardial infarction; PCI, percutaneous coronary intervention.
patients did not have more CAD than patients with intermediate-risk criteria. GRACE risk score, ESC and ACC/AHA guidelines had similar area under the curve (AUC) for obstructive CAD, with AUC of 0.59 (95% CI 0.55 to 0.62), 0.58 (95% CI 0.56 to 0.61) and 0.58 (95% CI 0.55 to 0.61), respectively. Age alone had a significantly higher AUC of 0.61 (95% CI 0.58 to 0.65, p=0.037) (figure 1). The main contributing variables in the GRACE risk score and guidelines risk criteria were age, systolic blood pressure at admission, prior PCI, Killip class and a positive stress test. We did not find more ST-T abnormalities in the ECG of patients with obstructive CAD.

Prediction of obstructive coronary artery disease
A history of typical angina symptoms, Canadian Cardiovascular Society angina grade 3 or 4, no variable threshold of exertional angina, no history of palpitations, prior PCI, positive stress testing, smoking, hypertension, age >65 years and male gender all added independently significant information in a multivariable model, increasing the AUC for obstructive CAD to 0.77 (95% CI 0.74 to 0.80, p<0.001) (table 2, figure 1), significantly higher than the GRACE risk score and guidelines risk criteria. The significant interaction term between age and prior PCI was also included. From the model, we derived a score predicting obstructive CAD with an OR of 1.40 (95% CI 1.33 to 1.47, p<0.001) per score level increase. With a cut-off level of <13, the NPV was 95% for prognostic significant CAD in 56% (n=546) of patients with UA referred for acute CAG. For the 44% (n=295) of patients with a score <12 the NPV was 97%. Stratified by sex, a cut-off level of <14 gave a negative predictive value of 95% for 82% (n=330) of females, and a cut-off level of <12 and <13 gave NPVs of respectively 96% for 20% (n=177) and 93% for 43% (n=251) of males (table 3).

In univariable analysis, shorter pain duration predicted obstructive CAD (<2–6 hours, OR 1.82, 95% CI 1.34 to 2.48, p<0.001), whereas chest pain related to change in body posture (n=23) gave lower odds for obstructive CAD (OR 0.18, 95% CI 0.05 to 0.68). We found that pain relief by nitrates, dyspnoea, pain radiation and number of chest pain episodes during the last 24 hours were not
### Table 2  Univariable and multivariable predictors of obstructive coronary artery disease in patients with unstable angina

| Characteristics          | n=979 | Univariable model, OR (95% CI) | Multivariable model, OR (95% CI) | Score |
|--------------------------|-------|-------------------------------|----------------------------------|-------|
| Age >65 years            | 410   | 1.92 (1.49 to 2.49)           | 2.94 (1.97 to 4.41)              | 3     |
| Male gender              | 578   | 1.85 (1.42 to 2.40)           | 2.03 (1.48 to 2.79)              | 2     |
| Prior PCI                | 382   | 1.75 (1.35 to 2.26)           | 1.85 (1.21 to 2.81)              | 2     |
| Hypertension*            |       |                               |                                  |       |
| 1                        | 303   | 2.79 (1.82 to 4.28)           | 2.26 (1.36 to 3.75)              | 2     |
| 2                        | 151   | 2.27 (1.40 to 3.69)           | 2.08 (1.20 to 3.61)              | 2     |

AUC, area under the curve; CAD, coronary obstructive artery disease.
associated with obstructive CAD. Neither were chest wall pain, pain related to breathing or self-reported similarity to prior CAD symptoms, but most patient records lacked this information. A GRACE risk score ≥109 was not significantly associated with obstructive CAD (OR 1.37, 95% CI 0.92 to 2.04).

In sensitivity analyses of the 340 patients included after the implementation of hs-cTnT, the AUC of the multivariable model improved from 0.77 (95% CI 0.74 to 0.80) to 0.81 (95% CI 0.76 to 0.85, although with larger CIs) (online supplementary Table 1). The derived risk score performed similarly on the subpopulation with OR of 1.39 (95% CI 1.28 to 1.52). With a cut-off level of <13, we were able to exclude or delay 59% of the patients (n=201) to acute CAG with an NPV of 96% for prognostic CAD. Further, with a cut-off level of <9 the score demonstrated an NPV of 96% for any obstructive CAD in 21% of the patients (n=73) (online supplementary Table 2).

**DISCUSSION**

In our population-based cohort, we have demonstrated that patients with presumed UA referred for acute CAG have low rates of obstructive CAD and low GRACE risk score. By implementing symptom characteristics and clinical information in a new risk score, it was possible to rule out a higher number of patients with lower rates of obstructive CAD than by applying guidelines risk criteria.

There is to our knowledge no other studies using symptoms to predict obstructive CAD in patients with UA. The HEART score includes the clinicians’ suspicion of critical disease to predict the risk of MI, PCI, CABG and death in an all-cause chest pain population. In stable angina, typical angina symptoms added to risk scores is known to improve the prediction of obstructive CAD. In our study, we found that a history of typical angina with a stable or consistently decreasing threshold in the time prior to the acute admission was strongly associated with obstructive CAD. The acute presentation leading to admission was of less importance. Traditional risk factors such as age and smoking were also strongly associated with obstructive CAD, followed by male gender, hypertension and prior PCI. Age however, was significantly reduced as risk factor for those with prior PCI. This led to a positive interaction term in the model and could indicate a protective effect of PCI, secondary prevention or most likely both.

**The definition of unstable angina**

Our population underwent clinical decision-making before referral. However, with rates of obstructive CAD as low as 29% in the end of the study period, patient selection was poor. It seems other aetiologies for chest pain dominated. We found that palpitations, a known symptom of panic disorder, was associated with lack of obstructive CAD on invasive angiography. Gastrointestinal, musculoskeletal and panic disorders are all known to be highly prevalent in patients with acute or stable chest pain and no evidence of myocardial ischemia, and were likely prevalent in our population.

Braunwald and Morrow suggested that increasingly sensitive troponins would make UA a redundant diagnosis. However in clinical practice, UA remains a challenging diagnosis as objective criteria are rarely present. The fear of uncertainty among clinicians and patients may lead to overuse of presumed UA as indication for acute CAG, even in patients with low clinical suspicion of CAD. This is a likely cause for the low rates of obstructive CAD in our population. Despite the low prevalence of CAD in our population, 79% satisfied the guidelines criteria for acute CAG within 72 hours, which in our opinion warrants better pre-test selection criteria.

**Relevance of guidelines risk criteria and GRACE risk score in the unstable angina population**

The GRACE risk score predicts 3-year mortality in acute coronary syndrome with a superior AUC of 0.82. The overall low GRACE score observed in both patients with and without obstructive CAD is reassuring and supports a low mortality in the present-day UA population. It may also explain why the GRACE risk score and guidelines encompassing non-ST elevation MI (NSTEMI) had poor discriminative ability for obstructive CAD in patients with UA. The low mortality of hs-cTn-negative UA is also demonstrated in other studies, with a 90-day mortality and MI rate for hs-cTnT-negative UA patients of 0.6% and 1.7%, respectively. Even high-risk UA have a 30-day combined death and MI rate of approximately 2%. Guidelines for NSTEMI/UA recommend an invasive approach in many patients with UA, but the implications of an invasive strategy are not known. Available trials do not report separate findings for patients with or have not implemented hs-cTn assays to discriminate between MI and UA. Meta-analyses of existing trials up to 2015 differ in opinion of the benefit of routine revascularisation for the combined UA and NSTEMI population. It seems likely that hs-cTn-negative UA patients will have less benefit than NSTEMI patients.

The low rate of obstructive CAD, MI and death, as well as an unsure prognostic benefit of revascularisation in the hs-cTn-negative UA patients, questions the resource utilisation of acute CAG in most patients with UA. Our study indicates that it is possible to rule out or delay CAG in more than half of the patients with UA by implementing a new risk score with symptoms characteristics and clinical information in addition to risk criteria in guidelines.

**Strengths and limitations**

The major strengths of our study are the inclusion of all consecutive CAGs performed on the indication of UA within a confined geographical area for eight subsequent years, and that all variables included in our risk score are obtained in daily clinical practice. A potential limitation is the relatively small numbers of patients with prognostic significant CAD. We have exclusively investigated patients with UA referred for CAG, and thereby do not know how
the limit of detection, we may have included NSTEMI. As the adjustment for standard troponin to hs-cTnT was risk of CAD, the authors believe that these patients chronic hs-cTn elevation without a significant rise and/or significant bias due to the exclusion of UA patients with months. Further, we did not have enough information on ESC guidelines’ recurrence of symptoms to validate its potential role. We used the peak troponin value to define patients with MI. Therefore, we cannot exclude a significant bias due to the exclusion of UA patients with chronic hs-cTnT elevation without a significant rise and/or or fall (eg, due to chronic heart failure or severe renal dysfunction). However, as these patients have a higher risk of CAD, the authors believe that these patients usually should be offered CAG on a lower threshold and should be addressed in own focused prospective studies. As the adjustment for standard troponin to hs-cTnT was only applicable for patients with troponin values above the limit of detection, we may have included NSTEMI patients before the implementation of hs-cTnT in 2009.

CONCLUSIONS
Our results suggest that by structuring symptom characteristics and clinical variables it may be possible to postpone or cancel acute CAG in over half of the patients referred with presumed UA. This would reduce cost for healthcare systems, avoid exposing patients to unnecessary risk of complications and release capacity for more critical diagnoses. Prospective studies are needed to validate our findings.
