Abstract
Critically ill patients admitted to hospital following SARS-CoV-2 infection often experience hypoxic respiratory failure and a proportion require invasive mechanical ventilation to maintain adequate oxygenation. The combination of prone positioning and non-invasive ventilation in conscious patients may have a role in improving oxygenation. The purpose of this study was to assess the effect of prone positioning in spontaneously ventilating patients receiving non-invasive ventilation admitted to the intensive care. Clinical data of 81 patients admitted with COVID 19 pneumonia and acute hypoxic respiratory failure were retrieved from electronic medical records and examined. Patients who had received prone positioning in combination with non-invasive ventilation were identified.

A total of 20 patients received prone positioning in conjunction with non-invasive ventilation. This resulted in improved oxygenation as measured by a change in PaO₂/FiO₂ (P/F) ratio of 28.7 mmHg while prone, without significant change in heart rate or respiratory rate. Patients on average underwent 5 cycles with a median duration of 3 hours. There were no reported deaths, 7 of the 20 patients (35%) failed non-invasive ventilation and subsequently required intubation and mechanical ventilation. In our cohort of 20 COVID-19 patients with moderate acute hypoxic respiratory failure, prone positioning with non-invasive ventilation resulted in improved oxygenation. Prone positioning with non-invasive ventilation may be considered as an early therapeutic intervention in COVID-19 patients with moderate acute hypoxic respiratory failure.

Introduction
The critical illness characterised by the SARS-CoV-2 viral infection (Coronavirus disease 2019; COVID-19) often results in respiratory symptoms leading to acute hypoxic respiratory failure (AHRF) necessitating mechanical ventilation. Supplemental oxygen is the initial mainstay of therapy. Non-invasive ventilation (NIV) has been shown to be a successful alternative to mechanical ventilation in the early stages of the related coronavirus severe acute respiratory syndrome (SARS) and in COVID-19 without a subsequent need for invasive mechanical ventilation\(^1\). Despite COVID-19 being a novel single disease entity, various phenotypic variations based on biological markers of immunity, prothrombotic features, ventilator mechanics and radiological changes have been documented\(^1\). Consequently, the response to specific therapies may vary between COVID-19 patients with AHRF.

Prone positioning has been often adopted to improve gas exchange in mechanically ventilated patients with moderate to severe refractory hypoxia associated with acute respiratory distress syndrome (ARDS). Prone position was not associated with an improved outcome in a Cochrane review of ARDS patients receiving invasive mechanical ventilation\(^2\). However, subgroup analysis demonstrated a better outcome among those patient groups with severe ARDS. The Prone Severe ARDS (PROSEVA) multicentre randomised-controlled trial has demonstrated improved survival in patients with severe ARDS who had received early, long sessions of prone positioning when compared to the control group of supine patients\(^3\). Despite most COVID-19 patients with AHRF fulfilling the ARDS clinical definition, there are demonstrable variations in response to therapy between COVID-19 lung disease and ARDS. Although the use of prone position in COVID-19 AHRF has not been formally evaluated by clinical trials, its use is supported by several international guidelines, including The Surviving Sepsis Campaign and ANZICS COVID-19 guidelines\(^4\). Moreover, recently a study demonstrated improved oxygenation during a single episode of prone positioning in awake non-ventilated COVID-19 patients\(^5\), while another has demonstrated its feasibility in a non-critical care environment\(^6\). A recent review of conscious proning in ARDS and COVID-19 infection which included a handful of studies with small number of patients and concluded short term improvements in the oxygenation\(^7\).

Here we build on this literature offering an examination of changes in oxygenation, as measured by PaO\(_2\)/FiO\(_2\), across multiple episodes of prone positioning in conscious patients, with moderate to severe hypoxia, undergoing non-invasive ventilation following admission to the intensive care unit for advanced respiratory support.

Methods
Study background
We collected data from all COVID-19 reverse transcriptase polymerase chain reaction (RT-PCR)-confirmed (nasal and throat swab specimens) admissions to the General Intensive Care Unit, University Hospital Southampton NHS Foundation Trust between 4\(^{th}\) March 2020 and 11\(^{th}\) May 2020. When clinical stability allowed, all patients presenting with AHRF needing additional respiratory support, beyond standard oxygen therapy, were trialled on non-invasive ventilation (either continuous positive airway pressure (CPAP) or bilevel positive airway pressure ventilation (BiPAP)). Moreover, depending on their tolerability, patients were encouraged to self-prone. All patients that deteriorated while on NIV went on to have endotracheal intubation and mechanical ventilation.

Ethical considerations
Ethical approval was obtained as part of the REACT COVID observational study (A longitudinal Cohort Study to facilitate Better understanding and Management of SARS-CoV-2 infection from hospital admission to discharge-across all levels of care): REC Reference 17/NW/0632 SRB Reference Number; SRB0025. Due to the nature of the study, the need for individual informed consent was waived.

Data collection and processing
Data was collected from our electronic clinical information (CIS) system using a combination of semi-automated data extraction and manual collection. We collected baseline demographics (age, gender, duration of symptoms, critical illness severity scores, presence of other comorbidities and laboratory variables), medical treatments received, ventilatory parameters, and position data. Position data are recorded hourly by the ICU nursing staff in the CIS and from this we derived number of prone cycles, timing and total duration. We defined NIV failure as the need for mechanical ventilation. On admission we also collected severity indices such as Acute Physiology and Chronic Health Evaluation (APACHE II), Sequential Organ Failure Assessment (SOFA) scores and oxygenation status. Arterial blood gas (ABG) results were collected alongside patient observations (heart rate (HR) and respiratory rate (RR)) from our CIS to measure change in parameters before, during and after prone position. We assessed the change in oxygenation by measuring the change in the arterial oxygen partial pressure (PaO\(_2\) in mmHg) to fractional inspired oxygen (FiO\(_2\)) ratio (ΔP/F), change in respiratory rate (ΔRR) and heart rate (ΔHR).

Statistical analysis
All statistical analysis and data processing were performed using R (R Core Team, Vienna, Austria). Data were tested for normality; those found to be normally distributed were presented as mean and standard deviations (SDs), while non-normally distributed data are presented as median and IQR. Changes in physiological parameters across prone cycles were tested using a paired t-test and are presented and mean and 95% confidence interval. Significance testing between groups was carried out using an independent 2-group t-test for normally distributed variables and the Mann-Whitney U-test for non-normally distributed variables.

Results
There were 81 COVID-19-confirmed patients admitted to the General Intensive Care Unit between 4\(^{th}\) of March and 11\(^{th}\) of May 2020. The outcomes are up to date as of 26 June 2020. Of those, 20 patients (25%) had a combination of both non-invasive ventilation and self-prone positioning. The mean
age of these patients was $53.4 \pm 8.3$, 55% were male and median admission APACHE II and SOFA severity indices were 11.5 (IQR 5) and 3 (IQR 0) respectively. Among those, 7 patients failed NIV and were subsequently intubated (NIV+IMV group). The characteristics of these patients with severity indices are presented in Table 1. Raw results for each patient are available as Underlying data.

There was a total number of 141 prone cycles performed between these patients. Although the duration of each cycle was variable between cycles and among individual patients, the median duration for each cycle was 3 hours (IQR 2) and the number of proning cycles per patient was 5 (IQR 6.3).

Five patients continued with prone positioning beyond 96 hours. Most cycles (46%), were between 1 and 3 hours, a summary detailing prone cycles and duration characteristics is shown in Table 2. Additionally, Figure 1 is a graphical representation of each patient’s time on NIV, demonstrating time spent in prone and supine positions. It follows each of the 20 patients, tracking their position throughout the duration of their admission, up until discharge from ICU or point of intubation.

The outcomes are shown in Table 3. Overall, there was an increment in P/F ratio of $28.7 \text{ mmHg}$ (3.83 kPa) (95% CI 18.7-38.6 mmHg, $p<0.01$) with no change in the heart rate or respiratory rate. The patients who had a successful NIV and prone positioning beyond 96 hours.

### Table 1. Patient demographics for all patients admitted and received non-invasive ventilation and self-prone positioning.

*Data are presented in mean ± standard deviation. †Data are presented in median and interquartile range.

The trial (65%) had a greater increment in P/F ratio of 40.8 mmHg (5.44 kPa) (95% CI 28.8-52.7 mmHg, p<0.01), while those who went on to be intubated did not have a significant improvement in P/F ratio (+5.06 mmHg (0.67 kPa), 95% CI -9.5-19.7 mmHg, p=0.48). Those patients who avoided IMV had a significantly shorter length of hospital stay (11 vs. 28 days, p<0.01) but no other significant differences in outcome or baseline characteristics were observed. Most of the improvement was seen within 24 hours and after this time point the incremental beneficial effect is less for both groups (Figure 2).

On average the NIV+IMV group spent 24% of their intensive care unit time pre-intubation in the prone position compared to only 12% for the NIV only group.

There were no deaths recorded in either group and all patients who had successful NIV and prone positioning without the need for mechanical ventilation were discharged home. Among those 7 patients who failed NIV (35%), 2 were transferred to the regional extra-corporeal membranous oxygenation (ECMO) centre, both were later discharged home.

**Table 2. Prone cycle characteristics for all patients.**

CI, confidence interval; ICU, intensive care unit; IMV, invasive mechanical ventilation; NIV, non-invasive ventilation; PaO₂/FIO₂, ratio of arterial oxygen partial pressure to fractional inspired oxygen; SARF, severe acute respiratory failure.

Figure 1. Time spent prone vs time spent supine (hours) for each patient throughout their admission. Patients that failed non-invasive ventilation and required invasive mechanical ventilation (NIV+IMV group) are shown in blue and non-invasive ventilation (NIV) only group in red.
There were no reported cases of any adverse events from these proning episodes.

**Discussion**

This is a single-centre retrospective observational study of the clinical outcomes of COVID-19 patients who received a combination of conscious proning and non-invasive ventilation as part of their initial ventilation strategy. Conscious proning and non-invasive ventilation was found to be feasible in 20 patients. Despite variations in patient tolerability and cycle duration, oxygenation improved during prone position period without adverse changes in respiratory rate or heart rate. This response was most marked in patients that did not require escalation to invasive ventilation (65%). Patients that went on to require invasive mechanical ventilation (35%) did not have an improvement in their P/F ratio; modest improvements observed in the first 24 hours (Figure 2) were not sustained beyond this initial period. These patients were similar to patients who received only NIV with respect to APACHE II, SOFA scores and degree of hypoxia defined by P/F ratio on admission.

The strain that the coronavirus pandemic has placed on national healthcare infrastructure is unprecedented. Although there is only limited data available on the effectiveness of non-invasive ventilation (NIV) in COVID-19, early provision of NIV in moderate to severe acute hypoxic respiratory failure is associated with reduced ICU mortality and intubation rate\(^\text{12}\). NIV is less resource intensive than IMV and can be managed outside of a critical care environment. NHS England COVID-19 specific guidance suggests that prone position may be of use in NIV patients to improve ventilation/perfusion mismatch, work of breathing and oxygenation\(^\text{13}\). Whilst the use of prone positioning is well defined and has been extensively evaluated in patients with ARDS by several randomised controlled trials,
the benefits of prone positioning in awake, conscious patients with moderate to severe AHRF or ARDS has not been fully explored. Reports from the COVID-19 pandemic from various countries suggests prone positioning in spontaneously ventilating patients may be of value in preventing progression to mechanical ventilation.

Our findings suggest that for a proportion of COVID-19 patients with moderate AHRF (P/F ratio <200 mmHg), non-invasive ventilation in combination with conscious proning can lead to an improvement in oxygenation, less requirement for invasive ventilation and potentially better overall outcomes. All patients with a sustained (>24 hours) positive response to prone positioning avoided intubation, affording them a shorter overall length of hospital stay. However, 35% of patients receiving NIV progressed to invasive mechanical ventilation, despite a similar overall number and duration of proning cycles per patient between both groups. Although none of these patients died, they required a much longer period of hospitalisation and therefore caution is advised when implementing non-invasive ventilation and prone positioning outside of a critical care environment with adequate resources to manage NIV failure.

The use of prone positioning in COVID-19 pneumonia is supported by our understanding of the pathophysiology of the disease. There is inhomogeneity in the lungs, and CT scans of COVID-19 patients typically shows areas of peripheral ground glass changes that later develop into linear consolidations. Areas of exudation, macrophage infiltration, fibrosis and mucous plugs are typical findings on autopsy of deceased patients with COVID 19. Placing patients in the prone position may help to drain secretions from the lung peripheries, improve lung dyshomogeneity, recruitment and ventilation/perfusion mismatch. Many international guidelines recommend prone positioning for intubated and mechanically ventilated patients for these reasons, so it seems reasonable to conclude that similar benefits may be gained by prone positioning in non-invasively ventilated patients with similar underlying pathology.

There are obvious risks associated with treating patients with AHRF with non-invasive ventilation. The primary risk to the patient is inappropriate delay in intubation and ventilation. COVID-19 AHRF frequently meets the criteria for ARDS and previous studies have suggested that in ARDS, delaying intubation due to the use of NIV is associated with increased mortality. Likewise, the SARS-CoV-2 virus is transmitted by respiratory droplets; non-invasive ventilation has been shown to produce droplets of >10 μm in size that are largely deposited on surfaces within a 1 meter radius. Therefore, NIV could potentially increase the risk of virus transmission to individuals in close proximity with the patient. This needs to be a consideration when devising guidelines for personal protective equipment and appropriate cohort allocation of infected patients to minimise infection risk.

There are some limitations of this study. This is a single-centre, retrospective cohort study only limited to small number of COVID-19 patients admitted to the intensive care unit setting with the option of subsequent escalation of care to mechanical ventilation. Most patients were in general young, with a median age of <60 years old and able to self-prone with non-invasive ventilation. These findings may not be transferable to older patient’s group or patients with severe acute hypoxic respiratory failure with P/F ratio of <100mmHg. The study was observational, there were no set criteria for NIV proning and NIV failure with subsequent endotracheal intubation. The clinical judgement and subsequent interventions provided may have been variable between individual senior clinicians and may not be reflective of other centres. Additionally, position data are only recorded hourly and as such some granularity of the data may be lost when the cycles were much shorter period of less than an hour.

Despite these limitations, our results are in line with the other recently published studies of conscious prone positioning in COVID-19 pneumonia. Several case reports and small (up to 25 patients) observational studies conducted in multiple settings (outside ICU, emergency department) with variations in respiratory support (non-invasive ventilation/high-flow nasal oxygen/standard face mask oxygen therapy) and varying severity of hypoxemia has demonstrated beneficial effects of prone positioning in COVID-19 pneumonia. All these studies suggest conscious prone position is associated with an increment in oxygenation and recovery without the need for mechanical ventilation in most cases. Our results demonstrate, specifically that a sustained response across multiple cycles, for a period >24 hours, is associated with successful treatment with NIV. Taken together, these results indicate that prone positioning in awake, non-intubated patients, in combination with non-invasive ventilation is feasible and may be considered as an early intervention in COVID-19 respiratory failure, particularly in the context of a severe pandemic to prevent mechanical ventilation and its subsequent complications. They also suggest that a loss of response to prone position may potentially be a sign of NIV failure and warrant early evaluation and consideration for endotracheal intubation.

Conclusion
In conclusion we demonstrate that prone positioning in conjunction with NIV can improve oxygenation in patients with COVID-19. This can be achieved without significant adverse effects and particularly in those with a sustained response, may avoid intubation. When used in a suitably monitored environment, with access to experienced clinicians able to facilitate invasive mechanical ventilation if required, prone positioning alongside NIV may be a useful tool in treating COVID-19 patients with moderate acute hypoxic respiratory failure.

This is a retrospective report on a subgroup of 20 patients with severe COVID-19 who were able to self-prone while receiving non-invasive ventilation in the ICU, among a grand total of 81 patients admitted to the ICU during the study period.

The primary outcome reported by the authors is change in PaO2/FiO2 ratio while in prone position. Clinical outcomes, such as mortality and the incidence of intubation, are also reported.

The retrospective nature of the report precludes any causal inferences with regards to the efficacy of awake proning. However, the authors do show that intubation can indeed be avoided in some patients with moderate ARDS due to COVID-19, and that awake proning is associated with improvements in PaO2/FiO2 ratios.

The authors assert that improvement in PaO2/FiO2 ratios predicted avoidance of intubation. Their data do not allow us to conclude whether this improvement is solely the response to awake proning, or natural evolution of patients who were already getting better in the first place, and would have avoided intubation whether or not they were subjected to awake proning. One may also wonder if reverse causality was also at play, and if patients who didn't improve their PaO2/FiO2 ratio were intubated precisely for that reason. Intubation is a soft outcome that relies on treating physician judgement, and it is difficult to disentangle cause and effect in this scenario.

In summary, the authors have shown that PaO2/FiO2 ratios may improve in response to awake proning, and they did not identify any obvious safety signals in this cohort of patients that were able to tolerate awake self-proning. Although this paper does not demonstrate efficacy of awake proning, it does add to the growing body of knowledge on this subject and allows comparisons with other cohorts which used different strategies in terms of duration of proning, as well as the type of respiratory support. Publication of such preliminary data is important, especially while awaiting definitive answers from randomized controlled trials.
In this retrospective observational cohort study, 20 spontaneously ventilating patients admitted to critical care with hypoxic respiratory failure consequent to COVID 19 pneumonia, who underwent proning while receiving non-invasive ventilation were identified from the EHR. The primary outcome examined was a change in PaO2/FiO2 (P/F) ratio while prone as compared with supine, which the authors report as improved while prone.

In terms of data quality and study design, since this is a retrospective study, no single protocol for awake proning was used, creating a large amount of variability in duration, cycle length and frequency of intervention. Similarly, total length of time spent on NIV, and total number of hours
/days spent awake proning appears very varied. This reduces the utility of the data significantly. No comparative statistics are presented between groups (correctly).

In terms of trajectory of illness, it would be helpful to plot the overall P/F ratio over time for both intubated and non-intubated groups, since from the data available it would appear that those patients who were ultimately intubated started with worse oxygenation and benefited least from the intervention.

It may also be useful to examine a control group of patients who did not self-prone, but did receive non-invasive ventilation during the study period.

The data presented do however, provide reassurance in terms of safety of the intervention in terms of hemodynamic and respiratory stability.

I do not agree that the data presented in this study demonstrate the potential for better overall outcomes with awake proning in COVID-19. More data is required to demonstrate that the trajectory of illness was altered by proning, which is not available in this study. Rather, the observation that patients who avoided intubation overall spent lower percentage of time prone and had a increased response to proning in terms of P/F ratio, suggests that those patients on the trajectory (who are not well described in this study) towards intubation did not have their outcome altered by proning. Rightly, in the discussion the authors discuss the risks associated with applying awake proning.

In summary Burton-Papp et al. have shown that P/F ratio may improve in proned patients on non-invasive ventilation with COVID-19 respiratory failure. Their data also suggests that awake proning on NIV in COVID-19 positive patients is safe in terms of cardiorespiratory stability in those patients who are able to tolerate the intervention. This intervention may therefore provide some clinical benefit, but it is not possible to determine from this study with limited numbers where no control group was presented. What they have not demonstrated is whether proning on NIV alters clinical course, prevents intubation, what protocol is most effective or who might benefit most from this intervention all of which would require prospective study or matched controlled. They further did not describe which features prevented patients from tolerating awake proning on NIV which may be useful in understanding the impact of the intervention.

Is the work clearly and accurately presented and does it cite the current literature?
Yes

Is the study design appropriate and is the work technically sound?
Partly

Are sufficient details of methods and analysis provided to allow replication by others?
Yes

If applicable, is the statistical analysis and its interpretation appropriate?
Yes

Are all the source data underlying the results available to ensure full reproducibility?
Yes

**Are the conclusions drawn adequately supported by the results?**
Partly

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Critical Care and Perioperative Medicine

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.
