On the Cycle Structure of Mallows Permutations

Alexey Gladkich\textsuperscript{1}       Ron Peled\textsuperscript{1}

September 12, 2017

Abstract

We study the length of cycles of random permutations drawn from the Mallows distribution. Under this distribution, the probability of a permutation $\pi \in S_n$ is proportional to $q^{\text{inv}(\pi)}$ where $q > 0$ and $\text{inv}(\pi)$ is the number of inversions in $\pi$.

We focus on the case that $q < 1$ and show that the expected length of the cycle containing a given point is of order $\min\{(1 - q)^{-2}, n\}$. This marks the existence of two asymptotic regimes: with high probability, when $n$ tends to infinity with $(1 - q)^{-2} \ll n$ then all cycles have size $o(n)$ whereas when $n$ tends to infinity with $(1 - q)^{-2} \gg n$ then macroscopic cycles, of size proportional to $n$, emerge. In the second regime, we prove that the distribution of normalized cycle lengths follows the Poisson-Dirichlet law, as in a uniformly random permutation. The results bear formal similarity with a conjectured localization transition for random band matrices.

Further results are presented for the variance of the cycle lengths, the expected diameter of cycles and the expected number of cycles. The proofs rely on the exact sampling algorithm for the Mallows distribution and make use of a special diagonal exposure process for the graph of the permutation.

1 Introduction

The cycle structure of a random permutation picked uniformly from $S_n$, the permutation group on $n$ elements, is a classic topic in probability theory. Of the abundant literature on it we mention two key facts: The distribution of the length of a cycle containing a given point is uniform on $\{1, \ldots, n\}$. Moreover, the joint distribution of the lengths of the longest cycles in the permutation has an explicit limit; the sorted vector of cycle lengths, normalized by $n$, converges in distribution to the Poisson-Dirichlet distribution with parameter one.

In this work we study the cycle structure of a random permutation distributed according to the Mallows distribution. The Mallows distribution is a non-uniform distribution on permutations which was introduced by Mallows in statistical ranking theory \cite{mallows}. It has recently been the focus of several studies in varied contexts including mixing times of Markov chains \cite{chung, janson}, statistical physics \cite{shnirman, chung}, learning theory \cite{charikar}, q-exchangeability

and the problem of the longest increasing subsequence \[21\] \[6\] \[5\]. Borodin, Diaconis and Fulman \[7\] Section 5] considered a class of models of random permutations (denoted \(P_\theta\) there) for which the Mallows distribution is the prime example. They noted that many of the “usual questions” of applied probability and enumerative combinatorics remain open for such models and asked “Picking a permutation randomly from \(P_\theta(\cdot)\), what is the distribution of the cycle structure, longest increasing subsequence, . . .?” Our work answers the part of this question pertaining to the cycle structure of the Mallows distribution.

The Mallows distribution on \(S_n\) is parameterized by a real number \(q > 0\) and is denoted \(\mu_{n,q}\). It is given by

\[
\mu_{n,q}[\pi] := \frac{q^{\text{inv}(\pi)}}{Z_{n,q}}
\]

where

\[
\text{inv}(\pi) := \left| \{(s, t) \mid s < t \text{ and } \pi_s > \pi_t\} \right|
\]

denotes the number of inversions in \(\pi\), and \(Z_{n,q}\) is a normalizing constant, given explicitly by the following formula \[26\] Corollary 1.3.13],

\[
Z_{n,q} = \prod_{i=1}^{n} \left(1 + q + \cdots + q^{i-1}\right) = \prod_{i=1}^{n} \frac{1 - q^i}{1 - q}.
\]

The Mallows distribution with parameter \(q = 1\) coincides with the uniform distribution on \(S_n\). In this paper we restrict attention to the case that \(0 < q < 1\) (a brief discussion of the case \(q > 1\) is given in Section 5). As is well known, \(\text{inv}(\pi)\) equals the minimal number of adjacent transpositions required to bring \(\pi\) to the identity. Thus, when \(0 < q < 1\), the Mallows distribution gives higher weight to permutations which are closer to the identity in an underlying one-dimensional geometry.

We are mainly interested in the properties of the Mallows distribution for \(q\) close to 1, usually as a function of \(n\), although our results apply in the full range of \(0 < q < 1\). Figure 1 depicts samples of the Mallows distribution. One simple feature of a Mallows distribution is that it typically displaces elements by a small amount. This is quantified in the following statement: there exists an absolute constant \(c > 0\) such that if \(\pi \sim \mu_{n,q}\) then for all \(0 < q < 1\) and \(1 \leq s \leq n\),

\[
c \cdot \min \left\{ \frac{q}{1 - q}, n - 1 \right\} \leq \mathbb{E} |\pi_s - s| \leq \min \left\{ \frac{2q}{1 - q}, n - 1 \right\},
\]

see \[6\] for a proof and related concentration bounds or \[8\] \[14\] for similar statements.

Thus the expected displacements are of order \(o(n)\) when \(\frac{1}{1-q} \ll n\) and it is natural to ask whether this also results in shorter cycles. Our first result determines the expected length of cycles.

**Notation:** For two quantities \(x, y\), which may depend on other parameters such as \(n\) or \(q\), we write \(x \approx y\) if there exist absolute constants \(c, C > 0\) such that \(c y \leq x \leq C y\).

For a permutation \(\pi \in S_n\) and \(1 \leq s \leq n\) we let \(C_s = C_s(\pi)\) be the orbit of \(s\) in \(\pi\), i.e., the set of points in the cycle of \(\pi\) which contains \(s\).

**Theorem 1.1 (Expected Cycle Length).** Let \(n \geq 1\), \(0 < q < 1\) and \(\pi \sim \mu_{n,q}\). Then

\[
\mathbb{E} |C_s| \approx \min \left\{ \frac{1}{(1 - q)^2}, n \right\} \quad \text{for all } 1 \leq s \leq n.
\]
Figure 1: Graphs of samples of the Mallows distribution $\mu_{n,q}$ with $n = 1000$, $q = 0.99$ (left) and $q = 0.995$ (right). The red lines are at vertical distance $\frac{2}{1-q}$ from the diagonal. They delimit a region containing most of the points of the permutation, see also [2].

Thus the expected length of the cycle containing a given point transitions from being $o(n)$ when $\frac{1}{1-q} \ll \sqrt{n}$ to being $\Omega(n)$ in the complementary regime. The same is true also for the maximal cycle length in the permutation, see Claim 4.14. We say this transition marks the emergence of macroscopic cycles in the permutation.

Theorem 1.1 identifies a similarity between the uniform distribution and the Mallows distribution in the regime that macroscopic cycles exist, namely, that the expected cycle lengths in both distributions are of order $n$. The two distributions are quite different in many other respects, for instance, when $\frac{1}{1-q} \ll n$ they are distinguished even by their typical displacements as measured by (2). Our next result shows that as far as the lengths of the long cycles are concerned, the similarities extend much further than what may initially be expected: the two distributions give rise to the same limit law.

**Theorem 1.2 (Poisson-Dirichlet Law).** Suppose that the sequence $(q_n)$ satisfies

$$0 < q_n < 1 \quad \text{and} \quad (1 - q_n)^2 \cdot n \to 0.$$

Let $\pi \sim \mu_{n,q_n}$ and let $\ell_1 \geq \ell_2 \geq \ldots$ be the sorted lengths of cycles in $\pi$. Then, as $n \to \infty$,

$$\frac{1}{n}(\ell_1, \ell_2, \ldots) \text{ converges in distribution to the Poisson-Dirichlet law with parameter one.}$$

In addition, for any sequence $(s_n)$ satisfying $1 \leq s_n \leq n$, as $n \to \infty$,

$$\frac{1}{n}|C_{s_n}| \text{ converges in distribution to the uniform distribution on } [0,1].$$

Our results provide further information on the cycle lengths in the regime in which there are no macroscopic cycles. We show that the cycle lengths are not concentrated in the sense that their standard deviation has the same order of magnitude as their expectation.

**Theorem 1.3 (Variance of Cycle Length).** Let $n \geq 1$, $0 < q < 1$ and $\pi \sim \mu_{n,q}$. Then

$$\text{Var}|C_s| \approx \min \left\{ \frac{q}{(1-q)^4}, (n-1)^2 \right\} \quad \text{for all } 1 \leq s \leq n.$$
The argument showing that the standard deviation is at least as large as the expectation, when $q$ is bounded away from 0, bears something of a general nature and may be applicable to other spatial permutation models such as the interchange model; see Section 1.2.4 and Section 5 for more details on these models.

Our next theorem considers the diameter of cycles, showing that the cycles are dense in their support in the sense that their lengths are comparable to their diameters on average.

**Theorem 1.4** (Expected Cycle Diameter). Let $n \geq 1$, $0 < q < 1$ and $\pi \sim \mu_{n,q}$. Then, for all $1 \leq s \leq n$,

$$
\mathbb{E}[\max(C_s) - \min(C_s)] \approx \min \left\{ \frac{q}{(1-q)^2}, n-1 \right\}
$$

(3)

and, moreover,

$$
\mathbb{E}[\max(C_s) - s] \approx \min \left\{ \frac{q}{(1-q)^2}, n-s \right\},
$$

(4)

$$
\mathbb{E}[s - \min(C_s)] \approx \min \left\{ \frac{q}{(1-q)^2}, s-1 \right\}.
$$

(5)

Given our previous theorems, naively, one may expect that a typical random Mallows permutation $\pi$ has about $n/ \min\{(1-q)^{-2}, n\}$ cycles, as the cycle containing a given point typically has length of order $\min\{(1-q)^{-2}, n\}$. However, such reasoning is known to be false even for a uniformly random permutation, in which the cycle containing a given point typically has length of order $n$, yet there are $\log n$ cycles on average. This phenomenon reflects the fact that while most cycles are short, most points lie in long cycles. Our last theorem clarifies that this is also the case for random Mallows permutations and gives the order of magnitude of the number of cycles.

**Theorem 1.5** (Expected Number of Cycles). Let $n \geq 1$, $0 < q < 1$ and $\pi \sim \mu_{n,q}$. Then

$$
\mathbb{E}[\text{number of cycles in } \pi] \approx (1-q) \cdot n + \log(n+1).
$$
1.1 Sampling Algorithm

Our results are based on an exact sampling algorithm for the Mallows distribution which goes back to the original work of Mallows [20]. The algorithm allows us to sample a permutation \( \pi \sim \mu_{n,q} \) sequentially as follows: Given \( \pi_1, \ldots, \pi_{s-1} \), the distribution of \( \pi_s \) is distributed on the remaining \( n-s+1 \) values in a geometric progression. Precisely, if the remaining values are \( j_1 < j_2 < \cdots < j_{n-s+1} \) then

\[
P[\pi_s = j_k \mid \pi_1, \ldots, \pi_{s-1}] = \frac{1 - q}{1 - q^{n-s+1}} \cdot q^{k-1}.
\]  

(6)

It is simple to verify the validity of this formula by noting that, given \( \pi_1, \ldots, \pi_{s-1} \), the assignment \( \pi_s = j_k \) creates exactly \( k-1 \) inversions between \( \pi_s \) and \( \pi_{s+1}, \ldots, \pi_n \); precisely, if \( \pi_s = j_k \) then necessarily \( |\{t \mid t > s, \pi_t < \pi_s\}| = k - 1 \).

In our proofs we develop more flexible versions of the above formula, allowing us to sample portions of the cycles of the permutation iteratively and control the evolution of these portions, see Section 3.2 and the beginning of Section 4.

There exist extensions of the Mallows distribution and the above formula (for \( q < 1 \)) to infinite permutations; one-to-one and onto functions \( \pi: \mathbb{N} \rightarrow \mathbb{N} \) or \( \pi: \mathbb{Z} \rightarrow \mathbb{Z} \). The extension to the case of \( \mathbb{N} \) is straightforward, one simply takes the limit \( n \rightarrow \infty \) in (6) to obtain a geometric distribution, see Gnedin and Olshanski [13]. The extension to a two-sided infinite permutation, when the index set is \( \mathbb{Z} \), is more complicated due to the fact that there is no natural initial position to start the sampling process from.

Generating methods for the two-sided infinite case were developed in [14]. In one of these methods, one samples two one-sided infinite Mallows permutations and uses a ‘stitching’ mechanism to merge these into a two-sided infinite permutation. We also present a method for sampling a Mallows permutation ‘from an interior point’, see Section 3.5. The method is presented for finite \( n \) and may be used also for the two-sided infinite case via an approximation theorem from [14, Section 7.2]. This method may serve as a bridge to transfer results from the finite \( n \) case to the two-sided infinite case.

1.2 Relation with other models

In this section we briefly describe other models for which related results have been obtained or are conjectured.

1.2.1 Permutons

The regime of parameters in which \( n \cdot (1 - q) \rightarrow \beta \) is also of special interest as in this case there is a limiting density to the empirical measure of the points in the graph of a Mallows permutation. Starr [27] obtained an explicit formula for the limiting density as a function of \( \beta \). In modern terminology, the limiting density is called a permuton. Recently, Mukherjee [22] proved Poisson limit theorems for the lengths of short cycles for models converging to permutons, including the Mallows model as a special case. See also Kenyon, Král’, Radin and Winkler [17] for relations with permutons with fixed pattern densities.
1.2.2 Band Matrices

In the study of random matrices, models of matrices with a band structure are of interest. We elaborate on one representative model: Let $A$ be an $n \times n$ random matrix in which, for a given band width $0 < W \leq n$, the entries $A_{i,j}$, $|i - j| < W$, are independent and identically distributed standard Gaussian random variables and the other entries are set to zero. Define the symmetric band matrix $H$ by

$$ H := \frac{A + A^t}{\sqrt{2}}. $$

The main focus in these studies is on the eigenvalues and eigenvectors of $H$.

In one extreme case $W = 1$, meaning that the matrix $H$ is diagonal, the eigenvectors are the standard basis vectors. The other extreme case, when $W = n$, results in the Gaussian Orthogonal Ensemble (GOE) distribution (up to scaling). In this case the distribution of $H$ is invariant under conjugation by orthogonal matrices, implying that the eigenvectors of $H$ form a uniformly distributed orthonormal basis.

It is conjectured that random matrices of this kind undergo a localization / delocalization transition as the band width $W$ increases beyond the threshold $\sqrt{n}$. More precisely, one expects that when $W \ll \sqrt{n}$, the eigenvectors are localized in the sense that most of their $\ell^2$ mass lies on a set whose size is $o(n)$ (possibly even in an interval of such size), whereas if $W \gg \sqrt{n}$ the eigenvectors have their $\ell^2$ mass approximately uniformly spread. Furthermore, in the second regime, it is expected that the local eigenvalue statistics have the same limit as in the GOE case as $n$ tends to infinity. Informally, we may say that the local eigenvalue statistics should have the mean-field limit in the delocalized regime.

See the survey of Spencer [25] and references within for more on these topics.

Our results prove an analogous transition for the Mallows distribution. One may consider the permutation matrix $H_\pi$ associated with a random permutation $\pi \sim \mu_{n,q}$. By (2), this matrix has an approximate band structure in the sense that few of its non-zero entries $(H_\pi)_{s,s}$ have $|\pi_s - s|$ greater than a constant multiple of the band width $W = \min\left\{\frac{1}{1 - q}, n\right\}$ (in fact, the probability that $|\pi_s - s| \geq tW$ decays exponentially in $t$, see [6, Theorem 1.1] and Figure 1). Such a matrix is orthogonal, having its eigenvalues on the unit circle. The eigenvalues and eigenvectors of $H_\pi$ are determined by the cycle structure of $\pi$: associated with each cycle of length $\ell$, one has the $\ell$ eigenvalues $\exp\left(\frac{2\pi i j}{\ell}\right)$, $0 \leq j \leq \ell - 1$, and correspondingly $\ell$ eigenvectors, supported on the coordinates of the cycle and giving equal mass to all points of it. Thus, a localization / delocalization transition corresponds to the emergence of cycles whose length is of order $n$. Theorem 1.1 shows that such a transition occurs as the band width increases beyond $\sqrt{n}$, paralleling the conjecture for random band matrices. Moreover, Theorem 1.2 shows that in the delocalized regime, the statistics of long cycles approach the Poisson-Dirichlet distribution, the limiting statistics for uniform random permutations, in analogy with the above prediction for the local eigenvalue statistics.

The reader is also referred to the survey of Olshanski [23] for other analogies between random permutations and random matrices, discussing, in particular, analogies between random permutations distributed according to the Ewens measure (see also Section 5) and deformations of Dyson’s circular ensemble of random matrices.
1.2.3 Card Shuffling

There are many natural dynamics on permutations for which the uniform distribution is stationary. Diaconis and Shahshahani [10] consider the following natural card shuffling scheme: Start with a deck of \( n \) cards. At each step choose two cards uniformly and independently and exchange their positions in the deck. How many steps does one need to perform in order for the deck to become almost perfectly shuffled? In a beautiful application of representation theory to the study of Markov chains, it is proved in [10] that the state of the deck after \( \frac{1}{2} n \log n + cn \) such steps is close to uniform (in the total variation distance) when \( c \) is a large positive constant, and is far from uniform when \( c \) is a large negative constant. The latter bound follows from the analysis of the coupon collector problem: when \( c \) is a large negative constant there will be many cards in the deck which have not moved from their initial position, creating a permutation with many fixed points. Thus, the result of [10] may be interpreted as saying that the number of short cycles is the main obstacle for a permutation to become approximately uniform in this card shuffling scheme.

Schramm [24] considered the above card shuffling scheme further, investigating the state of the deck after \( tn \) steps are performed. The analysis in [24] proceeds by drawing an associated graph on the vertex set \( \{1, \ldots, n\} \), in which an edge is put between \( i \) and \( j \) if the cards at positions \( i \) and \( j \) in the deck have been exchanged. This associated graph is distributed as an Erdős-Rényi random graph, allowing one to deduce from the standard literature that when \( t \leq \frac{1}{2} \), all cycles in the random permutation have size \( o(n) \). Schramm’s work focuses on the case that \( t > \frac{1}{2} \) and proves that macroscopic cycles emerge in this regime (see also Berestycki [3] for a later simpler argument). Moreover, confirming a conjecture of Aldous, it is proved that the limiting joint distribution of these macroscopic cycles obeys the same Poisson-Dirichlet law observed for uniform permutations. Thus, although it takes about \( \frac{1}{2} n \log n \) steps for the full permutation to become approximately uniform, it takes far fewer steps for macroscopic cycles to start emerging and the joint distribution of these macroscopic cycles converges very quickly to the limiting joint distribution. A similar fact is true for the Mallows model by our results: when \( q \) increases beyond the threshold \( 1 - \frac{1}{\sqrt{n}} \), although the Mallows permutation is still far from uniform (distinguished by its displacements, say, as in [2]), macroscopic cycles begin to emerge and their joint distribution converges to the Poisson-Dirichlet law.

In this context we mention that the Mallows permutation also arises via a shuffling algorithm. As proved by Benjamini, Berger, Hoffman and Mossel [2], it arises as the stationary distribution of a biased card-shuffling algorithm. In this algorithm, one starts with a deck of cards numbered \( \{1, \ldots, n\} \) and at each iteration picks uniformly a pair of adjacent cards in the deck. One flips a coin with probability \( p = \frac{1}{q+1} \) for heads and rearranges the two cards according to the coin result, in increasing order if heads and in decreasing order if tails. The iterations are done independently of one another.

1.2.4 Spatial Random Permutations

A spatial random permutation is a random permutation which is biased towards the identity in some underlying geometry. This broad idea covers many models, among them the Mallows distribution which is biased towards the identity in a one-dimensional geometry. In this section we briefly describe two other models in this class for which
related results have been proved.

Let $G = (V, E)$ be a finite or infinite bounded-degree graph. The interchange process (also called the stirring process in some of the literature) gives a dynamics on permutations in $S_V$, one-to-one and onto functions $\pi : V \to V$, which is associated to the structure of the graph. Each edge of the graph is endowed with an independent Poisson process of rate 1. An edge is said to ring at time $t$ if an event of its Poisson process occurs at that time. Starting from the identity permutation $\pi^0 \in S_V$, the interchange process, introduced by Tóth [30], is the permutation-valued stochastic process $(\pi^t)$ obtained by performing a transposition along each edge at each time that it rings.

The interchange process on the complete graph coincides with a continuous time version of the Diaconis-Shashahani card shuffling algorithm discussed in the Section 1.2.3. Special attention has been given to the case that the graph $G = \mathbb{Z}^d$, where the interchange process is related to the magnetization of the quantum Heisenberg ferromagnet [30]. In particular, the following conjecture of Bálint Tóth has attracted significant attention but remains unresolved: When $d = 2$, for any $t > 0$, all cycles of $\pi^t$ are finite almost surely. In contrast, when $d \geq 3$ and $t$ is sufficiently large, $\pi^t$ has an infinite cycle almost surely.

Besides the case of the complete graph, results on the existence of long cycles in the interchange process are currently available only for trees, by Angel [15] and Hammond [16], and for the hypercube graph, by Kotecký, Miloš and Ueltschi [18].

Recently, a quantitative study of the interchange process in a one-dimensional geometry, $V = \{1, \ldots, n\}$ with $i$ adjacent to $i + 1$, was performed by Kozma and Sidoravicius. Here, as each $(\pi^t_s)_{t>0}$ is a simple random walk, the typical displacement $|\pi^t_s - s|$ is of order $\min\{\sqrt{t}, n\}$. Thus, the graph of $\pi^t$ has a band structure similar to the graph of a Mallows permutation, see Figure 3 and the two models seem graphically similar when one takes

$$q = 1 - \frac{1}{1 + \sqrt{t}}. \quad (7)$$

In a work in preparation, Kozma and Sidoravicius prove that the expected length of the cycle containing a given point in $\pi^t$ has order $\min\{t + 1, n\}$. This result, whose mathe-
matical details were completed before our work began, is analogous to our Theorem 1.1.

A second model of spatial random permutations, related to the Feynman-Kac representation of the ideal Bose gas in quantum statistical mechanics, has also received significant attention, see [4] and references within. In this model, one samples a random collection of points \((x_1, \ldots, x_n)\) in a finite box \(\Lambda \subset \mathbb{R}^d\) and a random permutation \(\pi\) on these points. The distribution is such that permutations with large displacements \(\pi(x_i) - x_i\) have lower density. In the physical context, the emergence of macroscopic cycles in the model is related to the phenomenon of Bose-Einstein condensation. In recent work, Betz and Ueltschi [4] (see also Sütő [29]) have shown that the following phase transition takes place in the model when \(d \geq 3\): Define the density of points per unit area \(\rho = \frac{n}{|\Lambda|}\). There exists a critical density \(\rho_c\) such that, with probability tending to 1 as \(n\) tends to infinity, if the density is fixed to a value \(\rho < \rho_c\) then all cycles have length \(o(n)\), whereas if it is fixed to a value \(\rho > \rho_c\) then macroscopic cycles, of size proportional to \(n\), emerge. Moreover, in the second regime, the distribution of suitably normalized cycle lengths converges in distribution to the Poisson-Dirichlet law.

1.3 Reader’s Guide

Section 2 introduces notation and preliminary facts used throughout the paper. Section 3 develops flexible sampling methods for the Mallows distribution and studies closely related random processes: In Section 3.1 we develop tools for sampling the graph of a random Mallows permutation sequentially. These are used in Section 3.2 to introduce a ‘diagonal’ exposure procedure for the graph. There, we also define the ‘arc chain’ of a permutation, which tracks the number of open arcs (incomplete cycles) throughout the diagonal exposure process, and analyze its basic properties. Concentration bounds for the arc chain process are developed in Section 3.3 and used significantly in later proofs. Section 3.4 provides bounds on the time it takes an arc chain to reach zero, of use in the regime where \(q\) is bounded away from 1. Analogous bounds on return times also appeared in the recent work [5] of Basu and Bhatnagar where a related Markov chain is introduced. Section 3.5 considers the distribution of rectangular subsets of the graph of a Mallows permutation. These provide the starting point for a method to sample a Mallows permutation ‘from a mid-point’, which is further extended to a sampling method for the two-sided infinite case, when \(\pi : \mathbb{Z} \to \mathbb{Z}\).

Our main theorems are proved in Section 4. Section 4.1 is dedicated to the proof of Theorem 1.5 regarding the number of cycles. In Section 4.2 we prove Theorem 1.4 on the diameter of cycles by providing deviation bounds for the distribution of the maximal and minimal element of the cycle containing a given point. In Section 4.3 we prove Theorem 1.1 regarding the length of cycles. Section 4.4 is dedicated to the proof of Theorem 1.3 which provides bounds on the variance of the cycle lengths. Theorem 1.2 on the Poisson-Dirichlet law is proved in Section 4.5.

We conclude in Section 5 with a discussion and a selection of open questions.
2 Notation and Preliminaries

- Throughout the rest of the paper $n$ is a positive integer whilst $q \in (0,1)$ is a real parameter.
- For two quantities $x, y \geq 0$, which may depend on other parameters such as $n$ or $q$, we write $x \lesssim y$ if there exists an absolute constant $c > 0$ such that $x \leq c \cdot y$. Note that $x \approx y$ is equivalent to $x \lesssim y$ and $y \lesssim x$.
- $\mathbb{N}$ is the set of positive integers while $[n] := \{ i \in \mathbb{N} \mid i \leq n \} = \{1, 2, \ldots, n\}$.
- $1_A$ and $\mathbb{1}\{A\}$ denote the indicator random variable of an event $A$.
- Throughout the paper we denote by $\xi = \xi_q$ the following
  \[ \xi := \min \{ i \in \mathbb{N} \mid q^i \leq \frac{1}{2} \} = \left[ \log_q \frac{1}{2} \right] \approx \frac{1}{1-q}. \] (8)
- In order to avoid cumbersome expressions we will use an abbreviated notation when referring to subsets of $\mathbb{Z}^2$. We write, for instance
  \[ \{ x < a, y < b \} \quad \text{instead of} \quad \{ (x, y) \in \mathbb{Z}^2 \mid x < a, y < b \} \]
  and analogous expressions involving other subsets of $\mathbb{Z}^2$.
- We introduce two useful symmetries of the Mallows distribution $\mu_{n,q}$, i.e., bijections $S_n \leftrightarrow S_n$ that preserve $\mu_{n,q}$. The inverse symmetry is induced by the inversion map
  \[ \mu_{n,q}[\pi] = \mu_{n,q}[\pi^{-1}]. \] (9)
  The reversal symetry is defined via the reversal map $r: s \mapsto n + 1 - s$ by
  \[ \mu_{n,q}[\pi] = \mu_{n,q}[r \circ \pi \circ r], \] (10)
where we note that $\pi_i = j$ if and only if $(r \circ \pi \circ r)(n + 1 - i) = n + 1 - j$. The fact that the two maps $\pi \mapsto \pi^{-1}$ and $\pi \mapsto r \circ \pi \circ r$ preserve the Mallows distribution follows simply by checking that they preserve the number of inversions. These two symmetries will prove useful as they also preserve the cycle structure. Specifically, if $C$ is a cycle of $\pi$ then $C^{-1}$ and $r \circ C \circ r$ are cycles of $\pi^{-1}$ and $r \circ \pi \circ r$, respectively.

3 The Sampling Algorithm and the Arc Chain

In this section we present a sampling algorithm for the Mallows distribution which will be fundamental in our analysis. We further identify a Markov chain associated to this sampling algorithm, termed the arc chain, and explore its basic properties.

3.1 Generating the Graph of a Mallows Permutation

In Section 1.1 a method is presented for sampling the values $(\pi_s)$ of a Mallows permutation iteratively. Here we explain a related method which generates the graph of the permutation
  \[ \Gamma_\pi := \{(s, \pi_s) \mid s \geq 1\} \]
in an iterative manner, allowing to expose portions of the graph in various orders.

Although our focus is on finite permutations, for clarity, we start by discussing the case of infinite one-sided permutations $\pi : \mathbb{N} \to \mathbb{N}$ in which the construction is simpler. In this case, as explained in Section 1.1,

$$\mathbb{P}[\pi_s = t \mid \pi_1, \ldots, \pi_{s-1}] = (1 - q) \cdot q^{|\{\pi_1, \ldots, \pi_{s-1}\}|-1} \text{ for } t \notin \{\pi_1, \ldots, \pi_{s-1}\}. $$

In other words, the value of $\pi_s$, conditioned on the values of $\pi_1, \ldots, \pi_{s-1}$, has the geometric distribution with success probability $1 - q$ on the values in $\mathbb{N} \setminus \{\pi_1, \ldots, \pi_{s-1}\}$. This gives rise to the following sampling method: starting with a two-dimensional infinite array $(a_{s,t})_{s,t \geq 1}$ of independent Bernoulli random variables, each satisfying

$$\mathbb{P}[a_{s,t} = 1] = 1 - \mathbb{P}[a_{s,t} = 0] = 1 - q,$$

we may generate the permutation $\pi$ by setting

$$\pi_s := \min\{t \geq 1 \mid t \notin \{\pi_1, \ldots, \pi_{s-1}\}, a_{s,t} = 1\}.$$ 

Examination of this formula shows that the rule for deciding whether the point $(s, t)$ belongs to the graph $\Gamma_{\pi}$ depends only on the value of the bit $a_{s,t}$ and the portions of the graph $\Gamma_{\pi}$ which lie strictly below $(s, t)$ or strictly to the left of $(s, t)$,

$$\Gamma_{\pi} \cap \{x < s, y = t\} \text{ and } \Gamma_{\pi} \cap \{x = s, y < t\}. \quad (11)$$

Precisely, $(s, t) \in \Gamma_{\pi}$ if and only if $a_{s,t} = 1$ and the two sets in (11) are empty. This viewpoint allows for iterative generation of the graph $\Gamma_{\pi}$ in many different manners. In the sequel we shall focus on diagonal generation, in which we expose the portion of the graph intersecting the square $\{x < t, y < t\}$ for increasing values of $t$.

Our next lemma gives an analogous generating method for the graph of a finite Mallows permutation, $\pi \in S_n$, showing that many of the essential features of the above construction are preserved.

**Lemma 3.1.** Let $\pi \sim \mu_{n,q}$, let $s, t \in [n]$ and set $U := \{x < s \text{ or } y < t\}$. Then

$${\mathbb{P}}[\pi_s = t \mid \Gamma_\pi \cap U] = \frac{1 - q}{1 - q^{n(|U^c|)}} \cdot 1 \left\{ \begin{array}{c} \Gamma_\pi \cap \{x < s, y = t\} = \emptyset \\
\Gamma_\pi \cap \{x = s, y < t\} = \emptyset \end{array} \right\}. \quad (12)$$

We point out that the right-hand side of (12) does not depend on the full information in $\Gamma_\pi \cap U$. Indeed, to evaluate the right-hand side one only needs to know whether the sets in (11) are empty and the size of the set $|\Gamma_\pi \cap U^c|$, which may be computed, for instance, via

$$|\Gamma_\pi \cap U^c| = n - s - t + 2 + |\Gamma_\pi \cap \{x < s, y < t\}|. \quad (13)$$

As one application, one may use the equality (12) iteratively to compute the probability distribution of the portion of the graph $\Gamma_\pi \cap \{x \geq i, y < j\}$ conditioned on the portion of the graph $\Gamma_\pi \cap \{x < i, y < j\}$. The equality (12) shows that this probability distribution remains the same if we condition additionally on $\Gamma_\pi \cap \{x < i, y \geq j\}$. Therefore, we obtain the following conditional independence statement: for each $i, j \in [n],$

conditionally on $\Gamma_\pi \cap \{x < i, y < j\},$

$$\Gamma_\pi \cap \{x \geq i, y < j\} \text{ and } \Gamma_\pi \cap \{x < i, y \geq j\} \text{ are independent.} \quad (14)$$
Proof of Lemma 3.1. Our proof relies upon the formula (6). In the notation used there,

$$\mathbb{P}[\pi_s = j_k \mid \pi_1, \ldots, \pi_{s-1}, \pi_s \geq j_k] = \frac{1 - q}{1 - q^{n-s-k+2}}.$$  \hspace{1cm} (15)

We first claim that

$$\mathbb{P}[\pi_s = t \mid \Gamma_\pi \cap U \cap \{x \leq s\}] = \frac{1 - q}{1 - q^{n-s-k+2}} \cdot 1_A,$$  \hspace{1cm} (16)

where $A := \{\Gamma_\pi \cap \{x < s, y = t\} = \emptyset \}$ and note that, by (13), $|\Gamma_\pi \cap U| = n - s - k + 2$. Observe that, in the notation of (15), we have that $t$ is the last element of $\pi_1, \ldots, \pi_{s-1}$ out of $[t-1]$. It then follows from formula (15) that

$$\mathbb{P}[\pi_s = t \mid \Gamma_\pi \cap U \cap \{x \leq s\}] = \frac{1 - q}{1 - q^{n-s-k+2}} = \frac{1 - q}{1 - q^{n-s-k+2}} \quad \text{on } A,$$

finishing the proof of (16).

Next, we observe that the argument used above to derive (14) from (12) may also be used to derive (14) from (16). Applying (14) with $i = s+1$ and $j = t$ shows that $\pi_s$ is conditionally independent of $\Gamma_\pi \cap U \cap \{x > s\}$ conditioned on $\Gamma_\pi \cap U \cap \{x \leq s\}$. Thus the formula (12) is a consequence of (16).

3.2 Diagonal Exposure and the Arc Chain Process

The main lemma of the previous section, Lemma [3.1], provides a procedure for calculating the distribution of certain portions of the graph $\Gamma_\pi$, of a Mallows permutation $\pi$, given others. This gives rise to several iterative algorithms for exposing the full graph. The proofs of our main theorems rely on a particular method of exposing $\Gamma_\pi$ which will turn out to be particularly convenient. The total portion of $\Gamma_\pi$ that will be revealed by time $t$ will consist of $\Gamma_\pi \cap \{x \leq t, y \leq t\}$. Equivalently, as we pass from time $t$ to $t+1$ we reveal

$$\Gamma_\pi \cap \{x = t+1, y \leq t\}, \quad \Gamma_\pi \cap \{x \leq t, y = t+1\} \quad \text{and} \quad \Gamma_\pi \cap \{x = t+1, y = t+1\}.$$  \hspace{1cm} (17)

Formally, we define a finite filtration consisting of the sigma-algebras

$$\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \ldots \subseteq \mathcal{F}_{n-1} \subseteq \mathcal{F}_n$$

defined by

$$\mathcal{F}_t := \sigma(\Gamma_\pi \cap \{x \leq t, y \leq t\}).$$  \hspace{1cm} (18)

Thus, $\mathcal{F}_0$ is the trivial sigma-algebra and $\mathcal{F}_n$ is the sigma-algebra generated by $\pi$. We call this exposure procedure the diagonal exposure of $\pi$ as the procedure exposes the graph in the diagonal direction. Corresponding to this filtration we introduce the notation

$$\mathbb{P}_t[A] := \mathbb{P}[A \mid \mathcal{F}_t] \quad \text{and} \quad \mathbb{E}_t[X] := \mathbb{E}[X \mid \mathcal{F}_t],$$

for an event $A$ and a random variable $X$. 

12
An important quantity to keep track of during the diagonal exposure process is the number of elements of $\pi$ in the revealed portion of the graph $\Gamma_\pi$ at each time $t$, i.e., $|\Gamma_\pi \cap \{x \leq t, y \leq t\}|$. Our next definition introduces the counting process of an equivalent quantity, $|\Gamma_\pi \cap \{x \leq t, y > t\}|$, which will appear more frequently in our analysis. This quantity, as we elaborate upon in Section 4, counts the number of open 'arcs', i.e., portions of cycles that are yet to be closed, which are known using the information in $\mathcal{F}_t$.

**Definition 3.2** (Arc Chain). The arc chain $(\kappa_t)$, $0 \leq t \leq n$, of a permutation $\pi \in S_n$ is defined by

$$\kappa_t = \kappa_t(\pi) := |\{i \in [t] \mid \pi_i > t\}| = t - |\Gamma_\pi \cap \{x \leq t, y \leq t\}|,$$

that is, $\kappa_t$ counts the number of $\pi_1, \ldots, \pi_t$ that are greater than $t$.

The arc chain is adapted to the filtration $(\mathcal{F}_t)$, that is, $\kappa_t$ is determined by $\mathcal{F}_t$. One should note that $\pi$ and $\pi^{-1}$ share the same arc chain, that is,

$$\kappa_t = |\{t < i \leq n \mid \pi_i \leq t\}|.$$

The next proposition formalizes the fact that $(\kappa_t)$ is a time-inhomogeneous Markov chain.

**Proposition 3.3.** Let $\pi \sim \mu_{n,q}$. The arc chain $\kappa$ of $\pi$ is a time-inhomogeneous Markov chain, with respect to the filtration $(\mathcal{F}_t)$, satisfying $\kappa_0 = 0$ and $|\kappa_{t+1} - \kappa_t| \leq 1$, with transition probabilities given by

$$P_t[\kappa_{t+1} = \kappa_t - 1] = \left(\frac{1 - q^{\kappa_t}}{1 - q^{n-t}}\right)^2,$$

$$P_t[\kappa_{t+1} = \kappa_t] = \frac{q^{\kappa_t} - q^{n-t}}{1 - q^{n-t}} \cdot \frac{2 - q^{\kappa_t} - q^{\kappa_t+1}}{1 - q^{n-t}},$$

$$P_t[\kappa_{t+1} = \kappa_t + 1] = \frac{q^{\kappa_t} - q^{n-t}}{1 - q^{n-t}} \cdot \frac{q^{\kappa_t+1} - q^{n-t}}{1 - q^{n-t}}.$$

As an illustration of the usefulness of the arc chain, we note that the probability that $\pi$ has a fixed point at position $t+1$, given the information in $\mathcal{F}_t$, has a simple expression in terms of $\kappa_t$.

**Lemma 3.4.** Let $\pi \sim \mu_{n,q}$ and $\kappa$ be its arc chain. Then

$$P_t[\pi_{t+1} = t + 1] = \frac{q^{\kappa_t} - q^{\kappa_t+1}}{1 - q^{n-t}} \cdot \frac{q^{\kappa_t} - q^{n-t}}{1 - q^{n-t}}, \quad 0 \leq t < n.$$

We prove the proposition and lemma together.

*Proof of Proposition 3.3 and Lemma 3.4.* The newly revealed portions of $\Gamma_\pi$ at time $t+1$ were described in (17). Denote the first two of these portions by

$$X := \Gamma_\pi \cap \{x = t + 1, y \leq t\} \quad \text{and} \quad Y := \Gamma_\pi \cap \{x \leq t, y = t + 1\}.$$ 

We claim that

$$P_t[X \neq \emptyset] = P_t[Y \neq \emptyset] = \frac{1 - q^{\kappa_t}}{1 - q^{n-t}}.$$ 

(22)
It is convenient to derive this directly from (6). Write \( j_1 < j_2 < \cdots < j_{n-t} \) for the values in \([n] \setminus \{ \pi_1, \ldots, \pi_t \}\) and observe that \( j_k \leq t \) if and only if \( k \leq \kappa_t \), see (20). Therefore, it follows from (6) that

\[
\mathbb{P}_t[X \neq \emptyset] = \mathbb{E}_t[\mathbb{P}[X \neq \emptyset | \pi_1, \ldots, \pi_t]] = \mathbb{E}_t\left[\sum_{k=1}^{\kappa_t} \frac{1 - q^{k - 1}}{1 - q^{n-t}} \cdot q^{k - 1}\right] = \frac{1 - q^{\kappa_t}}{1 - q^{n-t}}.
\]

The equality \( \mathbb{P}_t[X \neq \emptyset] = \mathbb{P}_t[Y \neq \emptyset] \) follows from the symmetry (9), as \( \pi \) and \( \pi^{-1} \) share the same arc chain.

Now note that

\[
\mathbb{P}_t[\pi_{t+1} = t + 1] = \mathbb{P}_t[X = Y = \emptyset] \cdot \mathbb{P}_t[\pi_{t+1} = t + 1 | X = Y = \emptyset].
\]

The second factor can be computed directly from Lemma 3.1

\[
\mathbb{P}_t[\pi_{t+1} = t + 1 | X = Y = \emptyset] = \frac{1 - q}{1 - q^{n-t-\kappa_t}}.
\]

In addition, observe that \( X \) and \( Y \) are conditionally independent given \( \mathcal{F}_t \), as follows from (14). Thus the value of the first factor may be calculated from (22), which completes the proof of Lemma 3.4.

Observe that \( \kappa_{t+1} - \kappa_t = 1 - |Z| \), where \( Z := X \cup Y \cup (\Gamma_\pi \cap \{(t+1, t+1)\}) \), as follows from the definition (19) of \( (\kappa_t) \). As \( |Z| \leq 2 \), it follows that \( |\kappa_{t+1} - \kappa_t| \leq 1 \). The equations in (21) can be verified by computations similar to the ones used to prove Lemma 3.4 as

\[
\mathbb{P}_t[\kappa_{t+1} = \kappa_t - 1] = \mathbb{P}_t[|Z| = 2] = \mathbb{P}_t[X \neq \emptyset \text{ and } Y \neq \emptyset],
\]

\[
\mathbb{P}_t[\kappa_{t+1} = \kappa_t + 1] = \mathbb{P}_t[|Z| = 0] = \mathbb{P}_t[X = Y = \emptyset] \cdot \mathbb{P}_t[\pi_{t+1} \neq t + 1 | X = Y = \emptyset],
\]

and the value of \( \mathbb{P}_t[\kappa_{t+1} = \kappa_t] \) is derived from these using that \( |\kappa_{t+1} - \kappa_t| \leq 1 \). \( \square \)

### 3.3 The Distribution of the Arc Chain

In this section we study the distribution of the arc chain of a Mallows permutation at a fixed time \( t \). Our main result, Theorem 3.6 below, states that the value of the chain is unlikely to be much larger than the value of \( \xi \) given in (8). Figure 4a depicts the percentiles of the distribution of the arc chain for certain values of \( t \) on \( \xi \) is unlikely to be much larger than the value of \( \xi \) given in (8). Figure 4a depicts the percentiles of the distribution of the arc chain for certain values of \( t \) on \( \xi \) is unlikely to be much larger than the value of \( \xi \). Figure 4a depicts the percentiles of the distribution of the arc chain for certain values of \( t \) on \( \xi \) is unlikely to be much larger than the value of \( \xi \).

These suggest that the typical values of the arc chain are close to \( \xi \) when \( t \) is bounded away from 1 and \( n \). For such times, we establish in Proposition 3.3 below a formula for the limiting distribution of the arc chain when \( n \) tends to infinity with \( q \) fixed.

It is convenient to refer to the arc chain as an abstract Markov chain, without reference to an underlying Mallows permutation, as facilitated by the following definition.

**Definition 3.5.** A random sequence \((\kappa_t)\), \( 0 \leq t \leq n \), is an \((n,q)\)-arc chain, denoted \( \kappa \sim \mathcal{AC}_{n,q} \), if \( \kappa \) is a time-inhomogeneous Markov chain with transition probabilities as in Proposition 3.3 and some initial distribution \( \kappa_0 \) supported in \( \{0, \ldots, n\} \).

We point out that the formulas in Proposition 3.3 constitute valid transition probabilities (that is, they are non-negative and sum to 1) when \( 0 \leq \kappa_t \leq n-t \). Using induction on \( t \), one checks that an \((n,q)\)-arc chain satisfies this condition for all \( t \) almost surely.
Theorem 3.6. Let $\kappa \sim \mathcal{AC}_{n,q}$ with $\kappa_0 = 0$. Then for all $0 \leq t \leq n$ and $d \in \mathbb{N}$ we have
\[
P[\kappa_t > \xi + d] \leq \frac{q^{d^2 + d}}{1 - q^{2d}}.
\] (23)

The idea of proof involves the definition of a limiting time-homogeneous Markov chain, corresponding formally to the case that $n = \infty$, and bounding the distribution of the $(n, q)$-arc chain by the stationary distribution of the limiting chain. Some of the tools that we develop here will be used later in the paper as well.

We recall that a time-homogeneous Markov chain $(\alpha_t)$ which takes values in the non-negative integers and satisfies $|\alpha_t - \alpha_{t+1}| \leq 1$ is called a birth-and-death chain.

Definition 3.7. A random sequence $(\hat{\kappa}_t)_{t \geq 0}$ is an $(\infty, q)$-arc chain, denoted $\hat{\kappa} \sim \mathcal{AC}_{\infty,q}$, if $\kappa$ is a birth-and-death chain with transition probabilities given by
\[
\begin{align*}
P[\hat{\kappa}_{t+1} = \hat{\kappa}_t - 1 \mid \hat{\kappa}_t] & = (1 - q^{\hat{\kappa}_t})^2, \\
P[\hat{\kappa}_{t+1} = \hat{\kappa}_t \mid \hat{\kappa}_t] & = 2q^{\hat{\kappa}_t} - q^{2\hat{\kappa}_t} - q^{2\hat{\kappa}_t+1}, \\
P[\hat{\kappa}_{t+1} = \hat{\kappa}_t + 1 \mid \hat{\kappa}_t] & = q^{2\hat{\kappa}_t+1}.
\end{align*}
\] (24)

There is a formula for the stationary measure of a birth-and-death chain. If $(\alpha_t)$ is a birth-and-death chain taking values in $\{0, \ldots, m\}$, where $m$ may be finite or infinite, having positive transition probabilities between consecutive integers in $\{0, \ldots, m\}$, then $\alpha$ has a stationary measure $z$ defined by\footnote{Here and later in the paper, to avoid introducing extra notation, we denote the transition probability of the chain from $i - 1$ to $i$ at time $t$ by $P[\alpha_{t+1} = i \mid \alpha_t = i - 1]$, even if $P[\alpha_t = i - 1] = 0$, and use similar notation for other transition probabilities.}
\[
\begin{align*}
z_0 & := 1 \quad \text{and} \quad z_s := \prod_{i=1}^{s} \frac{P[\alpha_{t+1} = i \mid \alpha_t = i - 1]}{P[\alpha_{t+1} = i - 1 \mid \alpha_t = i]} \quad \text{for} \ 1 \leq s \leq m.
\end{align*}
\] (25)
This is straightforward to verify directly. It is also not difficult to check that the stationary measure is unique up to scaling though we shall not use this fact (see also [19, Section 2.5]).

This fact allows us to find the stationary distribution of an \((\infty, q)\)-arc chain \(\hat{\kappa}\). Put

\[
\begin{align*}
  u_i := P[\hat{\kappa}_{t+1} = i | \hat{\kappa}_t = i - 1] &= q^{2i-1} > 0, \quad i \geq 1, \\
  v_i := P[\hat{\kappa}_{t+1} = i - 1 | \hat{\kappa}_t = i] &= (1-q^i)^2 > 0, \quad i \geq 1.
\end{align*}
\]

Then the sequence \((\nu_s), s \geq 0\), defined by

\[
\nu_s := \frac{\prod_{i=1}^s u_i}{\sum_{j \geq 0} \prod_{i=1}^j u_i}
\]

defines a stationary distribution for \(\hat{\kappa}\), where, as usual, an empty product is interpreted as 1. The denominator in (27) is finite since \(u_i \to 0\) and \(v_i \to 1\) as \(i \to \infty\). See Figure 4b for a graph of \(\nu\).

We study further the relation between the distributions of the \((n, q)\)-arc chain \(\kappa\) and the \((\infty, q)\)-arc chain \(\hat{\kappa}\). Our next proposition shows that in a suitable limit, in which \(q\) is fixed, the distribution of \(\kappa_t\) converges to the stationary distribution of \(\hat{\kappa}\). This proposition will be of use in Section 3.5.

**Proposition 3.8.** Let \(\kappa \sim AC_{n,q}\) with \(\kappa_0 = 0\) and set \(t = t_n\). If both \(t \to \infty\) and \(n - t \to \infty\) then the law of \(\kappa_t\) converges to the stationary distribution of \(AC_{\infty,q}\), as \(n\) tends to infinity with \(q\) fixed.

Our main tool for proving the above theorem and proposition is a coupling in which the \((\infty, q)\)-arc chain bounds the \((n, q)\)-arc chain at all times. We first introduce a general method for performing such couplings.

Let \(\alpha\) be a Markov chain, possibly time-inhomogeneous, taking values in the non-negative integers and satisfying \(|\alpha_i - \alpha_{i+1}| \leq 1\). Let \((U_t)\) be a sequence of independent random variables, each uniformly distributed on \([0, 1]\). One may couple the Markov chain \(\alpha\) with the sequence \(\Upsilon\) as follows. The initial distribution \(\alpha_0\) is taken independent of \(U\). Then, for each \(t \geq 0\), \(\alpha_{t+1} := \alpha_t + F_t^\alpha (\alpha_t, U_t)\) where

\[
F_t^\alpha (\alpha, U) := \mathbb{1}_{\{u > 1 - P[\alpha_{t+1} = a+1 | \alpha_t = a]\}} - \mathbb{1}_{\{u \leq P[\alpha_{t+1} = a-1 | \alpha_t = a]\}}.
\]

This can be understood as ‘\(\alpha_{t+1}\) is a monotone function of \(U_t\) for a given \(\alpha_t\)’. We say that a set of Markov chains of the above type is **monotonically coupled** if they are all coupled to the same sequence \(U\) via the above method.

**Proposition 3.9.** Let \(q, \hat{q} \in (0, 1)\) and \(n, \hat{n} \in \mathbb{N} \cup \{\infty\}\) satisfy \(q \leq \hat{q}\) and \(n \leq \hat{n}\). Let an \((n, q)\)-arc chain \(\kappa\) be monotonically coupled with an \((\hat{n}, \hat{q})\)-arc chain \(\hat{\kappa}\) that satisfies \(\kappa_0 \leq \hat{\kappa}_0\) almost surely. Then, almost surely, \(\kappa_t \leq \hat{\kappa}_t\) for all \(0 \leq t \leq n\).

**Definition 3.10 (Bounding Chain).** For an \((n, q)\)-arc chain \(\kappa\), a **bounding chain** is any \((\infty, q)\)-arc chain \(\hat{\kappa}\) that is monotonically coupled with \(\kappa\) and satisfies \(\kappa_0 \leq \hat{\kappa}_0\) almost surely. Proposition 3.9 implies that any bounding chain satisfies \(\kappa_t \leq \hat{\kappa}_t\), almost surely, for all \(0 \leq t \leq n\).
Proof of Proposition 3.9. The proof relies on the facts that \(|\kappa_{t+1} - \kappa_t| \leq 1, |\hat{\kappa}_{t+1} - \hat{\kappa}_t| \leq 1\) and the following three inequalities,

\[
\begin{align*}
\mathbb{P}[\kappa_{t+1} = k + 1 \mid \kappa_t = k] &\leq 1 - \mathbb{P}[\hat{\kappa}_{t+1} = k \mid \hat{\kappa}_t = k + 1], \quad 0 \leq k \leq \min\{n - t, \hat{n} - t - 1\}, \\
\mathbb{P}[\kappa_{t+1} = k - 1 | \kappa_t = k] &\geq \mathbb{P}[\hat{\kappa}_{t+1} = k - 1 | \hat{\kappa}_t = k], \quad 0 \leq k \leq n - t, \\
\mathbb{P}[\kappa_{t+1} = k + 1 | \kappa_t = k] &\leq \mathbb{P}[\hat{\kappa}_{t+1} = k + 1 | \hat{\kappa}_t = k], \quad 0 \leq k \leq n - t.
\end{align*}
\] (28)

To prove these inequalities, observe that the transition probabilities of arc chains are given by

\[
\begin{align*}
\mathbb{P}[\kappa_{t+1} = k - 1 | \kappa_t = k] &= \left( \frac{1 - q^k}{1 - q^{n-t}} \right)^2,
\mathbb{P}[\kappa_{t+1} = k + 1 | \kappa_t = k] &= \left( \frac{1 - q^k}{1 - q^{n-t}} \right) \cdot \left( \frac{1 - q^{k+1}}{1 - q^{n-t}} \right).
\end{align*}
\] (29)

Thus, the last two inequalities in (28) follow from the fact that \(\frac{1-q^a}{1-q^b} = \frac{1+q+\cdots+q^{a-1}}{1+q+\cdots+q^{b-1}}\), with \(1 \leq a \leq b\), decreases with both \(b\) and \(q\). The first inequality in (28) follows from the third inequality there and the fact that \(\mathbb{P}[\hat{\kappa}_{t+1} = k + 1 | \hat{\kappa}_t = k] \leq \mathbb{P}[\hat{\kappa}_{t+1} = k | \hat{\kappa}_t = k + 1]\). This last fact follows by substituting the formulas in (29), using that \(1 - x^2 = (1-x)(1+x)\) and taking out the non-negative common factor \(1 - \frac{q^{k+1}}{1 - q^{n-t}}\).

We proceed to prove the proposition. Suppose \(t < n\) is such that \(\kappa_t \leq \hat{\kappa}_t\) almost surely and let us show that \(\kappa_{t+1} \leq \hat{\kappa}_{t+1}\), almost surely. Recall that \(0 \leq \kappa_t \leq n - t\) and \(0 \leq \hat{\kappa}_t \leq \hat{n} - t\) almost surely, and let us consider separately the following three cases.

- The inequality is clear if \(\hat{\kappa}_t - \kappa_t \geq 2\).
- If \(\kappa_t = \hat{\kappa}_t - 1\) then \(\kappa_{t+1} \leq \hat{\kappa}_{t+1}\) follows from the first inequality in (28).
- Lastly, if \(\kappa_t = \hat{\kappa}_t\) then \(\kappa_{t+1} \leq \hat{\kappa}_{t+1}\) is a consequence of the second and third inequality in (28).

As a corollary of this proposition we deduce that an \((n,q)\)-arc chain \(\kappa\) with \(\kappa_0 = 0\) satisfies

\[
\mathbb{P}[\kappa_t \geq d] \leq \nu[d, \infty] = \sum_{i \geq d} \nu_i \quad \text{for all } t \leq n \text{ and } d \geq 0,
\] (30)

where \(\nu\) is the stationary distribution of an \((\infty,q)\)-arc chain, as given by (27). This follows by letting \(\hat{\kappa}\) be the bounding chain of \(\kappa\) having \(\hat{\kappa}_0 \sim \nu\). Then (30) is a consequence of the facts that \(\hat{\kappa}_t \sim \nu\) and \(\kappa_t \leq \hat{\kappa}_t\).

We are now ready to prove Theorem 3.6 and Proposition 3.8.

Proof of Theorem 3.6. By (30), it suffices to prove that the stationary distribution \(\nu\) of an \((\infty,q)\)-arc chain satisfies

\[
\nu[\xi + d + 1, \infty] \leq \frac{q^{\xi^2 + d}}{1 - q^{2d}}, \quad d \geq 1.
\] (31)

Let \(u_i\) and \(v_i\) be as in (26) and set \(w_i := u_i/v_i\). Formula (27) implies that

\[
\nu_{\xi+s+1} = \nu_{\xi+1} \cdot \prod_{j=1}^s w_{\xi+j+1} \leq \prod_{j=1}^s w_{\xi+j+1}, \quad s \geq 1.
\] (32)
Observe that \( u_{\xi+1} \leq \frac{1}{4} \) and \( v_{\xi+1} \geq \frac{1}{4} \), by the definition (5) of \( \xi \), yielding \( w_{\xi+1} \leq 1 \). One may verify that \( w_{i+1} \leq q^3 w_i \), which yields that \( w_{\xi+j+1} \leq q^{2j} w_{\xi+1} \leq q^{2j} \). By substituting this in (22) we conclude that

\[
\nu_{\xi+s+1} \leq q^{2+s}.
\]

Summing this inequality over \( s \geq d \) yields (31), by bounding the sum with a geometric progression with quotient \( q^{2d} \).

**Proof of Proposition 3.8.** Recall the convergence theorem for finite-state Markov chains: if a finite-state time-homogeneous Markov chain \( (a_i) \) is aperiodic and irreducible then it has a stationary distribution and the distribution of \( a_i \) converges to this stationary distribution as \( t \to \infty \).

Equation (30) states that \( \nu \) dominates \( \kappa \). We will construct distributions \( \tilde{\nu}_h \) that are asymptotically dominated by \( \kappa_t \) as \( t \to \infty \). Then, with the limit of \( \kappa_t \) sandwiched between \( \tilde{\nu}_h \) and \( \nu \), we will show that \( \tilde{\nu}_h \) approaches \( \nu \) as \( h \to \infty \). Let \( h \) be some fixed positive integer and assume without loss of generality that \( n - t \geq h \). Let \( \tilde{\kappa} \) be the birth-and-death chain having \( \tilde{\kappa}_0 = 0 \) and transition probabilities determined by

\[
\mathbb{P}[\tilde{\kappa}_{t+1} = \tilde{\kappa}_t - 1 \mid \tilde{\kappa}_t] = \left( \frac{1 - q^{\tilde{\kappa}_t}}{1 - q^h} \right)^2 \quad \text{and} \quad \mathbb{P}[\tilde{\kappa}_{t+1} = \tilde{\kappa}_t + 1 \mid \tilde{\kappa}_t] = \frac{q^{\tilde{\kappa}_t} - q^h q^{\tilde{\kappa}_t+1} - q^h}{1 - q^h}.
\]

Observe that \( 0 \leq \tilde{\kappa}_t \leq h \) for all \( t \), almost surely. Let \( \tilde{\kappa} \) be monotonically coupled with \( \kappa \). It is not hard to check that the pair \( (\tilde{\kappa}, \kappa) \) satisfies the analogous inequalities of (28) for \( t \leq n - h \), which implies, by following the proof of Proposition 3.9, that \( \tilde{\kappa}_t \leq \kappa_t \) for all \( t \leq n - h \), almost surely.

By applying the convergence theorem for finite-state Markov chains we obtain that \( \tilde{\kappa} \) has stationary distribution \( \tilde{\nu} = \tilde{\nu}_h \) and that \( \tilde{\kappa}_t \) converges to \( \tilde{\nu} \) in distribution. Since \( \kappa_t \) dominates \( \tilde{\kappa}_t \) for all \( t \leq n - h \), we obtain

\[
\tilde{\nu}[d, \infty] \leq \liminf \mathbb{P}[\kappa_t \geq d] \leq \limsup \mathbb{P}[\kappa_t \geq d] \leq \nu[d, \infty] \quad \text{for} \quad d \geq 0,
\]

where the limits are taken for \( n, t \to \infty \) with the restriction \( n - t \geq h \). It remains to verify, using (29) and the fact that the ratios \( \frac{\mathbb{P}[\kappa_{t+1} = \kappa_t + 1 \mid \kappa_t = i]}{\mathbb{P}[\kappa_{t+1} = \kappa_t \mid \kappa_t = i]} \) increase with \( h \), that \( \tilde{\nu}_s \to \nu_s \) as \( h \to \infty \), for all \( s \). Thus, \( \tilde{\nu}[d, \infty] \) converges to \( \nu[d, \infty] \) as \( h \to \infty \), completing the proof of the proposition.

**3.4 The Hitting Time of Zero**

The times in which the arc chain is at zero can be thought of as cut points for the graph of the permutation in the sense that if \( \kappa_t = 0 \) then \( \Gamma_t \subseteq \{ x \leq t, y \leq t \} \cup \{ x > t, y > t \} \).

This leads one to consider the evolution of the arc chain as performing a sequence of excursions away from zero; a point of view which will be useful for us in the regime that \( q \) is bounded away from 1 since, as we now prove, the excursions tend to be relatively short in this regime.

The recent work of Basu and Bhatnagar [5] uses a similar viewpoint in their analysis of the longest monotone subsequences in a random Mallows permutation. There, a Markov chain related to our \( (\infty, q) \)-arc chain is considered. While the two chains differ, they share
the same visit times to zero and the work [5] contains an analysis of the distribution of the return times to zero, related to our discussion here.

The following theorem will be instrumental in the proofs of the upper bounds of Theorem 1.1, Theorem 1.3 and Theorem 1.4 in this regime.

**Theorem 3.11.** Let \( \kappa \) be an \((n,q)\)-arc chain with \( \kappa_0 = 0 \) and let \( 0 \leq s \leq n \). For any \( \varepsilon > 0 \) there exists a constant \( c_\varepsilon > 0 \) such that

\[
T_s := \min \{ t \geq s \mid \kappa_t = 0 \} \quad \text{satisfies} \quad \mathbb{E}[(T_s - s)^2] \leq c_\varepsilon \cdot q, \quad \text{for all } q \in (0, 1 - \varepsilon).
\]

This theorem is a consequence of the following two statements.

**Proposition 3.12.** There exists a monotone non-decreasing function \( f : (0, 1) \rightarrow [0, \infty) \) such that the following holds. Let \( k \geq 0 \) and let \( \hat{\kappa} \) be an \((\infty,q)\)-arc chain with \( \hat{\kappa}_0 = k \). Then

\[
T := \min \{ t \geq 0 \mid \hat{\kappa}_t = 0 \} \quad \text{satisfies} \quad \mathbb{E}[T^2] \leq f(q) \cdot k^2, \quad \text{for all } k \geq 0.
\]

Recall the definition of \( \xi \) from (8).

**Lemma 3.13.** Let \( \nu \) be the stationary distribution of the \((\infty,q)\)-arc chain. One has

\[
\nu_x \leq \frac{2^{2q-x}}{x}, \quad \text{for } q \in (0, 1),
\]

\[
\nu_x \leq \frac{4q}{2^x}, \quad \text{for } x > 0 \text{ and } q \in (0, \frac{1}{4}).
\]

**Proof of Theorem 3.11.** Let \( \hat{\kappa} \) be a bounding chain of \( \kappa \) with \( \hat{\kappa}_0 \) having the stationary distribution of the \((\infty,q)\)-arc chain. Define \( \hat{T}_s \) by

\[
\hat{T}_s := \min \{ t \geq s \mid \hat{\kappa}_t = 0 \}.
\]

Proposition 3.9 implies that \( T_s \leq \hat{T}_s \). Hence it suffices to prove that there exists \( c_\varepsilon > 0 \) such that

\[
\mathbb{E}[(\hat{T}_s - s)^2] \leq c_\varepsilon \quad \text{for } q \in (0, 1 - \varepsilon), \quad \text{and} \quad \mathbb{E}[(\hat{T}_s - s)^2] \lesssim q \quad \text{for } q \in (0, \frac{1}{4}).
\]

As \( \hat{\kappa} \) is a time-homogeneous Markov chain, Proposition 3.12 implies that

\[
\mathbb{E}[(\hat{T}_s - s)^2 \mid \hat{\kappa}_s] \leq f(q) \cdot \hat{\kappa}_s^2.
\]

By taking expectations we obtain

\[
\mathbb{E}[(\hat{T}_s - s)^2] \leq f(q) \cdot \sum_{k > 0} k^2 \cdot \nu_k. \tag{35}
\]

Using the geometric bounds on \( \nu_s \) provided in (33) and the fact that \( f \) is a monotone non-decreasing function, it follows that the right-hand side in (35) is uniformly bounded for \( q \in (0, 1 - \varepsilon) \).

Now consider the case \( q \leq \frac{1}{4} \). By applying (34) to (35) we conclude that

\[
\mathbb{E}[(\hat{T}_s - s)^2] \leq f(\frac{1}{4}) \cdot \sum_{k > 0} \nu_k \cdot k^2 \leq 4q \cdot f(\frac{1}{4}) \cdot \sum_{k > 0} \frac{k^2}{2^k} \lesssim q.
\]
Now we need only prove Lemma 3.13 and Proposition 3.12.

**Proof of Lemma 3.13.** Let \( u_i \) and \( v_i \) be as in (26). As \( u_i \) is monotone decreasing in \( i \) and \( v_i \) is monotone increasing in \( i \) it follows that for \( i > 2\xi \) one has

\[
\frac{u_i}{v_i} \leq \frac{u_{2\xi+1}}{v_{\xi}} \leq q^{\xi} \cdot \frac{u_{\xi+1}}{v_{\xi}} \leq q^{\xi} \leq \frac{1}{2},
\]

where we have used that \( u_{\xi+1} \leq \frac{1}{4} \) and \( v_{\xi} \geq \frac{1}{4} \). Thus, using (25), we obtain

\[
\nu_x = \nu_{2\xi} \cdot \prod_{i=2\xi+1}^x \frac{u_i}{v_i} \leq \nu_{2\xi} \cdot 2^{q^\xi-1} \leq 2^{q^\xi-2} \quad \text{for } x > 2\xi.
\] (36)

This completes the proof of (33). We proceed with the proof of (34) and assume \( q \leq \frac{1}{4} \). In this case one may verify that \( \frac{u_i}{v_i} \leq \frac{1}{4} \) for \( s > 1 \), while \( \frac{u_i}{v_i} \leq 2q \). Similarly as we obtained (36) we conclude

\[
\nu_x \leq \frac{q}{2^{s-2}} \nu_0 \leq \frac{q}{2^{s-2}} \quad \text{for } x > 0. \tag{38}
\]

We proceed to prove Proposition 3.12. Let \( \hat{k} \) be an \((\infty, q)\)-arc chain. We shall write \( E^k \) to denote the expectation under the measure where \( \hat{k} = k \). We also define the stopping times,

\[
\tau_i = \min\{t \geq 0 \mid \hat{k}_t \leq i\}, \quad i \geq 0.
\]

**Claim 3.14.** If \( k > 4\xi \) then \( E^k[3^{\tau_4}] \leq 9^{k-4\xi} \) and if \( 1 \leq k \leq 4\xi \) then \( E^k[\lambda_{k,q}^{\tau_k-1}] < \infty \) for some \( \lambda_{k,q} > 1 \).

**Proof.** Suppose first that \( k > 4\xi \). Consider the random sequence \( X_t = 3^k t^{-\xi} e^{i} \) and note that \( X_0 = 9^{k-4\xi} \). Let \( u_i \) and \( v_i \) be as in (26) with \( v_0 = 0 \). The sequence \((X_t)\) satisfies

\[
E^k[X_{t+1} \mid \hat{k}_t = i] = (27 \cdot u_{i+1} + 3 \cdot (1 - u_{i+1} - v_i) + \frac{1}{3} v_i) \cdot X_t.
\]

One may verify that for all \( i > 4\xi \) one has \( 27 \cdot u_{i+1} + 3 \cdot (1 - u_{i+1} - v_i) + \frac{1}{3} v_i \leq \frac{2}{3} X_t \). This implies that

\[
E^k[X_{t+1} \mid \hat{k}_t = i] \leq \frac{2}{3} X_t \quad \text{for all } i > 4\xi.
\]

Denoting \( t \wedge \tau_4 = \min\{t, \tau_4\} \) and using the facts that \( \tau_4 \) is a stopping time for \((X_t)\) and \( \hat{k}_t > 4\xi \) when \( \tau_4 > t \), it follows that \( E^k[X_{t \wedge \tau_4}] \) is non-increasing in \( t \). As \( 3^{t \wedge \tau_4} \leq X_{t \wedge \tau_4} \), we conclude by the monotone convergence theorem that

\[
E^k[3^{\tau_4}] = \lim_{t \to \infty} E^k[3^{t \wedge \tau_4}] \leq \lim_{t \to \infty} E^k[X_{t \wedge \tau_4}] = X_0 = 9^{k-4\xi}.
\]

Now suppose that \( 1 \leq k \leq 4\xi \). By induction and using the previous case we may assume that there exists some \( \lambda_{k+1,q} > 1 \) for which

\[
E^{k+1}[\lambda_{k+1,q}^{\tau_k-1}] < \infty. \tag{37}
\]

Let \( t \geq 1 \) and \( 1 < \lambda < \lambda_{k+1,q} \). By conditioning on the first step of the Markov chain we have

\[
E^k[\lambda_{k-1}^{\tau_k-1}] = v_k \lambda + (1 - u_{k+1} - v_k) E^k[\lambda_{k-1}^{\tau_k-1} \mid \hat{k}_1 = k] + u_{k+1} E^k[\lambda_{k-1}^{\tau_k-1} \mid \hat{k}_1 = k + 1]
\]

\[
= v_k \lambda + (1 - u_{k+1} - v_k) E^k[\lambda^{(1+\tau_{k-1})\wedge t}] + u_{k+1} E^{k+1}[\lambda^{(1+\tau_{k-1})\wedge t}]. \tag{38}
\]
Thus, using (37), we may pick bounds into (38) and rearranging the terms we conclude that almost surely finite under the measure where \( \hat{E} \) positive. With this choice, we conclude that the limit of \( \Gamma \) to the left and below this portion. In our proof of Theorem 1.2, pertaining to \( \pi \) of a portion of the graph \( \Gamma \), we will need to understand the distribution of portions 'to the left and below this portion'. In our proof of Theorem 1.2, pertaining to the Poisson-Dirichlet limit law, we will need to understand the distribution of portions 'to the left and below this portion'.

Our discussion so far was based on the results of Section 3.1, describing the distribution of a portion of the graph \( \Gamma_\pi \) of a Mallows permutation \( \pi \) conditioned on the parts of the graph 'to the left and below this portion'.

Proof of Proposition 3.12. The proposition is trivial for \( k = 0 \) so we assume that \( k \geq 1 \).

Observe that \( T = T_{4\xi} + \sum_{i=0}^{4\xi-1} (\tau_i - \tau_{i+1}) \).

The Cauchy-Schwartz inequality then implies that

\[
T^2 \leq (4\xi + 1) \left(T_{4\xi}^2 + \sum_{i=0}^{4\xi-1} (\tau_i - \tau_{i+1})^2\right).
\]

If \( i \geq k \) then \( \tau_i = \tau_{i+1} \) whereas if \( i < k \) then the strong Markov property and Claim 3.14 imply that

\[
E^k[(\tau_i - \tau_{i+1})^2] = E^{i+1}[\tau_i^2] < \infty.
\]

Similarly, if \( 4\xi \geq k \) then \( T_{4\xi} = 0 \) while if \( 4\xi < k \) it follows from Claim 3.14 and the fact that \( \log_3 x \) is concave for \( x \geq e \) that

\[
E^k[\tau_{4\xi}^2] = E^k[\log_3^2(3^{\tau_{4\xi}})] \leq \log_3^2 E^k[3^{\tau_{4\xi}}] \leq g(q)k^2
\]

for some \( g(q) > 0 \). Combining all of the above facts we conclude that

\[
E^k[T^2] \leq g(q)(4\xi + 1)k^2 + (4\xi + 1) \cdot 4\xi \cdot \max_{0 \leq i \leq 4\xi-1} E^k[(\tau_i - \tau_{i+1})^2] \leq h(q)k^2
\]

for some \( h(q) > 0 \). This bound implies a similar bound in which \( h \) is replaced by a monotone non-decreasing function \( f \) as \( E^k[T^2] \) is a non-decreasing function of \( q \) by Proposition 3.9.

### 3.5 Induced Mallows Permutations and a Stitching Process

Our discussion so far was based on the results of Section 3.1 describing the distribution of a portion of the graph \( \Gamma_\pi \) of a Mallows permutation \( \pi \) conditioned on the parts of the graph 'to the left and below this portion'. In our proof of Theorem 1.2 pertaining to the Poisson-Dirichlet limit law, we will need to understand the distribution of portions of \( \Gamma_\pi \) under more general conditioning events. Our first result in this section discusses the distribution of \( \Gamma_\pi \) restricted to a rectangle, given the complementary part of \( \Gamma_\pi \). As
it turns out, in this case the relative ordering of the points of $\Gamma$ is itself distributed via a Mallows distribution. This is formulated precisely below.

Given a finite set of points $\Gamma \subseteq \mathbb{R}^2$, no two of which have equal $x$ or equal $y$ coordinate, we define the relative order of $\Gamma$ as a permutation $\lambda$ characterized by the following properties:

$$\lambda \in S_k \quad \text{and} \quad \lambda_i := |\Gamma \cap \{ y \leq y_i \}|. \quad (39)$$

The name relative order stems from the fact that for each pair $i, j \in [k]$, one has $\lambda_i < \lambda_j$ if and only if $y_i < y_j$.

**Lemma 3.15.** Let $R := \{ x_1 \leq x \leq x_2, y_1 \leq y \leq y_2 \} \subseteq [n]^2$ be a discrete rectangle. Let $\pi \sim \mu_{n,q}$ and $\Gamma_{\pi}$ be the graph of $\pi$. When $\Gamma_{\pi} \cap R$ is non-empty the relative order $(39)$ of $\Gamma_{\pi} \cap R$, conditioned on $\Gamma_{\pi} \setminus R$, has the Mallows distribution $\mu_{m,q}$ with $m := |\Gamma_{\pi} \cap R|$.

The lemma generalizes the more familiar special case where $R$ is a vertical rectangle $\{ x_1 \leq x \leq x_2 \}$ (see, for instance, [6, Corollary 2.7] for a proof of this special case). The original paper of Mallows [20] contained a discussion of related facts. In fact, the above lemma can be deduced from the special case, though we will provide a direct proof below.

So far we have discussed methods for sampling the graph of a Mallows permutation iteratively ‘from beginning to end’. The above lemma gives rise to a method for sampling the graph ‘from a mid-point’. Indeed, one can consider, say, the top and bottom parts of the graph,

$$A := \Gamma_{\pi} \cap \{ y \leq s \} \quad \text{and} \quad B := \Gamma_{\pi} \cap \{ y > s \} \quad (40)$$

for a given $0 \leq s \leq n$. Then, due to the lemma, the relative orders of $A$ and $B$ are independent and have distributions $\mu_{s,q}$ and $\mu_{n-s,q}$, respectively. We now provide a ‘stitching’ procedure for determining the full permutation $\pi$ from the relative orders. Indeed, given the relative orders, one may determine the full permutation from the projections of $A$ and $B$ on the $x$-axis. Defining the process $(\chi_t), 0 \leq t \leq n,$ by

$$\chi_t := |\Gamma_{\pi} \cap \{ x > t, y \leq s \}| \quad (41)$$

we note that the projection of $A$ on the $x$-axis is exactly the set of descents of $\chi$, $\{ t \in [n] \mid \chi_t = \chi_{t-1} - 1 \}$, and the projection of $B$ on the $x$-axis is the complementary set. Thus, the following lemma provides a computational procedure for determining these projections.

**Lemma 3.16.** The process $\chi$ defined in $(41)$ is a time-inhomogeneous Markov chain with transition probabilities given by

$$P[\chi_{t+1} = \chi_t - 1 \mid \pi_1, \ldots, \pi_t] = \frac{1 - q^{\chi_t}}{1 - q^{n-t}} \quad \text{and} \quad P[\chi_{t+1} = \chi_t \mid \pi_1, \ldots, \pi_t] = \frac{q^{\chi_t} - q^{n-t}}{1 - q^{n-t}}. \quad (42)$$

We remark that the formulas $(42)$ provide more than the transition probabilities of $\chi$; namely, that these probabilities remain the same even when conditioning on $\pi_1, \ldots, \pi_t$.

Putting together the above two lemmas we obtain the following method for sampling a Mallows permutation $\pi$. Let $0 \leq s \leq n$ and let $A$ and $B$ be as in $(40)$. Observe that,
according to Lemma 3.15 the relative order of $A$ is independent of $\chi$, as $\chi$ is determined by $B$. Similarly, the relative order of $B$ is independent of both $\chi$ and $A$. Thus we may sample $\pi$ by independently sampling $\chi$, the relative order of $A$ and the relative order of $B$. The sampling of $\chi$ can be performed using the transition probabilities given in Lemma 3.16. The usual sampling algorithm (6) may then be used to sample the relative orders of $A$ and $B$.

The Infinite Case: Gnedin and Olshanski defined an infinite two-sided Mallows distribution as the unique q-exchangeable measure on one-to-one and onto $\pi : \mathbb{Z} \to \mathbb{Z}$, see [14] for details. A method for sampling from this distribution was given in [14]. Although the infinite two-sided Mallows distribution is not used in our work, we note here that the above sampling algorithm may be extended to produce another sampling method for it.

We do not define the infinite two-sided Mallows distribution and shall rely only on the fact, proved in [14] Proposition 7.6, that this distribution is the limit of the distributions of finite Mallows permutations in a suitable sense. To give precise meaning to this let us extend the definition of the finite Mallows permutation to arbitrary finite, non-empty, intervals increasing to $\mathbb{Z}$.

\begin{proof}[Proof of Claim 3.18] Let $(I_n)$ be an arbitrary sequence of finite, non-empty, intervals increasing to $\mathbb{Z}$ and let $\pi^{(n)} \sim \mu_{I_n,q}$. Then $\pi^{(n)}$ converges in distribution to the infinite two-sided Mallows distribution.

We augment this with the following useful tightness property.

Claim 3.18. Let $(I_n)$ be an arbitrary sequence of finite, non-empty, intervals increasing to $\mathbb{Z}$ and let $\pi^{(n)} \sim \mu_{I_n,q}$. Then

$$\limsup_{t \to \infty} \sup_n \mathbb{P}[\Gamma_{\pi^{(n)}} \cap \{x > t, y \leq 0\} \neq \emptyset] = 0.$$ 

Here and later, similarly to before, given $\pi : I \to I$ with $I \subseteq \mathbb{Z}$, we write

$$\Gamma_\pi := \{(s, \pi_s) \mid s \in I\}.$$ 

\end{proof}

Proof of Claim 3.18 The claim follows either from Theorem 3.11 or from tail bounds on the displacement of elements as in, say, [6] Theorem 1.1. Let us argue from Theorem 3.11. Write $I_n = \{-a, -a+1, \ldots, b\}$ and assume that $a,b \geq 0$ as otherwise, deterministically, $\Gamma_{\pi^{(n)}}$ does not intersect the quadrant $\{x > 0, y \leq 0\}$. Let $\tilde{\pi}^{(n)} \sim \mu_{b+a+1,q}$. By the definition of $\mu_{I_n,q}$, we see that

$$\mathbb{P}[\Gamma_{\tilde{\pi}^{(n)}} \cap \{x > t, y \leq 0\} \neq \emptyset] = \mathbb{P}[\Gamma_{\tilde{\pi}^{(n)}} \cap \{x > t + a, y \leq a\} \neq \emptyset].$$

Let $\kappa$ be the arc chain of $\tilde{\pi}^{(n)}$ and define $T := \min\{s \geq a \mid \kappa_s = 0\}$. By (20), assuming also $t \geq 0$,

$$\{\Gamma_{\tilde{\pi}^{(n)}} \cap \{x > t + a, y \leq a\} \neq \emptyset\} \subseteq \{T > t + a\}.$$ 

Thus, Theorem 3.11 and Markov’s inequality imply that the probabilities in (43) are at most $c_q/t^2$ for some $c_q > 0$ depending only on $q$, from which the claim follows. \qed
We require the notion of an infinite one-sided Mallows distribution. We recall that one may define an infinite one-sided Mallows permutation \( \pi : \mathbb{N} \to \mathbb{N} \) with parameter \( 0 < q < 1 \) via the formula (6) with the formal substitution \( n = \infty \) and this yields a convenient sampling algorithm. This construction may be slightly generalized: For a countably infinite subset \( I \subset \mathbb{Z} \) with either a minimal or maximal element let \( P_I \) be the unique monotone bijection \( P_I : \mathbb{N} \to I \) (increasing if \( I \) has a minimal element and decreasing if it has a maximal element). Given two countably infinite \( I, J \subset \mathbb{Z} \), each with a minimal or maximal element, one defines the infinite one-sided Mallows distribution from \( I \) to \( J \) with parameter \( q \) as the measure on bijections \( \pi : I \to J \) satisfying that \( P_J^{-1} \circ \pi \circ P_I \) has the Mallows distribution from \( \mathbb{N} \) to \( \mathbb{N} \) with parameter \( q \).

We now describe the sampling algorithm for the infinite two-sided case. Let \( \pi : \mathbb{Z} \to \mathbb{Z} \) have the infinite two-sided Mallows distribution with parameter \( q \). We require the notion of an infinite one-sided Mallows distribution. We recall that \( \pi \) is distributed as the stationary distribution of the \((\infty, q)\)-arc chain, see (27). (45)

\[
\chi_t := |\Gamma_\pi \cap \{ x > t, y \leq 0 \}|, \quad t \in \mathbb{Z}
\]

and note that \( A_x \) is exactly the set of descents of \( \chi \), i.e., \( A_x = \{ t \in \mathbb{Z} \mid \chi_t = \chi_{t-1} - 1 \} \). The distribution of \( (\chi_t)_{t \geq 0} \) is described by the following two facts, whose proof we postpone:

\[
\chi_0 \text{ is distributed as the stationary distribution of the } (\infty, q)\text{-arc chain, see (27). (45)}
\]

\[
\chi \text{ is a time-homogeneous Markov chain with transition probabilities given by (46)}
\]

\[
P[\chi_{t+1} = \chi_t - 1 \mid \pi_i \text{ for } i \leq t] = 1 - q^{\chi_t} \quad \text{and} \quad P[\chi_{t+1} = \chi_t \mid \pi_i \text{ for } i \leq t] = q^{\chi_t}.
\]

Thus, we may easily sample \( A_x \cap \mathbb{N} \). To finish, we need only sample \( B_x \setminus \mathbb{N} \) conditioned on \( A_x \cap \mathbb{N} \) and \( \chi_0 \), as \( B_x \setminus \mathbb{N} \) together with \( A_x \cap \mathbb{N} \) determine both \( A_x \) and \( B_x \). To this end we rely on the following facts, whose proof is again postponed:

\[
\text{Given } \chi_0, A_x \cap \mathbb{N} \text{ and } B_x \setminus \mathbb{N} \text{ are conditionally independent and have the same distribution up to reflection. Precisely, given } \chi_0, B_x \setminus \mathbb{N} \overset{d}{=} -(A_x \cap \mathbb{N}) + 1. \quad (47)
\]

In conclusion, one may sample \( A_x \) and \( B_x \) as follows: First sample \( \chi_0 \) from the distribution (27). Make two independent samples of \( (\chi_t)_{t \geq 0} \), with the same given \( \chi_0 \), via the Markov
chain transition probabilities in (46). Then take \(A_x \cap \mathbb{N}\) to be the set of descents of the first copy of \((\chi_t)_{t \geq 0}\) and reconstruct \(B_x\) by taking \(1 - (B_x \setminus \mathbb{N})\) to be the set of descents of the second copy of \((\chi_t)_{t \geq 0}\). The sets \(A_x\) and \(B_x\) are determined from \(A_x \cap \mathbb{N}\) and \(B_x \setminus \mathbb{N}\). The full permutation \(\pi\) may now be reconstructed using the property (44) and the sampling algorithm for infinite one-sided Mallows permutations.

We now return to prove (45), (46) and (47). Define the discrete intervals
\[
I_n = \{-n + 1, -n, \ldots, n\}
\]
and let \(\pi^{(n)} \sim \mu_{\pi, q}\). Define the processes \(\chi^{(n)}\) by
\[
\chi^{(n)}_t := |\Gamma^{(n)} \cap \{x > t, y \leq 0\}|, \quad t \in \mathbb{Z}.
\]
Then Fact 3.17 together with Claim 3.18 imply that
\[
\chi^{(n)} \text{ converges in distribution to } \chi.
\]
(48)

Let us elaborate on the proof of this fact. Observe that
\[
\chi^{(n)}_t - \chi^{(n)}_s = |\{i \mid t < i \leq s, \pi^{(n)}_i \leq 0\}| \quad \text{and} \quad \chi^{(n)}_t - \chi^{(n)}_s = |\{i \mid t < i \leq s, \pi_i \leq 0\}|, \quad t \leq s,
\]
so that these differences depend only on the value of the permutations at finitely many indices. Thus, Fact 3.17 implies that \((\chi^{(n)}_t - \chi^{(n)}_s)_{t \leq s}\) converges in distribution to \((\chi_t - \chi_s)_{t \leq s}\). This may be upgraded to (48) by using the fact that \(\mathbb{P}[^{\chi_s \neq 0}] \xrightarrow{s \to \infty} 0\) (since \(A_x\) has a maximal element, almost surely) and \(\sup_{s} \mathbb{P}[^{\chi_s^{(n)} \neq 0}] \xrightarrow{s \to \infty} 0\) by Claim 3.18.

Observe that \(\chi^{(n)}_0\) has the distribution of the arc chain of \(\pi^{(n)}\) at 0. By using (48), property (45) follows from Proposition 3.8 and property (46) follows from Lemma 3.16. Finally, property (47) is a consequence of the reversal symmetry (10) and Lemma 3.16 applied to \(\pi^{(n)}\).

Proofs of Lemma 3.15 and Lemma 3.16. To complete this section we need only prove these two lemmas.

Proof of Lemma 3.15. Throughout the proof we condition on \(\Gamma_{\pi} \setminus R\) and assume that \(|\Gamma_{\pi} \cap R| > 0\). Let \(\rho\) be the relative order of \(\Gamma_{\pi} \cap R\). Observe that the permutation \(\rho\) uniquely determines \(\pi\) and \(\rho\) may assume, with positive probability, any value in \(S_{|\Gamma_{\pi} \cap R|}\). Hence, the distribution of \(\rho\) is proportional to \(q^{\text{inv}(\pi)}\) by the definition of the Mallows distribution (11); while we need to prove that the distribution of \(\rho\) is proportional to \(q^{\text{inv}(\rho)}\). Therefore, it suffices to verify that
\[
\text{inv}(\pi) - \text{inv}(\rho) \quad \text{is determined by } \Gamma_{\pi} \setminus R.
\]
(49)

We say that two points \((v_x, v_y), (w_x, w_y) \in \mathbb{R}^2\) form an inversion if \((v_x - w_x) \cdot (v_y - w_y) < 0\). For two finite subsets \(V, W \subset \mathbb{R}^2\) we define
\[
\text{inv}(V, W) := |\{(v, w) \in V \times W \mid (v, w) \text{ forms an inversion}\}| \quad \text{and} \quad \text{inv}(V) := \frac{1}{2} \text{inv}(V, V).
\]
The definitions are chosen so that \(\text{inv}(\sigma) = \text{inv}(\Gamma_{\sigma})\) for any permutation \(\sigma\). Consider the following equality,
\[
\text{inv}(\pi) = \text{inv}(\Gamma_{\pi} \setminus R) + \text{inv}(\Gamma_{\pi} \setminus R, \Gamma_{\pi} \cap R) + \text{inv}(\Gamma_{\pi} \cap R).
\]
Observe that $\text{inv}(\Gamma_\pi \setminus R)$ is determined by $\Gamma_\pi \setminus R$ and that $\text{inv}(\rho) = \text{inv}(\Gamma_\pi \cap R)$. Thus we need only prove that

$$\text{inv}(\Gamma_\pi \setminus R, \Gamma_\pi \cap R) = \sum_{u \in \Gamma_\pi \setminus R} \text{inv}(\{u\}, \Gamma_\pi \cap R) \quad \text{is determined by } \Gamma_\pi \setminus R. \quad (50)$$

Let $u = (u_x, u_y) \in \Gamma_\pi \setminus R$. Since $u \in R^c$, we know that at least one of four inequalities occur: $u_x < x_1, u_x > x_2, u_y < y_1, u_y > y_2$. Assume $u_x > x_2$. We have

$$\text{inv}(\{u\}, \Gamma_\pi \cap R) = |\{(x, y) \in \Gamma_\pi \cap R \mid y > u_y\}| = n - u_y - |\{(x, y) \in \Gamma_\pi \setminus R \mid y > u_y\}|.$$

Thus $\text{inv}(\{u\}, \Gamma_\pi \cap R)$ is determined by $\Gamma_\pi \setminus R$ and $u$. Applying similar reasoning in the other three cases shows that (50) and hence (19) holds.

**Proof of Lemma 3.16.** As $0 \leq \chi_t - \chi_{t+1} \leq 1$, it suffices to establish the formula for $\text{Pr}[\chi_{t+1} = \chi_t - 1 \mid \pi_1, \ldots, \pi_t]$. It is convenient to use the formula (19). Let $j_1 < \ldots < j_{n-t}$ be the elements of $[n] \setminus \{\pi_1, \ldots, \pi_t\}$. Observe that $j_k \leq s$ if and only if $k \leq \chi_t$. Hence by (19) and the definition of $\chi_t$ we have

$$\text{Pr}[\chi_{t+1} = \chi_t - 1 \mid \pi_1, \ldots, \pi_t] = \sum_{k=1}^{\chi_t} \text{Pr}[\pi_{t+1} = j_k \mid \pi_1, \ldots, \pi_t] = \frac{1 - q^{\chi_t}}{1 - q^{n-t}}. \quad \Box$$

### 4 Main Theorems

We start by introducing several definitions which we will need for proving our main theorems. A non-empty subset $a$ of $[n]$ is called an *arc* of the permutation $\pi \in S_n$ if its elements can be ordered so that $a = \{a_1, \ldots, a_{|a|}\}$ with $\pi(a_i) = a_{i+1}$ for $1 \leq i < |a|$. We say the arc has *length* $|a|$ and say the arc is *closed* if it forms a cycle, that is, if also $\pi(a_{|a|}) = a_1$. A non-closed arc is called *open*. When the arc is open the above ordering is unique, in which case we call $a_1$ and $a_{|a|}$ the *tail* and *head* of the arc $a$, respectively, and denote them by $\text{tail}(a)$ and $\text{head}(a)$.

In our proofs of the main theorems we will rely upon the diagonal exposure process introduced in Section 3.2. We recall that by time $t$ of this process, we expose the portion of the graph $\Gamma_\pi$ contained in $\{x \leq t, y \leq t\}$. This information allows us to determine all arcs which are contained in $[t]$ and, moreover, to tell whether each such arc is open or closed. This motivates the following definitions.

Let $\pi \in S_n$ and $0 \leq t \leq n$. We say that an arc $a$ of $\pi$ is $[t]$-maximal (with respect to inclusion) if $a \subseteq [t]$ and if every arc $b \subseteq [t]$ which contains $a$ is in fact equal to $a$. Denote

$$\mathcal{A}_t(\pi) := \{a \mid a \text{ is } [t]\text{-maximal}\},$$

$$\mathcal{O}_t(\pi) := \{a \mid a \text{ is } [t]\text{-maximal and open}\}.$$

Recalling the definition of the arc chain $\kappa$ from (19) we observe that

$$\kappa_t(\pi) = |\mathcal{O}_t(\pi)|, \quad (51)$$

which is the origin of the name ‘arc chain’. We note further that for each $1 \leq s \leq t$ there exists a unique $[t]$-maximal arc containing $s$ and we denote this arc by $\text{arc}_s^t(\pi)$. When
Figure 5: Graph of the permutation \((18726)(3)(45)\) alongside its arc chain process \((\kappa_t)\), its maximal open arcs process \((\mathcal{O}_t)\) and its maximal closed arcs process \((\mathcal{A}_t \setminus \mathcal{O}_t)\).

The permutation \(\pi\) is clear from the context we shall abbreviate \(\text{arc}_t(\pi), \mathcal{A}_t(\pi)\) and \(\mathcal{O}_t(\pi)\) to \(\text{arc}_t, \mathcal{A}_t\) and \(\mathcal{O}_t\).

Let us describe how \(\mathcal{A}_t\) evolves during the diagonal exposure process, i.e., the relationship between \(\mathcal{A}_t\) and \(\mathcal{A}_{t+1}\); see Figure 5 for an example. The newly exposed portions of the graph \(\Gamma_\pi\) at time \(t + 1\) were described in (17). Thus, the set of \([t + 1]\)-maximal arcs is formed from the set of \([t]\)-maximal arcs by having the element \(t + 1\) either: (i) form an, open or closed, arc by itself; (ii) extend an open arc to a new, open or closed, longer arc; or (iii) merge two open arcs into a longer open arc. These three possibilities are considered below according to their effect on the number of open arcs.

- If \(\kappa_{t+1} = \kappa_t + 1\) then necessarily \(\{t + 1\}\) is a \([t + 1]\)-maximal open arc and \(\mathcal{A}_{t+1}\) equals \(\mathcal{A}_t\) with \(\{t + 1\}\) added.
- If \(\kappa_{t+1} = \kappa_t\) then either \(t + 1\) is a fixed point of \(\pi\) or \(t + 1\) extends an open arc in \(\mathcal{A}_t\) to a longer open arc in \(\mathcal{A}_{t+1}\), either as the head or as the tail of the arc.
- If \(\kappa_{t+1} = \kappa_t - 1\) then either two open arcs were merged via \(t + 1\) or an open arc was extended by \(t + 1\) to a closed arc.

We now consider the probabilities for the process \((\mathcal{A}_t)\) to evolve according to the above possibilities when \(\pi\) is a Mallows random permutation. As mentioned above, we note that \(\mathcal{A}_t\) and \(\mathcal{O}_t\) are measurable with respect to \(\mathcal{F}_t\), i.e., \(\mathcal{A}\) and \(\mathcal{O}\) are adapted to the diagonal exposure filtration.

The probability, conditioned on \(\mathcal{F}_t\), that the element \(t + 1\) forms a \([t + 1]\)-maximal arc by itself was already calculated in Proposition 3.3 (for the case that it forms an open arc, or equivalently that \(\kappa_{t+1} = \kappa_t + 1\)) and Lemma 3.4 (for the case that it is a fixed point).

The other options, in which the element \(t + 1\) either extends an existing arc or merges two arcs, are determined from the basic events \(\{\pi_t^{-1} = \text{head}(a)\}\) and \(\{\pi_{t+1} = \text{tail}(a)\}\) for an arc \(a \in \mathcal{O}_t\). Indeed, for the merging event one checks in a straightforward manner that if \(a, b \in \mathcal{O}_t\) are distinct arcs then

\[
\{a \cup \{t + 1\} \cup b \in \mathcal{O}_{t+1} \text{ and } \pi_{t+1} \in b\} \iff \{\pi_{t+1} = \text{head}(a) \text{ and } \pi_{t+1} = \text{tail}(b)\}
\]
and for the event that \( t + 1 \) extends the open arc \( a \in \mathcal{O}_t \) to a closed arc we have
\[
\{a \cup \{t + 1\} \in \mathcal{A}_{t+1} \setminus \mathcal{O}_{t+1}\} \iff \{\pi_{t+1}^{-1} = \text{head}(a) \text{ and } \pi_{t+1} = \text{tail}(a)\}.
\]
The event that \( t + 1 \) extends an open arc to a longer open arc is the complement of the other possibilities. Thus the probabilities of these events may be derived from the following lemma.

**Lemma 4.1.** Let \( \pi \sim \mu_{n,q} \), let \( 0 \leq t < n \) and let \( a, b \in \mathcal{O}_t \) be two, not necessarily distinct, arcs. The events \( \{\pi_{t+1}^{-1} = \text{head}(a)\} \) and \( \{\pi_{t+1} = \text{tail}(b)\} \) are conditionally independent given \( \mathcal{F}_t \). Furthermore,
\[
\mathbb{P}_t[\pi_{t+1}^{-1} = \text{head}(a)] = q_i^b \cdot \frac{1 - q}{1 - q^{n-t}} \quad \text{and} \quad \mathbb{P}_t[\pi_{t+1} = \text{tail}(b)] = q_i^b \cdot \frac{1 - q}{1 - q^{n-t}},
\]
where
\[
i_i^b = |\{c \in \mathcal{O}_t \mid \text{head}(c) < \text{head}(a)\}| \quad \text{and} \quad i_i^b = |\{c \in \mathcal{O}_t \mid \text{tail}(c) < \text{tail}(b)\}|.
\]

A consequence of the lemma is that for \( q \geq \frac{1}{2} \) and any two open arcs \( a, b \in \mathcal{O}_t \) one has
\[
\mathbb{P}_t[\pi_{t+1}^{-1} = \text{head}(a) \text{ and } \pi_{t+1} = \text{tail}(b)] \approx \left(\frac{1 - q}{1 - q^{n-t}}\right)^2 \text{ on } \{\kappa_t \leq 2\xi\},
\]
which eventually leads to the appearance of the length scale \( \frac{1}{(1-q)^2} \) in our theorems.

**Proof of Lemma 4.1.** The fact that the events \( \{\pi_{t+1}^{-1} = \text{head}(a)\} \) and \( \{\pi_{t+1} = \text{tail}(b)\} \) are conditionally independent given \( \mathcal{F}_t \) is a direct consequence of (14).

It is not difficult to verify that
\[
i_i^b = |\{1 \leq j < \text{tail}(b) \mid j \notin \{\pi_1, \ldots, \pi_t\}\}|.
\]
Thus, the sampling formula (6) yields that
\[
\mathbb{P}_t[\pi_{t+1} = \text{tail}(b)] = \mathbb{E}_t \mathbb{P}[\pi_{t+1} = \text{tail}(b) \mid \pi_1, \ldots, \pi_t] = \mathbb{E}_t \left[q_i^b \cdot \frac{1 - q}{1 - q^{n-t}}\right] = q_i^b \cdot \frac{1 - q}{1 - q^{n-t}}
\]
as we wanted to show. The formula for \( \mathbb{P}_t[\pi_{t+1}^{-1} = \text{head}(a)] \) follows from the formula for \( \mathbb{P}_t[\pi_{t+1} = \text{tail}(b)] \) applied to the inverse permutation \( \pi^{-1} \), as we have the inverse symmetry (9) and the fact that \( \mathcal{F}_t \) and \( \mathcal{O}_t \) are invariant under this symmetry. \( \square \)

### 4.1 Expected Number of Cycles

In this section we prove Theorem 1.5. Let \( \pi \sim \mu_{n,q} \) and \( \kappa \) be the arc chain of \( \pi \). Recall from the Introduction that \( \mathcal{C}_s \) is the set of points in the cycle of \( \pi \) which contains \( s \).

Our proof is based on the fact that the number of cycles in \( \pi \) equals the number of points \( s \in [n] \) that satisfy \( s = \max(\mathcal{C}_s) \), i.e.,
\[
\text{number of cycles in } \pi = |\{s \in [n] \mid s = \max(\mathcal{C}_s)\}| = \sum_{s \in [n]} 1_{\{s = \max(\mathcal{C}_s)\}}.
\]

The following proposition provides an estimate for the conditional probability of the event \( \{s = \max(\mathcal{C}_s)\} \) given \( \mathcal{F}_{s-1} \).

28
Proposition 4.2. For $1 \leq s \leq n$ one has
\[
q^{\kappa_{s-1}} \cdot \frac{1 - q}{1 - q^{n-s+1}} \leq P_{s-1}[s = \max(C_s)] \leq \frac{1 - q}{1 - q^{n-s+1}}.
\]

Proof. Given $\pi_1, \ldots, \pi_{s-1}$ there is a unique element $t \in [n]$, distinct from $\pi_1, \ldots, \pi_{s-1}$, such that $s = \max(C_s)$ if and only if $\pi_s = t$ (indeed, there is a unique $k \geq 1$ and unique distinct $t_1, \ldots, t_k \in [s]$ satisfying $t_k = s$, $\pi_{t_i} = t_{i+1}$ for $1 \leq i \leq k - 1$ and $t_1 \notin \{\pi_1, \ldots, \pi_{s-1}\}$ whence we set $t = t_1$). We shall derive the proposition from this fact and formula (6). Write $j_1 < \cdots < j_{n-s+1}$ for the elements of $[n] \setminus \{\pi_1, \ldots, \pi_{s-1}\}$ and let $k$ be such that $t = j_k$. Then
\[
P_{s-1}[s = \max(C_s)] = E_{s-1}[\pi_s = t | \pi_1, \ldots, \pi_{s-1}] = E_{s-1}\left[q^{k-1} \frac{1 - q}{1 - q^{n-s+1}}\right].
\]

The proposition follows as $0 \leq k - 1 \leq \kappa_{s-1}$.

We augment this proposition with the following simple estimate on $q^{\kappa_{s-1}}$.

Claim 4.3. For $1 \leq s \leq n$ one has
\[
E[q^{\kappa_{s-1}}] \approx 1.
\]

Proof. Clearly, $q^{\kappa_{s-1}} \leq 1$ so we only need to prove the lower bound. We consider two cases. If $q \geq \frac{1}{8}$ then, by Theorem 3.6
\[
E[q^{\kappa_{s-1}}] \geq q^{2\xi} P[\kappa_{s-1} \leq 2\xi] \geq \frac{1}{4} \left(1 - \frac{q^{2+\xi}}{1 - q^\xi}\right) \gtrsim 1.
\]

Whereas if $q \leq \frac{1}{8}$ then, by (30) and Lemma 3.13
\[
E[q^{\kappa_{s-1}}] \geq P[\kappa_{s-1} = 0] \gtrsim 1.
\]

Putting together (53) and the previous two estimates shows that
\[
E[\text{number of cycles in } \pi] \approx \sum_{s=1}^{n} \frac{1 - q}{1 - q^{n-s+1}}.
\]

Theorem 1.5 is a direct consequence of this fact, together with the observation that
\[
\frac{1 - q}{1 - q^k} \approx 1 - q + \frac{1}{k}, \quad k \geq 1.
\]

(54)

To verify (54) we consider two cases. Recall $\xi$ from (8).

If $k \geq \xi$ then $q^k \leq \frac{1}{2}$ and $\frac{1}{k} \lesssim 1 - q$; therefore $\frac{1 - q}{1 - q^k} \approx 1 - q \approx 1 - q + \frac{1}{k}$.

If $k < \xi$ then $q^k > \frac{1}{2}$ and $\frac{1}{k} \gtrsim 1 - q$; thus $\frac{1 - q}{1 - q^k} = \frac{1}{1 + q + \cdots + q^{k-1}} \approx \frac{1}{k} \approx 1 - q + \frac{1}{k}$.

29
4.2 Expected Cycle Diameter

In this section we prove Theorem 1.4. Some of the tools developed here will also be used in proving the rest of our main theorems.

We prove the lower and upper bounds on the quantity \( E[\max(C_s) - s] \) as given in (4).

Lower bound: Let us begin with the proof of the lower bound of (4), i.e.,

\[
E[\max(C_s) - s] \gtrsim \min\{q \cdot \xi^2, n - s\},
\]

where we recall the definition of \( \xi \) from (8). First we are going to provide upper bounds for closing the cycle of \( s \) at time \( t \leq s < n \). Observe that for \( s \leq t < n \), conditioned on the event \( \{\text{arc}_{t+1}^s \text{ is open}\} \), one has,

\[
\text{arc}_{t+1}^s \text{ is closed} \iff \pi_{t+1}^{-1} = \text{head}(\text{arc}_t^s) \quad \text{and} \quad \pi_{t+1} = \text{tail}(\text{arc}_t^s).
\]

Hence the following equation is an immediate corollary of Lemma 4.1:

\[
\text{for } s \leq t < n, \quad \mathbb{P}_t[\text{arc}_{t+1}^s \text{ is closed}] \leq \left( \frac{1-q}{1-q^{n-t}} \right)^2 \quad \text{on } \{\text{arc}_t^s \in O_t\}. \tag{56}
\]

It is worth noting that the probability of closing the cycle of \( s \) at time \( t = s \) has a larger estimate, as given in Proposition 4.2, as the event \( s = \max(C_s) \) occurs either when \( s \) is a fixed point or when any one of the open arcs closes at time \( t = s \).

Combining Proposition 4.2 with (56) we derive by induction the following corollary.

**Corollary 4.4.** For \( 0 < s \leq t \leq n \) one has\(^2\)

\[
\mathbb{P}_{s-1}[\text{arc}_s^t \text{ is open}] \geq \frac{q - q^{n-s+1}}{1 - q^{n-s+1}} \prod_{s \leq i < t} \left( 1 - \left( \frac{1-q}{1-q^{n-i}} \right)^2 \right).
\]

Now we state the main proposition.

**Proposition 4.5.** Let \( 1 \leq s < n \) and set \( r := \min\{s + \xi^2, n - 1\} \). Then for \( q \geq \frac{1}{2} \) we have

\[
\mathbb{P}_{s-1}[\text{arc}_s^r \text{ is open}] \gtrsim 1.
\]

Observe that equation (55) in the case \( q \geq \frac{1}{2} \) is an immediate corollary of this proposition. One may also verify that Proposition 4.2 yields (55) in the case \( q \leq \frac{1}{2} \). Hence it suffices to prove Proposition 4.5.

We use the following calculus fact: for a sequence \((x_i)\) with \( x_i \in [0, 1)\) one has

\[
\text{if } \sum_i x_i \lesssim 1 \text{ and } 1 - x_i \gtrsim 1 \text{ for all } i, \text{ then } \prod_i (1 - x_i) \gtrsim 1. \tag{57}
\]

\(^2\)In the case when \( s = t \) the empty product is assumed to be 1.
Proof of Proposition 4.5. Due to Corollary 4.4 and the fact that \( \frac{q - q^{n-s+1}}{1 - q^{n-s+1}} \geq \frac{q - q^2}{1 - q^2} \geq \frac{1}{3}, \) it suffices to verify that
\[
\prod_{s \leq i < r} \left( 1 - \left( \frac{1 - q}{1 - q^{n-i}} \right)^2 \right) \geq 1.
\]
Due to (57) we need only verify that one has
\[
1 - \left( \frac{1 - q}{1 - q^{n-i}} \right)^2 \geq 1, \quad \text{for } s \leq i < r, \quad \text{and} \quad \sum_{s \leq i < r} \left( \frac{1 - q}{1 - q^{n-i}} \right)^2 \lesssim 1.
\]
The first inequality follows from the fact that \( q \geq \frac{1}{2} \) and \( i < n - 1 \). For the second inequality, observe that
\[
\sum_{s \leq i < r} \left( \frac{1 - q}{1 - q^{n-i}} \right)^2 \leq \sum_{t=1}^{r-s} \left( \frac{1 - q}{1 - q^t} \right)^2 \lesssim \sum_{t=1}^{\xi^2} \left( (1 - q)^2 + \frac{1}{t^2} \right) \lesssim 1,
\]
where we applied the estimate \( \left( \frac{1 - q}{1 - q^t} \right)^2 \lesssim (1 - q)^2 + \frac{1}{t^2} \) which follows from (54).

Upper bound: We proceed to establish the upper bound
\[
\mathbb{E}[\max(C_s) - s] \lesssim \min\{q \cdot \xi^2, n - s\}. \tag{58}
\]
We are going to state analogues to (56) and Corollary 4.4 for the upper bound. Lemma 4.1 implies that
\[
\text{for } s \leq t < n, \quad \mathbb{P}_t [\text{arc}_s^{t+1} \text{ is open and } \kappa_i \leq d \text{ for all } i \in [s, t]] \leq \exp \left( - (t - s) \cdot (1 - q)^2 \cdot q^{2d} \right). \tag{60}
\]

Proposition 4.6. For \( 1 \leq s \leq t \leq n \) and \( d \geq 0 \) we have
\[
\mathbb{P}_s [\text{arc}_s^t \text{ is open and } \kappa_i \leq d \text{ for all } i \in [s, t]] \leq \exp \left( - (t - s) \cdot (1 - q)^2 \cdot q^{2d} \right). \tag{60}
\]
Proof. For \( s < r \leq n \) we set
\[
E_r := \{ \text{arc}_s^r \text{ is open and } \kappa_i \leq d \text{ for all } i \in [s, r] \}.
\]
Via (59) one may verify that for such \( r \),
\[
\mathbb{P}_s[E_r] \leq \mathbb{P}_s[E_{r-1} \cap \{ \text{arc}_s^r \text{ is open} \}] \leq \mathbb{P}_s[E_{r-1}] \cdot \left( 1 - \left( \frac{q^d - q^{d+1}}{1 - q^{n-r+1}} \right)^2 \right)
\]
\[
\leq \mathbb{P}_s[E_{r-1}] \cdot \exp \left( - (1 - q)^2 \cdot q^{2d} \right).
\]
By applying this inequality for all \( s < r \leq t \) we obtain inequality (60). \( \square \)

Proposition 4.7. For \( 1 \leq s \leq n \) one has
\[
\mathbb{E}[(\max(C_s) - s) \geq \min\{q \cdot \xi^4, (n - s)^2\}. \tag{60}
\]
This proposition implies \([58]\) for \(q \geq \frac{1}{2}\) using the fact that \(\mathbb{E}[X^2] \geq \mathbb{E}[X]^2\) for any integrable random variable \(X\). For \(q \leq \frac{1}{2}\) we use the fact that \(\max(C_s) - s \leq (\max(C_s) - s)^2\) to again deduce \([58]\) from the same proposition.

Proposition \([4.7]\) is stronger than what we need here as it bounds the second moment of \(\max(C_s) - s\), but this extra strength will be used in the proof of Theorem \([3.3]\).

**Proof.** The inequality \(\max(C_s) - s \leq n - s\) holds true by definition. So we need only verify \(\mathbb{E}[(\max(C_s) - s)^2] \lesssim q \cdot \xi^4\). In the regime when \(q\) is bounded away from 1, the inequality is a direct consequence of Theorem \([3.11]\) due to:

\[
\kappa_t = 0 \quad \implies \quad \max(C_i) \leq t \quad \text{for all } i \leq t,
\]

as \(\kappa_t\) counts the number of open arcs at time \(t\), see \([51]\). Thus to complete the proof of proposition it suffices to verify that

\[
\mathbb{E}[(\max(C_s) - s)^2] \lesssim \xi^4, \quad \text{for } q \text{ sufficiently close to } 1. \tag{61}
\]

We assume without loss of generality that \(n > s + 2\xi^2\). Our starting point is the inequality

\[
\mathbb{E}[(\max(C_s) - s)^2] \leq 4\xi^4 + 3 \sum_{t=s+2\xi^2}^{n-1} (t-s) \cdot \mathbb{P}[\max(C_s) > t]. \tag{62}
\]

Define

\[
d_t := \left\lceil \frac{1}{t} \log_1(q \left(\frac{t-s}{t}^q\right)) \right\rceil \quad \text{and} \quad E_t := \{\kappa_i \leq d_t + \xi \text{ for all } i \in [s, t]\}.
\]

Now write

\[
\sum_{t=s+2\xi^2}^{n-1} (t-s) \mathbb{P}[\max(C_s) > t] \leq \sum_{t=s+2\xi^2}^{n-1} (t-s) \mathbb{P}[E_t^c] + \sum_{t=s+2\xi^2}^{n-1} (t-s) \mathbb{P}[\max(C_s) > t] \cap E_t.
\]

We estimate the two sums separately. For the first sum, using Theorem \([3.6]\) and the observation that \(d_t \geq 12\) for \(t \geq s + 2\xi^2\) as we assumed that \(q\) is sufficiently close to 1, we obtain

\[
\sum_{t=s+2\xi^2}^{n-1} (t-s) \mathbb{P}[E_t^c] \lesssim \sum_{t=s+2\xi^2}^{n-1} (t-s) q^{2d_t} \lesssim \sum_{t=s+2\xi^2}^{n-1} (t-s) \left(\frac{\xi^4}{t-s}\right)^3 \lesssim \xi^4.
\]

For the second sum, Proposition \([4.7]\) implies that

\[
\sum_{t=s+2\xi^2}^{n-1} (t-s) \mathbb{P}[\{\max(C_s) > t\} \cap E_t] \leq \sum_{t=s+2\xi^2}^{n-1} (t-s) \exp \left(- (t-s)(1-q)^2 q^{2d_t+2\xi}\right)
\]

\[
\leq \sum_{t=s+2\xi^2}^{n-1} (t-s) \exp \left(- (t-s)(1-q)^2 q^{2d_t+2\xi}\right)
\]

\[
\leq \sum_{t=s+2\xi^2}^{n-1} (t-s) \exp \left(-c\sqrt{t-s} (1-q)\right) \lesssim \xi^4,
\]

for a positive absolute constant \(c > 0\), where the last estimate is not difficult to check directly. \(\square\)
4.3 Expected Cycle Length

In this section we prove Theorem 1.1. As \(|C_s| \leq \text{diam}(C_s) + 1\) the upper bound for \(E|C_s|\) follows immediately from the upper bound on the diameter of \(C_s\) proved in Theorem 1.4. Thus we need only prove the lower bound, namely that

\[
E|C_s| \gtrsim \min\{\xi^2, n\}. \tag{63}
\]

Since \(|C_s| \geq 1\) we may and will restrict, for the rest of the section, to the regime where \(q\) is sufficiently close to 1 and \(n\) is sufficiently large.

Our starting point is the formula

\[
E|C_s| = \sum_{t \in [n]} P[t \in C_s].
\]

The lower bound (63) is an immediate consequence of this formula combined with the next lemma.

Lemma 4.8. Let \(s, t \in [n]\) satisfy \(|t - s| \leq \xi^2\) then

\[
P[t \in C_s] \gtrsim 1.
\]

Proof. It suffices to consider the case \(s < t\). Define the events \((V_r), t \leq r \leq n\) by

\[
V_t := \{\text{arc}_s^t = \text{arc}_t^s\} \quad \text{and} \quad V_r := \{\text{arc}_s^r = \text{arc}_t^r \text{ and } \text{arc}_s^{r-1} \neq \text{arc}_t^{r-1}\} \quad \text{for } r > t.
\]

By definition, \(V_r\) occurs if and only if the arc of \(s\) and the arc of \(t\) merge exactly at time \(r\). Hence \(\{t \in C_s\}\) is the disjoint union \(\bigcup_{t \leq r \leq n} V_r\), yielding that

\[
P[t \in C_s] = \sum_{t \leq r \leq n} P[V_r].
\]

We shall prove the following estimates,

\[
P[V_t] \gtrsim \frac{1 - q}{1 - q^{n-t+1}} \quad \text{and} \quad P[V_r] \gtrsim \left(\frac{1 - q}{1 - q^{n-r+1}}\right)^2 \quad \text{for } t < r < \min\{t + \xi^2, n - 2\}. \tag{64}
\]

The lemma follows easily from these, as if \(t + \xi^2 < n - 2\) one may sum the estimates for \(P[V_r]\) and otherwise it suffices to consider only the estimate for \(P[V_t]\) or \(P[V_{n-3}]\). Let us prove these estimates. The following inequality is an immediate consequence of Lemma 4.1,

\[
P_{t-1}[V_t] \geq q^{2\xi} \cdot \frac{1 - q}{1 - q^{n-t+1}} \cdot 1_{A \cap \{k_{t-1} \leq 2\xi\}}, \quad \text{where } A := \{\text{arc}_s^{t-1} \text{ is open}\}. \tag{65}
\]

Thus the estimate for \(P[V_t]\) follows by noting that \(P[A \cap \{k_{t-1} \leq 2\xi\}] \gtrsim 1\) for \(q\) sufficiently close to 1. Indeed, \(P[A] \gtrsim 1\) by Proposition 4.5 and \(P[k_{t-1} \leq 2\xi]\) tends to 1 as \(q\) tends to 1, uniformly in \(t\) and \(n\), by Theorem 3.6.

We proceed to estimate \(P[V_r]\) for \(t < r < \min\{t + \xi^2, n - 2\}\). Define

\[
B_i := \{\text{arc}_s^i \text{ and } \text{arc}_t^i \text{ are open and distinct}\}, \quad t \leq i \leq n.
\]
Similarly to (65), we have
\[ P_{r-1}[V_r] \geq q^{4\xi} \cdot \left( \frac{1-q^{n-1+r}}{1-q^{n-1+r}} \right)^2 \cdot 1_{B_{r-1} \cap \{ \kappa_{r-1} \leq 2\xi \}} \]
and, as before, it suffices to show that \( P[B_{r-1}] \gtrsim 1 \). Lemma 4.1 implies that for \( i > t \),
\[ P[B_i] = E \left[ 1_{B_{i-1}} \cdot \left( 1 - P_{i-1} \left[ \pi_{i-1} \in \{ \text{tail}(arc_{s-1}^{i-1}), \pi_{i-1} \notin \text{head}(arc_{s}^{i-1}) \} \right] \right) \right] \]
\[ \geq P[B_{i-1}] \cdot \left( 1 - 4 \left( \frac{1-q^{n-1+r}}{1-q^{n-1+r}} \right)^2 \right). \]
Furthermore, for \( i = t \) we obtain using Proposition 4.2 and Lemma 4.1 that
\[ P[B_t] = P[A \cap \{ \pi_t \neq \text{tail}(arc_{s-1}^{t-1}), \pi_{t-1} \neq \text{head}(arc_{s}^{t-1}), t \neq \max(C_t) \}] \]
\[ \geq P[A] \cdot \left( 1 - 3 \cdot \frac{1-q^{n-1+r}}{1-q^{n-1+r}} \right). \]
Combining these inequalities with the estimate \( P[A] \gtrsim 1 \) proved previously shows that
\[ P[B_{r-1}] \gtrsim \left( 1 - 3 \cdot \frac{1-q^{n-1+r}}{1-q^{n-1+r}} \right) \prod_{t < i < r} \left( 1 - 4 \left( \frac{1-q^{n-1+r}}{1-q^{n-1+r}} \right)^2 \right) \]
By estimating the product as in the proof of Proposition 4.5 we conclude that \( P[B_{r-1}] \gtrsim 1 \), as we wanted to show. \( \square \)

4.4 Variance of Cycle Length

In this section we prove Theorem 1.3. Throughout we let \( \pi \sim \mu_{n,q} \). We need to show that for every \( s \in [n] \) we have
\[ \text{Var}(|C_s|) \approx \min \left\{ q \cdot \xi^4, (n-1)^2 \right\}. \]
We divide the proof into 3 cases:

1. The lower bound for \( q \geq \frac{1}{8} \) follows from a general non-concentration argument together with Theorem 1.1.

2. The lower bound for \( q \leq \frac{1}{8} \) is a corollary of Lemma 3.3.

3. The upper bound is a direct corollary of Proposition 4.7.

Case 1: Assume that \( q \geq \frac{1}{8} \). Assume that \( n > 2 \) as the case \( n = 1 \) is trivial. Further, using the reversal symmetry (110), assume that \( s < n \).

We consider the following equivalence relation on \( S_n \): we say that \( \sigma_1 \sim \sigma_2 \) if
\[ \sigma_1 \in \{ \sigma_2, \tau \circ \sigma_2, \sigma_2 \circ \tau, \tau \circ \sigma_2 \circ \tau \} \text{ where } \tau := (s, s+1). \]
Let \( X \) be the random equivalence class of \( \pi \) in this equivalence relation. We shall prove that
\[ \text{Var}(|C_s| \mid X) \geq E[|C_s|^2 \mid X]. \tag{66} \]
The equivalence class $X$.

Remark 4.9. A consequence of (67). Choosing such a $\rho$ of cycle lengths, i.e., that $1 - H$ may be applied to other random permutation models satisfying the following assumption.

$|C_1|$ or $|C_0|$.

It follows that any two permutations $\sigma_1 \sim \sigma_2$ satisfy $|\text{inv}(\sigma_1) - \text{inv}(\sigma_2)| \leq 2$, whence (1) implies that $\mathbb{P}[\pi = \sigma_1] \approx \mathbb{P}[\pi = \sigma_2]$. As $X$ is an equivalence class of $\mathbb{S}_n$ of size at most 4, we conclude that

$$\mathbb{P}[\pi = \sigma \mid X] \approx 1, \quad \text{for all } \sigma \in X.$$ (67)

The equivalence class $X$ necessarily contains a permutation $\rho$ satisfying $C_s(\rho) \neq C_{s+1}(\rho)$. Choosing such a $\rho$, one checks that for each $\sigma \in X$, $|C_s(\sigma)|$ is either $|C_s(\rho)|$, $|C_{s+1}(\rho)|$ or $|C_s(\rho)| + |C_{s+1}(\rho)|$ and each of these values occurs for some $\sigma \in X$. Thus (66) is a consequence of (67).

**Remark 4.9.** The above argument is a general argument for showing non-concentration of cycle lengths, i.e., that

$$\text{Var}(|C_s|) \gtrsim \mathbb{E}[|C_s|^2].$$

It may be applied to other random permutation models satisfying the following assumption. There exists some $1 \leq t \leq n$, different from $s$, for which

$$\mathbb{P}[\sigma] \approx \mathbb{P}[\sigma \circ (s, t)] \approx \mathbb{P}[(s, t) \circ \sigma] \quad \text{for all } \sigma \in \mathbb{S}_n.$$ (Case 2:)

Assume now that $q \leq \frac{1}{8}$. We need to prove that

$$\text{Var}|C_s| \gtrsim q \quad \text{for } n > 1.$$ (Case 2:)

It suffices to verify that

$$1 - \mathbb{P}[|C_s| = 1] \gtrsim q \quad \text{and} \quad \mathbb{P}[|C_s| = 1] \gtrsim 1.$$ (Case 2:)

Let $\kappa$ be the arc chain of $\pi$. Due to the reversal symmetry (10) we may assume that $n - s \geq 1$. Lemma 3.3 implies that

$$\mathbb{P}[|C_s| = 1] = \mathbb{P}[\pi_s = s] = \mathbb{E}\left[\frac{\kappa_{s-1} - \kappa_{s-1} + 1}{1 - q^{n-s+1}} \cdot \frac{\kappa_{n-s} - \kappa_{n-s+1}}{1 - q^{n-s+1}}\right] \leq \frac{1 - q}{1 - q^2} = \frac{1}{1 + q}.$$ (Case 2:)

Hence $1 - \mathbb{P}[|C_s| = 1] \gtrsim \frac{q}{1+q} \gtrsim q$. Now we shall verify that $\mathbb{P}[|C_s| = 1] \gtrsim 1$. Observe that

$$\mathbb{P}[\pi_s = s] \geq \mathbb{P}[\pi_s = s \mid \kappa_{s-1} = 0] \cdot \mathbb{P}[\kappa_{s-1} = 0] \geq (1 - q) \cdot \mathbb{P}[\kappa_{s-1} = 0] \gtrsim \mathbb{P}[\kappa_{s-1} = 0]$$

by Lemma 3.4 and our assumption that $q \leq \frac{1}{8}$. The fact that $\mathbb{P}[\kappa_{s-1} = 0] \gtrsim 1$ follows from (30) and Lemma 3.13.

**Case 3:** We prove the upper bound for the variance of cycle length. Since $|C_s| \geq 1$ it follows that

$$\text{Var}|C_s| \leq \mathbb{E}[|C_s - 1|^2] \leq \mathbb{E}[\text{diam}(C_s)^2] \leq 2\mathbb{E}[(\max(C_s) - s)^2 + (s - \min(C_s))^2].$$ (68)

Proposition 1.14, via the reversal symmetry (10), states that

$$\mathbb{E}[\max(C_s)^2] \lesssim \min\{q\xi^4, (n-s)^2\} \quad \text{and} \quad \mathbb{E}[(s - \min(C_s))^2] \lesssim \min\{q\xi^4, (s-1)^2\},$$

which yields the upper bound via (68).
4.5 Poisson-Dirichlet Law

In this section we prove Theorem 1.2. We need to prove two facts: that the normalized length $\frac{1}{n}|C_{s_n}|$ converges in distribution to the uniform distribution on $[0,1]$ for any sequence $(s_n)$ with $s_n \in [n]$ and that the distribution of the sorted and normalized cycle lengths converges to the Poisson-Dirichlet law. The proofs of these two facts are similar and we shall focus on the proof for the Poisson-Dirichlet law. At the end of the section we point out the needed modifications to obtain the limiting distribution of $\frac{1}{n}|C_{s_n}|$.

The Poisson-Dirichlet law in a space of multisets of reals: Denote by $D$ the space of sorted sequences $(\alpha_i, i \geq 1, \alpha_1 \geq \alpha_2 \geq \ldots$ of non-negative reals with finite sum. The space $D$ is endowed with the product topology, the topology inherited from $\mathbb{R}^N$. We shall consider also the $\ell^2$ metric on sequences in $D$ and take note of the fact that convergence in the $\ell^2$ metric implies convergence in the product topology.

The Poisson-Dirichlet law with parameter one, denoted by $PD$, is a distribution on $D$, supported on sequences with sum 1. We will not need the precise definition of $PD$, instead relying only on its relation with uniform random permutations, and the reader is referred, e.g., to [12] for further background. Specifically, we shall use that if $\sigma$ is a uniformly random permutation in $S_k$ and $\ell_1 \geq \ell_2 \geq \ldots$ are the sorted lengths of cycles in $\sigma$ then

$$\frac{1}{k}(\ell_1, \ell_2, \ldots) \overset{d}{\to} PD \quad \text{as } k \to \infty,$$

where a finite sequence is viewed as an element of $D$ by adding to it a trailing sequence of zeros.

It is convenient to work with an alternative, equivalent, description of the space $D$. A sequence in $D$ may be equivalently described by a multiset of non-negative reals with finite sum (summing elements according to their multiplicities), in which the multiplicity of each number is the number of its occurrences in the sequence. Note that 0 is the only number possibly having an infinite multiplicity in this representation. We denote the space of such multisets by $M$ and make the identification of $D$ and $M$ in the sequel, putting the induced topology on $M$, i.e., the push-forward of the product topology via the identification map. We denote by $d$ the metric on $M$ obtained as the push-forward of the $\ell^2$ metric on $D$. The metric $d$ has the following explicit expression: given two multisets $X, Y \in M$,

$$d(X, Y) := \min_{\varphi} \sqrt{\sum_{x \in X} (\varphi(x) - x)^2},$$

where the minimum is taken over all bijections $\varphi: X \to Y$ and it is understood that bijections may assign different images to multiple occurrences of the same element. To see that $d$ coincides with the push-forward of the $\ell^2$ metric on $D$ we note that the minimum in (70) is obtained by taking $\varphi$ to be a monotone non-decreasing mapping.

We will also consider multisets of finite cardinality of non-negative reals as members of $M$ by adding an infinite amount of zeros to the multiset.

Convergence Criterion: Here we state a convergence criterion to the Poisson-Dirichlet distribution which generalizes (69). We start with some definitions.

For a permutation $\sigma: S \to S$ and a weight function $w: S \to \mathbb{R}$, where $S$ is a non-empty
finite set, we define the weighted length function \( L(\sigma, w) \) to be the multiset

\[
L(\sigma, w) := \left\{ \sum_{i \in C_1} w_i, \ldots, \sum_{i \in C_m} w_i \right\},
\]

where \( C_1, \ldots, C_m \) is a decomposition of \( S \) into orbits of \( \sigma \). For instance, \( L(\sigma, \mathbb{1}) \), where \( \mathbb{1} \) denotes the constant 1 function, is the multiset of cycle lengths of \( \sigma \).

The plan is to show that the lengths of the long cycles can be coupled closely with the \( \pi \) analyze

For instance, we may take

\[
\text{Proof of Proposition 4.10.}
\]

Using the notation of (71), the following inequality follows from (70).

\[
d^2(L(\sigma, \frac{1}{|S|} \mathbb{1}), L(\sigma, w)) \leq \sum_{r} \left( \sum_{s \in C^r} (\frac{1}{|S|} - w_s) \right)^2 = \sum_{s \in S} \sum_{t \in S} (\frac{1}{|S|} - w_s)(\frac{1}{|S|} - w_t) \cdot 1\{t \in C_s(\sigma)\}. \tag{72}
\]

For each \( s \in S \), as \( \mathbb{P}[t \in C_s(\sigma)] = \frac{1}{2} \mathbb{1}_{s=t} + \frac{1}{2} \),

\[
\mathbb{E}\left[ \sum_{t \in S} (\frac{1}{|S|} - w_s)(\frac{1}{|S|} - w_t) \cdot 1\{t \in C_s(\sigma)\} \right] = \frac{1}{2}\left( (\frac{1}{|S|} - w_s)(1 - \sum_{t \in S} w_t) + (\frac{1}{|S|} - w_s)^2 \right). \tag{73}
\]

The proposition follows by taking expectation in (72) and substituting (73).

**Proof of the Poisson-Dirichlet Law:** Let \( q = q_n \) satisfy

\[
(1 - q)^2 \cdot n \to 0 \quad \text{as} \quad n \to \infty. \tag{74}
\]

Let \( m = m_n \in \mathbb{N} \) be a sequence that converges to infinity sufficiently slowly so that

\[
\frac{m}{n} \to 0 \quad \text{and} \quad q^{m^2} \to 1 \quad \text{as} \quad n \to \infty. \tag{75}
\]

For instance, we may take \( m = \lfloor n^{1/4} \rfloor \) or \( m = \lfloor \log(n + 1) \rfloor \). Let \( \pi \sim \mu_{n,q} \). We shall analyze \( \pi \) conditioned on \( \Gamma_{\pi} \cap U \), where

\[
U := \{ x \leq n - m \text{ or } y > n - m \}.
\]

The plan is to show that the lengths of the long cycles can be coupled closely with the lengths of cycles in a uniform permutation. To do it we first show that, despite the fact
that $\Gamma_\pi \cap U$ is almost the whole graph of $\pi$, with high probability, it provides little to no information on the lengths of the long cycles of $\pi$. The lengths of the long cycles, given $\Gamma_\pi \cap U$, are mostly decided by $\Gamma_\pi \setminus U$, the remaining portion of the graph. We shall then conclude by utilizing the fact that the relative order (see (39)) of $\Gamma_\pi \setminus U$ is very close to a uniformly distributed permutation.

Our proof requires us to define permutations over a finite random set $\mathcal{O}_U$ and analyze the multiset $\mathcal{L}(\cdot, \omega)$ of such permutations for various weight tuples $\omega$. The set $\mathcal{O}_U$ may be empty, though this case does not impact on our analysis as its probability tends to 0. To avoid treating it in a special manner, as much as possible, we define the set of permutations over the empty set to consist of a single element denoted $\text{id}_\emptyset$. This element has no cycles and, in particular, $\mathcal{L}(\text{id}_\emptyset, \omega) = \emptyset$ for all $\omega$.

Let us begin the proof. We introduce additional definitions to discuss arcs which are determined by $\Gamma_\pi \cap U$. We say that an arc $a$ of $\pi$ belongs to $U$ if one may order its elements $a = \{a_1, \ldots, a_{|a|}\}$ so that $a_{i+1} = \pi(a_i)$ and $(a_i, a_{i+1}) \in U$ for all $1 \leq i < |a|$. If, in addition, $a_1 = \pi(a_{|a|})$ and $(a_{|a|}, a_1) \in U$ we say that $a$ is relatively closed and otherwise deem it relatively open. When the arc is relatively open then the above ordering is unique, in which case we call the elements $a_1$ and $a_{|a|}$ the tail and head of the arc $a$, respectively, and denote them by $\text{tail}(a)$ and $\text{head}(a)$. We say that an arc $a$ is $U$-maximal if $a$ belongs to $U$ and there are no other arcs that belong to $U$ and contain $a$. Let $\mathcal{A}_U$ be the set of $U$-maximal arcs and let $\mathcal{O}_U$ be the set of relatively open $U$-maximal arcs. One should note that $\mathcal{A}_U$ and $\mathcal{O}_U$ are determined by $\Gamma_\pi \cap U$ and that $\sum_{a \in \mathcal{A}_U} |a| = n$. The last equality follows from the fact that every element of $[n]$ belongs to exactly one of the arcs of $\mathcal{A}_U$ (possibly to an arc containing only this element).

We proceed to discuss the way that the cycles of $\pi$ are formed from the arcs in $\mathcal{A}_U$ and the portion of the graph $\Gamma_\pi \setminus U$. Each point $(s, t) \in \Gamma_\pi \setminus U$ satisfies $s = \text{head}(a)$ and $t = \text{tail}(b)$ for some $a, b \in \mathcal{O}_U$. Conversely, for each $a \in \mathcal{O}_U$ there exist points $(s, t), (s', t') \in \Gamma_\pi \setminus U$ satisfying $s = \text{head}(a)$ and $t' = \text{tail}(a)$. Thus we may define a permutation $\tau : \mathcal{O}_U \to \mathcal{O}_U$ by setting

$$\tau(a) = b \quad \text{if and only if} \quad (\text{head}(a), \text{tail}(b)) \in \Gamma_\pi.$$ 

It is straightforward to check that each cycle of $\pi$ is then either a cycle in $\mathcal{A}_U \setminus \mathcal{O}_U$, or formed by merging the open arcs in $\mathcal{O}_U$ which are in the same orbit of $\tau$. In particular,

$$\mathcal{L}(\pi, \frac{1}{n} \mathbb{1}) = \left\{ \frac{1}{n} |a| \mid a \in \mathcal{A}_U \setminus \mathcal{O}_U \right\} \cup \left\{ \frac{1}{n} \sum_{a \in C} |a| \mid C \text{ is a cycle of } \tau \right\},$$

where the equality and union are in the sense of multisets. Write $|\cdot|$ for the length map on arcs, $a \mapsto |a|$. Recalling (70), we conclude that

$$d \left( \mathcal{L}(\pi, \frac{1}{n} \mathbb{1}), \mathcal{L}(\pi, \frac{1}{n} \mathbb{1}) \right) \leq \sqrt{\sum_{a \in \mathcal{A}_U \setminus \mathcal{O}_U} \frac{|a|^2}{n^2}} \leq \sum_{a \in \mathcal{A}_U \setminus \mathcal{O}_U} \frac{|a|}{n} = 1 - \sum_{a \in \mathcal{O}_U} \frac{|a|}{n}. \quad (76)$$

The Poisson-Dirichlet law is a consequence of this inequality and the following lemma, which states the properties of the Mallows model that we require.
Lemma 4.11. Let $\pi \sim \mu_{n,q}$ and suppose $n \to \infty$ with (74) and (75) holding. Then:

(i) \[ \frac{1}{n} \max_{a \in O_U} |a| \to 0 \quad \text{and} \quad \frac{1}{n} \sum_{a \in O_U} |a| \to 1 \quad \text{in probability.} \] (77)

(ii) There exists a coupling of $\tau$ and a permutation $\sigma : O_U \to O_U$ such that

\[ P[\sigma \neq \tau] \to 0 \quad \text{as } n \to \infty \]

and, conditioned on $\Gamma_x \cap U$, $\sigma$ has the uniform distribution on permutations of $O_U$.

To obtain the Poisson-Dirichlet limit law, let $\sigma$ be the random permutation given by part (ii) of Lemma 4.11. Observe that

\[ d \left( \mathcal{L}(\pi, \frac{1}{n} \mathbf{1}), \mathcal{L}(\sigma, \frac{1}{|O_U|} \mathbf{1}) \right) \leq \]

\[ d \left( \mathcal{L}(\pi, \frac{1}{n} \mathbf{1}), \mathcal{L}(\tau, \frac{1}{n} \mathbf{1}) \right) + d \left( \mathcal{L}(\tau, \frac{1}{n} \mathbf{1}), \mathcal{L}(\sigma, \frac{1}{n} \mathbf{1}) \right) + d \left( \mathcal{L}(\sigma, \frac{1}{n} \mathbf{1}), \mathcal{L}(\sigma, \frac{1}{|O_U|} \mathbf{1}) \right). \]

We estimate the expectation of each of the last three summands separately. By (76) and part (i) of Lemma 4.11,

\[ E[I] \leq E \left[ 1 - \sum_{a \in O_U} \frac{|a|}{n} \right] \to 0 \quad \text{as } n \to \infty. \]

Note that as $d \left( \mathcal{L}(\alpha, w), \mathcal{L}(\beta, w) \right) \leq 2 \sum_i |w_i|$ for any two permutations $\alpha, \beta$ on a finite set $S$ and weight tuple $w : S \to \mathbb{R}$, we have $II \leq 2 \cdot P[\sigma \neq \tau]$. Thus, by part (ii) of Lemma 4.11,

\[ E[II] \leq 2 \cdot P[\sigma \neq \tau] \to 0 \quad \text{as } n \to \infty. \]

Lastly, $III = 0$ when $O_U = \emptyset$ and by Proposition 4.10,

\[ E[(III)^2 | \Gamma_x \cap U] \leq \frac{1}{2} \left( (1 - \frac{1}{n} \sum_{a \in O_U} |a|)^2 + \sum_{a \in O_U} \left( \frac{1}{|O_U|} - \frac{|a|}{n} \right)^2 \right) \quad \text{on } \{O_U \neq \emptyset\}. \]

Thus, applying part (i) of Lemma 4.11 and observing that it implies, in particular, that $|O_U| \to \infty$ in probability as $n \to \infty$, we obtain

\[ E[III] \leq \sqrt{E[(III)^2]} \to 0 \quad \text{as } n \to \infty. \]

We conclude that

\[ E \left[ d \left( \mathcal{L}(\pi, \frac{1}{n} \mathbf{1}), \mathcal{L}(\sigma, \frac{1}{|O_U|} \mathbf{1}) \right) \right] \to 0 \quad \text{as } n \to \infty. \]

The limiting distribution of $\mathcal{L}(\sigma, \frac{1}{|O_U|} \mathbf{1})$ is the $\mathcal{PD}$ distribution as, conditioned on $\Gamma_x \cap U$, $\sigma$ is a uniform permutation on $O_U$ by part (ii) of Lemma 4.11 using (69) and relying again on the fact that $|O_U| \to \infty$ in probability as $n \to \infty$. Thus $\mathcal{L}(\pi, \frac{1}{n} \mathbf{1})$ converges also to the $\mathcal{PD}$ distribution, as we wanted to prove.
Proof of part (ii) of Lemma 4.11: This is a corollary of Lemma 3.15. On the event \( \{ \mathcal{O}_U = \emptyset \} \) we simply set \( \sigma = \tau \). On the complementary event \( \{ \mathcal{O}_U \neq \emptyset \} \) we do as follows. Set \( k := |\mathcal{O}_U| \). Let \( \tilde{\tau} \) be the relative order, see (39), of \( \Gamma_\pi \cap U \). By our construction,

\[
\tau = \alpha \circ \tilde{\tau} \circ \beta
\]

for two bijections, \( \alpha : [k] \to \mathcal{O}_U \) and \( \beta : \mathcal{O}_U \to [k] \), which are determined by \( \Gamma_\pi \cap U \). Explicitly, this follows by viewing \( \tau : \mathcal{O}_U \to [k] \) as the composition of 5 maps:

\[
\mathcal{O}_U \xrightarrow{\text{head}} \text{head}(\mathcal{O}_U) \xrightarrow{\text{monotone}} [k] \xrightarrow{\tilde{\tau}} [k] \xrightarrow{\text{monotone}} \text{tail}(\mathcal{O}_U) \xrightarrow{\text{tail}^{-1}} \mathcal{O}_U,
\]

where \( A \xrightarrow{\text{monotone}} B \) stands for the unique monotone increasing bijection from \( A \) to \( B \), provided that \( A \) and \( B \) are subsets of \( \mathbb{N} \) of the same size.

It thus suffices to couple \( \tilde{\tau} \) with a permutation \( \tilde{\sigma} : [k] \to [k] \) in a way that

\[
P[\tilde{\tau} \neq \tilde{\sigma} \mid k \geq 1] \to 0 \quad \text{as } n \to \infty
\]

and, conditioned on \( \Gamma_\pi \cap U \), \( \tilde{\sigma} \) has the uniform distribution on \( \mathbb{S}_k \), as we may then take \( \sigma := \alpha \circ \tilde{\sigma} \circ \beta \).

By Lemma 3.15 conditioned on \( \Gamma_\pi \cap U \), we have that \( \tilde{\tau} \sim \mu_{k,q} \). Hence the following claim suffices to finish the proof, using our assumption (75) and the fact that \( k \leq m \).

Claim 4.12. Let \( k \in \mathbb{N} \), \( 0 < q \leq 1 \) and \( \rho \sim \mu_{k,q} \). Then \( \rho \) may be coupled with a uniform random permutation \( \lambda \) in \( \mathbb{S}_k \) such that

\[
P[\rho \neq \lambda] \leq 1 - q^{k^2}.
\]

Proof. We recall (see, e.g., [19, Proposition 4.7]) that the total variation distance of two probability distributions \( \mu \) and \( \nu \) on a finite set \( S \) is given by

\[
\text{TV}(\mu, \nu) := \frac{1}{2} \sum_{s \in S} |\mu[s] - \nu[s]| = 1 - \sum_{s \in S} \min\{\mu[s], \nu[s]\},
\]

and that there exists a coupling of the two distributions, i.e., random variables \( X, Y \) with \( X \) distributed \( \mu \) and \( Y \) distributed \( \nu \), so that \( P[X \neq Y] = \text{TV}(\mu, \nu) \) (and, moreover, there is no coupling achieving a smaller value for \( P[X \neq Y] \)). Thus it suffices to show that the total variation distance of \( \mu_{k,q} \) and the uniform distribution on \( \mathbb{S}_k \) is at most \( 1 - q^{k^2} \).

Let \( Z_{k,q} \) be as in the definition (1) of the Mallows permutation and note that \( Z_{k,q} \leq k! \). Since \( \text{inv}(\sigma) \leq k^2 \) for all \( \sigma \in \mathbb{S}_k \), we obtain from (1) that \( \mu_{k,q}[\sigma] \geq \frac{q^2}{k^2} \) for all \( \sigma \in \mathbb{S}_k \). Thus the required total variation distance is at most \( 1 - \sum_{\sigma \in \mathbb{S}_k} \min\{\frac{q^2}{k^2}, \frac{1}{k!}\} = 1 - q^{k^2} \). \( \square \)

Proof of part (i) of Lemma 4.11. The claim is derived from the following proposition regarding diagonal arcs.

Proposition 4.13. For \( 1 \leq s \leq r \leq n \) one has

\[
\mathbb{E}[\{1 \leq i \leq r \mid \text{arc}^s_i \text{ is closed}\}] \leq 1 + (1 - q)^2 \cdot n^2 + \frac{1}{n-r+1} \cdot n,
\]

(78)

\[
\mathbb{E}[\text{arc}^s_i] \leq 1 + (1 - q)^2 \cdot n^2 + \frac{1}{n-r+1} \cdot n.
\]

(79)
Since each open arc of $A_{n-m}$ extends to an arc of $O_U$, inequality (78), applied with $r = n - m$, implies the second limit in (77) by our assumptions that $m$ tends to infinity with $n$ and that (74) and (75) hold.

To derive the first limit in (77) we use the following general claim.

Claim 4.14. Let $I$ be a non-empty finite set. Let $A_1, \ldots, A_k$, where $k \in \mathbb{N}$ is random, be pairwise disjoint random subsets of $I$ with union $I$. For $i \in I$ let $\ell_i$ be the size of the $A_j$ to which $i$ belongs. Then

$$\left( \frac{1}{|I|} \mathbb{E} \max_{i \in I} \ell_i \right)^3 \leq \frac{1}{|I|} \max_{i \in I} \mathbb{E} \ell_i.$$ 

Now, inequality (79) yields that $\frac{1}{n} \mathbb{E} |\text{arc}^{n-m}_s| \to 0$ uniformly over all $s \in [n-m]$ by our assumptions that $m$ tends to infinity with $n$ and that (74) and (75) hold. Claim 4.14 applied with $I = [n-m]$ and $A_1, \ldots, A_k$ being the diagonal arcs of $A_{n-m}$, allows one to deduce that in fact

$$\frac{1}{n} \mathbb{E} \left[ \max_{a \in A_{n-m}} |a| \right] = \frac{1}{n} \mathbb{E} \left[ \max_{s \in [n-m]} |\text{arc}^{n-m}_s| \right] \to 0. \quad (80)$$

Since restricting an arc of $O_U$ to $[n-m]$ yields an open arc of $A_{n-m}$ which is shorter by at most $m$ elements, the first limit in (77) follows from (80) using our assumption that $\frac{m}{n} \to 0$.

Proof of Claim 4.14. Set $L = \max_{i \in I} \ell_i$ and $\alpha := \frac{1}{|I|} \mathbb{E} [L]$. Due to $0 \leq L \leq |I|$, Markov’s inequality, for $|I| - L$, implies that

$$\mathbb{P}[L \geq \frac{1}{2} \alpha |I|] \geq \alpha. \quad (81)$$

The sum of the $\ell_i$ satisfies

$$\sum_{i \in I} \ell_i \geq \mathbb{1}\{L \geq \frac{1}{2} \alpha |I|\} \cdot \sum_{i \in I} \ell_i \geq \frac{\alpha^2 |I|^2}{4} \cdot \mathbb{1}\{L \geq \frac{1}{2} \alpha |I|\}. \quad (82)$$

The second inequality is due to the fact that on the event $\{L \geq \frac{1}{2} \alpha |I|\}$ there are at least $\frac{1}{2} \alpha |I|$ values of $i \in I$ for which $\ell_i \geq \frac{1}{2} \alpha |I|$. By taking expectation in (82) and substituting (81) we obtain

$$|I| \cdot \max_{i \in I} \mathbb{E}[\ell_i] \geq \sum_{i \in I} \mathbb{E}[\ell_i] \geq \frac{\alpha^2 |I|^2}{4} \mathbb{P}[L \geq \frac{1}{2} \alpha |I|] \geq \alpha^3 |I|^2. \quad \Box$$

Proof of Proposition 4.13. Fix $s, r$ satisfying $1 \leq s \leq r \leq n$. Define

$$M_t := |\{1 \leq i \leq t \mid \text{arc}^t_i \text{ is closed}\}| \quad \text{and for } t \geq s \text{ let } N_t := |\text{arc}^t_s|. \quad \text{Our intention is to provide bounds for } \mathbb{E}[N_s], \mathbb{E}[N_{t+1} - N_t] \text{ and } \mathbb{E}[M_{t+1} - M_t], \text{ and to derive the proposition from these bounds. Observe that}

$$N_s = 1 + \sum_{a \in O_{s-1}} |a| \cdot \mathbb{1}\{\begin{array}{ll} \pi_s = \text{tail}(a) & \text{or} \\
\pi_{s-1} = \text{head}(a) & \end{array}\} ,$$

41
as arc consists of and up to two arcs of that have merged with via either their head or their tail. In light of this equality, Lemma 4.4 and the fact that \( \sum_{a \in O_{s-1}} |a| \leq n \) imply the following bound,

\[
E[N_s] \lesssim 1 + n \cdot \frac{1 - q}{1 - q^{n-s+1}}.
\] (83)

To bound \( N_{t+1} - N_t \) and \( M_{t+1} - M_t \) we define the events

\[
\mathcal{M}_{t+1}(a, b) := \left\{ \begin{array}{l}
\pi_{t+1} = \text{tail}(a) \text{ or } \\
\pi_{t+1} = \text{head}(b)
\end{array} \right\} \bigcup \left\{ \begin{array}{l}
\pi_{t+1} = \text{tail}(a) \\
\pi_{t+1} = \text{head}(b)
\end{array} \right\}, \quad a, b \in O_t,
\]

denoting the merging of \( a \) and \( b \) when the two arcs are distinct and the closure of \( a \) when they are equal. Note that \( \mathbb{P}_t[\mathcal{M}_{t+1}(a, b)] \leq (\frac{1-q}{1-q^{n-t}})^2 \) for all \( a, b \in O_t \), as Lemma 4.1 implies.

Observe that for \( t \geq s \) one has \( N_{t+1} - N_t = 0 \) if \( \text{arc}_t^s \) is closed and otherwise one has

\[
N_{t+1} - N_t = 1 \left\{ \begin{array}{l}
\pi_{t+1} = \text{tail}(\text{arc}_t^s) \text{ or } \\
\pi_{t+1} = \text{head}(\text{arc}_t^s)
\end{array} \right\} + \sum_{a \in O_t \setminus \{\text{arc}_t^s\}} |a| \cdot I_{\mathcal{M}_{t+1}(a, \text{arc}_t^s)} \quad \text{on } \{\text{arc}_t^s \in O_t\},
\]

as \( N_{t+1} - N_t > 0 \) only when \( \{t+1\} \) has merged with \( \text{arc}_t^s \), in which case \( N_{t+1} - N_t = |a| + 1 \) if \( \{t+1\} \) has also merged with another arc \( a \in O_t \setminus \{\text{arc}_t^s\} \) and otherwise \( N_{t+1} - N_t = 1 \).

For the difference \( M_{t+1} - M_t \), observe that

\[
M_{t+1} - M_t = I \{ t + 1 = \pi_{t+1} \} + \sum_{a \in O_t} (|a| + 1) \cdot I_{\mathcal{M}_{t+1}(a, a)}
\]

\[
= I \{ t + 1 = \max(G_{t+1}) \} + \sum_{a \in O_t} |a| \cdot I_{\mathcal{M}_{t+1}(a, a)},
\]

as \( M_{t+1} - M_t > 0 \) only when \( t + 1 \) closes a cycle, in which case \( M_{t+1} - M_t = |a| + 1 \) when \( t + 1 \) closes the arc \( a \in O_t \) and \( M_{t+1} - M_t = 1 \) when \( t + 1 \) forms a fixed point.

Note that \( \sum_{a \in O_t} |a| \leq n \) and apply Lemma 4.1 and Proposition 4.2 to the above formulas for \( N_{t+1} - N_t \) and \( M_{t+1} - M_t \) to obtain

\[
E[M_{t+1} - M_t] \lesssim \frac{1 - q}{1 - q^{n-t}} + n \cdot \frac{(1 - q)^2}{(1 - q^{n-t})^2} \quad \text{for } t \geq 0,
\] (84)

\[
E[N_{t+1} - N_t] \lesssim \frac{1 - q}{1 - q^{n-t}} + n \cdot \frac{(1 - q)^2}{(1 - q^{n-t})^2} \quad \text{for } t \geq s.
\] (85)

By using the bounds (83), (84) and (85) one may show that both \( E[N_t] \) and \( E[M_t] \) are bounded, up to multiplication by a positive absolute constant, by

\[
1 + n \cdot \frac{1 - q}{1 - q^{n-t+1}} + \sum_{t=0}^{r-1} \frac{1 - q}{1 - q^{n-t}} + n \cdot \sum_{t=0}^{r-1} \frac{(1 - q)^2}{(1 - q^{n-t})^2},
\]

The bounds (78) and (79) follow by using (54). □
Limiting Distribution of $\frac{1}{n}|C_{s_n}|$: Our proof of the fact that $\frac{1}{n}|C_{s_n}|$ converges in distribution to $U[0,1]$, the uniform distribution on $[0,1]$, is very similar to our proof of the Poisson-Dirichlet limit law. Therefore, let us only elaborate on the main differences.

The proof is based on the following simple fact: For $k \in \mathbb{N}$ let $\rho \in S_k$ be a uniformly random permutation and let $i_k \in [k]$ be arbitrary. Then,

$$\frac{1}{k}|C_{i_k}(\rho)| \to U[0,1] \text{ in distribution as } k \to \infty.$$  \hspace{1cm} (86)

We use the same notation as in the proof of the Poisson-Dirichlet limit law, e.g., $\sigma$ is the random permutation over $O_U$ from part (ii) of Lemma 4.11. For $a \in O_U$ we denote by $C_a(\sigma)$ the orbit of $\sigma$ and similarly with $\tau$.

Let $a$ be the arc of $A_U$ that contains $s_n$. We first claim that

$$\mathbb{P}[a \in O_U] \to 1 \text{ as } n \to \infty.$$  \hspace{1cm} (87)

Indeed, this is a consequence of Corollary 4.4 used with the reversal symmetry (10) if $s_n > n-m$, and our assumptions that $m$ tends to infinity with $n$ and that (74) and (75) hold.

In addition, we recall that $|O_U| \to \infty$ in probability as $n \to \infty$ as a consequence of (77). Now, the limits (86) and (87) and the fact that, given $|O_U|$, the distribution of $\sigma$ is uniform imply that

$$\frac{1}{|O_U|}|C_a(\sigma)| \to U[0,1] \text{ in distribution as } n \to \infty,$$

where it is understood that in the case when $a \notin O_U$ we set $\frac{1}{|O_U|}|C_a(\sigma)| := 0$. It thus suffices to show that

$$\left|\frac{1}{n}|C_{s_n}(\pi)| - \frac{1}{|O_U|}|C_a(\sigma)|\right| \to 0 \text{ in probability as } n \to \infty.$$

To see this, we write, similarly as in the proof of the Poisson-Dirichlet limit law, interpreting $C_a(\tau)$ and $C_a(\sigma)$ as empty when $a \notin O_U$,

$$\left|\frac{1}{n}|C_{s_n}(\pi)| - \frac{1}{|O_U|}|C_a(\sigma)|\right| \leq \left|\frac{1}{n}|C_{s_n}(\pi)| - \sum_{b \in C_a(\tau)} \frac{|b|}{n}\right| + \left|\sum_{b \in C_a(\tau)} \frac{|b|}{n} - \sum_{b \in C_a(\sigma)} \frac{|b|}{n}\right| + \left|\sum_{b \in C_a(\sigma)} \frac{|b|}{n} - \frac{1}{|O_U|}|C_a(\sigma)|\right|.$$

The first of the terms on the right-hand side is small, in probability, due to (87). The second term is small by part (ii) of Lemma 4.11. The last term can be bounded in a similar manner as in the proof of Proposition 4.10 and shown to be small by part (i) of Lemma 4.11

5 Discussion and Open Questions

In this work we study the Mallows model for random permutations, providing estimates for the typical length and diameter of cycles. We observe that macroscopic cycles emerge in the parameter range $\frac{1}{(1-q)^2} \gg n$. In this regime we prove further that the joint
distribution of the lengths of long cycles in the permutation converges to the Poisson-Dirichlet distribution. In this section we discuss several further questions on the Mallows model as well as questions pertaining to other related models of random permutations.

The limiting distributions of the cycle length and cycle diameter. Let $\pi$ have the Mallows distribution with parameters $n$ and $q$. Recall that $C_s$ stands for the cycle in $\pi$ containing the point $1 \leq s \leq n$, so that $|C_s|$ and $\max(C_s) - \min(C_s)$ are the length and diameter of $C_s$ respectively. What can be said about the limiting distributions of these quantities when $q \to 1$ and $n \to \infty$? To avoid boundary effects, we restrict to the case that there is some $\alpha \in (0, 1)$ for which $s_n = s_n/n$ satisfies $s_n/n \to \alpha$. We consider three cases.

Macroscopic cycles: Suppose that $n(1 - q)^2 \to 0$. In this regime, as shown in Theorem 1.2, the normalized cycle length $\frac{1}{n} |C_s|$ converges in distribution to the uniform distribution on $[0, 1]$. Figures 2b and 6b suggest that, in fact, a stronger convergence takes place. For any sequence $1 \leq k_n \leq n$ bounded away from 1 and $n$ in a suitable manner, one has $P[|C_s| = k_n] \cdot n \to 1$.

Using Corollary 4.4, it may additionally be shown that the cycle spans the full interval, in the sense of the following convergence in distribution,

$$\frac{\min(C_s)}{n} \to 0 \quad \text{and} \quad \frac{\max(C_s)}{n} \to 1.$$  

Microscopic cycles: Suppose that $n(1 - q)^2 \to \infty$. It appears from simulations (see Figures 2 and 6) that the limiting distribution of the normalized cycle length $(1 - q)^2 |C_s|$ exists in this regime, but it is unclear what its form is. This limiting distribution, if it indeed exists, cannot be concentrated on a single point due to the lower bound on the variance of $(1 - q)^2 |C_s|$ given in Theorem 1.3, used together with the bounds in Proposition 4.6 and Theorem 3.6.

The normalized cycle diameter $(1 - q)^2 (\max(C_s) - \min(C_s))$ seems simpler to analyze. Our results imply that there exist absolute constants $0 < c_1 \leq c_2 < \infty$ such that for any fixed $x \geq 0$,

$$\lim \inf P[(1 - q)^2 (\max(C_s) - s) \geq x] \geq e^{-c_2 x},$$

$$\lim \sup P[(1 - q)^2 (\max(C_s) - s) \geq x] \leq e^{-c_1 x}.$$  

The lower bound follows from Corollary 4.4 and the upper bound follows by again considering Proposition 4.6 together with Theorem 3.6. We conjecture that, in fact, there exists a single absolute constant $c > 0$ for which

$$\lim P[(1 - q)^2 (\max(C_s) - s) \geq x] = e^{-cx}, \quad x \geq 0.$$  

That is, that the limiting distribution of $(1 - q)^2 (\max(C_s) - s)$ is exponential. By symmetry, the same is conjectured for $(1 - q)^2 (s - \min(C_s))$. Furthermore, we conjecture that the dependence between $\max(C_s)$ and $\min(C_s)$ disappears in this limit, so that the diameter $(1 - q)^2 (\max(C_s) - \min(C_s))$ converges in distribution to the sum of two independent, identically distributed, exponential random variables.

Intermediate regime: Suppose that $n(1 - q)^2 \to \beta \in (0, \infty)$. We expect the limiting distributions to still exist in this regime and interpolate in a continuous manner the
previous two cases. For the cycle diameter, this interpolation may possibly be achieved by truncation, as certainly \( \max(C_s) - s \leq n - s \). Recalling that \( \frac{1}{n} \to \alpha \), we conjecture, for instance, that the limiting distribution of \( (1 - q)^2(\max(C_s) - s) \) is equal to that of \( \min\{X, \beta(1 - \alpha)\} \) where \( X \) is the exponential random variable conjectured to give the limiting distribution in the previous regime.

\[ \text{Figure 6: Distribution of the length of the cycle containing a uniform random point. Obtained empirically with 1000000 samples.} \]

**Extensions of the parameter range.** As discussed in the introduction, there exist extensions of the Mallows distribution to infinite permutations; one-to-one and onto functions \( \pi: N \to N \) or \( \pi: Z \to Z \). We expect the analogues of our main theorems regarding the expected length, variance of the length and expected diameter of cycles, Theorem 1.1, Theorem 1.3 and equation \( (3) \) of Theorem 1.4 to continue to hold for these models, plugging formally \( n = \infty \) and taking \( s \in N \) or \( s \in Z \) according to the case. Such results may follow from our methods, using the sampling mechanism described in Section 3.5 for the case \( \pi: Z \to Z \), but we do not develop this further. The approximation theorems of Gnedin and Olshanski [14, Section 7.2] may also prove useful in this context.

The Mallows distribution with parameters \( n \) and \( q \) is defined for the case that \( q > 1 \) via the same formula (1). The distributions with parameters \( q \) and \( \frac{1}{q} \) are related: If \( \pi \sim \mu_{n,q} \) then \( \pi \circ r \), with \( r_s = n - s + 1 \), is distributed \( \mu_{n,1/q} \). This operation corresponds to reflecting the graph of the permutation \( \pi \) across the line \( x = \frac{n+1}{2} \). Cycles are significantly affected by this operation as, when \( \pi \sim \mu_{n,q} \) with \( q > 1 \), \( \pi_i \) typically lies around \( n + 1 - i \), as follows from (2) and the above relation. Thus, for instance, the diameter of the cycle containing 1 in \( \pi \) may be close to \( n \) for all \( q > 1 \). Still, we would expect that for all \( q > 1 \) the expected cycle lengths are still of order \( \min\left\{\frac{1}{(1-1/q)^2}, n\right\} \) as in Theorem 1.1 and further expect a Poisson-Dirichlet limit law for the long cycles when \( n \to \infty \), \( q \to 1+ \) and \( n(q-1)^2 \to 0 \) as in Theorem 1.2. This is suggested by the fact that composing \( \pi \) with itself leads to a permutation whose graph is qualitatively similar to that of the Mallows model with \( q < 1 \), see Figure 7.

Our study of the cycle lengths of the Mallows permutation with parameter \( q < 1 \) was based on the diagonal exposure process. Possibly, a similar process may be used to study
Figure 7: On the left is a graph of a sample of the Mallows distribution $\mu_{n,q}$ with $n = 1000$ and $q = 1.02$. On the right is the graph of the composition of the same permutation with itself. The red lines are at vertical distance $\frac{2}{1-q}$ (left) and $\frac{2\sqrt{2}}{1-q}$ (right) from the diagonal. They delimit a region containing most of the points of the permutation.

the case $q > 1$ by exposing the graph of the permutation ‘from the center outwards’. That is, exposing after $t$ iterations the portion of the graph contained in a square of side length $2t$ around the mid-point $\left(\frac{n+1}{2}, \frac{n+1}{2}\right)$. The ideas in Section 3.5 may be useful in making such an approach rigorous.

**Band models.** We expect analogues of our results to hold for other natural models of random permutations whose graph typically has a ‘band structure’. For instance, for the interchange model on the one-dimensional graph $\{1, \ldots, n\}$ with nearest-neighbor edges. In this case, as briefly discussed in Section 1.2.4, the analogous result for the expected cycle length has been proved by Kozma and Sidoravicius. Another natural model is the band-Poisson model. Here, for an integer $n \geq 1$ and real $0 < w \leq n$, one considers a Poisson point process with intensity $\frac{1}{w}$ in the continuous band given by

$$\{(x, y) \in [0, n]^2 \mid |x - y| \leq w\},$$

where the parameter $w$ controls the width of the band. With this definition, each vertical strip of width 1 in $[0, n]^2$ contains on average a constant number of points. Each realization of the process gives rise to a permutation by taking the relative order of the points as in (39). We expect the analogues of our results to hold for this model with $w$ standing for $\frac{q}{1-q}$.

**Higher dimensions and general graphs.** As discussed in Section 1.2.4, the study of cycles of spatial random permutations, random permutations biased towards the identity in an underlying geometry, is of great interest. The special case in which the geometry is that of $\mathbb{R}^d$ or $\mathbb{Z}^d$ is particularly significant with relations to models of statistical physics. In this context, our work pertains to the case $d = 1$. With other geometries in mind, we note here that a Mallows model may be defined on any finite connected graph $G = (V, E)$ and parameter $0 < q \leq 1$ by letting the probability of a permutation $\pi : V \to V$ be given by

$$\mathbb{P}_{G,q}[\pi] = \frac{1}{Z_{G,q}} q^{d(\pi, \text{Id})},$$

46
where $Z_{G,q}$ is a normalization constant and $d(\pi, \text{Id})$ stands for the minimal number of adjacent transpositions required to change $\pi$ to the identity permutation $\text{Id}$: $v \mapsto v$. Here, an adjacent transposition is a transposition of the endpoints of an edge of $G$. For instance, any transposition is allowed on the complete graph on $n$ vertices $K_n$, whence the model coincides with the well-studied Ewens model \cite{11}, with parameter $\theta = \frac{1}{q}$. This follows from the fact that $$p_{K_n,q}[\pi] = \frac{q^n}{Z_{K_n,q}}q^{-N(\pi)}$$ with $N(\pi)$ denoting the number of cycles (including fixed points) in $\pi$. Our analysis of the Mallows model is based on the exact sampling algorithm given by \cite{6}. Unfortunately, we are not aware of corresponding algorithms for general graphs (though in the specific case of the Ewens model an algorithm is given by the so-called Chinese restaurant process). Nonetheless, it is of interest to obtain results on the length of long cycles for general graphs $G$, with the case that $G$ is a box in $\mathbb{Z}^d$, $d \geq 2$, having special significance.

Acknowledgment. We thank Nayantara Bhatnagar, Gady Kozma, Grigori Olshanski and Sasha Sodin for useful discussions. We are also grateful to an anonymous referee for a detailed reading of the paper and many excellent comments which contributed significantly to the presentation.
