ABSTRACT: We discuss numerically the non-perturbative effects in exponential random graphs which are analogue of eigenvalue instantons in matrix models. The phase structure of exponential random graphs with chemical potential for 4-cycles $\mu_4$ and degree preserving constraint is clarified. The first order phase transition at critical value of chemical potential for 4-cycles $\mu^{RRG}_4$ into bipartite phase with a formation of fixed number of bipartite clusters is found for ensemble of random regular graphs (RRG). We consider the similar phase transition in combinatorial quantum gravity based of the Ollivier graph curvature for RRG supplemented with hard-core constraint and show that a order of a phase transition at $\mu^{RRG}_4$ and the structure of emerging phase depend on a vertex degree $d$ in RRG. For $d = 3$ the bipartite closed ribbon emerges at $\mu_4 > \mu^{RRG}_4$ while for $d > 3$ the ensemble of isolated or weakly interacting hypercubes supplemented with the bipartite closed ribbon gets emerged at the first order phase transition with a clear-cut hysteresis. If the additional connectedness condition is imposed the phase at $\mu_4 > \mu^{RRG}_4$ gets identified as the closed chain of weakly coupled hypercubes. Since the ground state of isolated hypercube is the thermofield double (TFD) we suggest that the dual holographic picture involves multiboundary wormholes. Treating RRG as a model of a Hilbert space for a interacting many-body system we discuss the patterns of the Hilbert space fragmentation at the phase transition. We also briefly comment on a possible relation of the found phase transition to the problem of holographic interpretation of a partial deconfinement transition in the gauge theories.

1 Corresponding author.
1 Introduction

Matrix models play a prominent role in a description of chaotic systems with large number degrees of freedom. They govern, for instance, a spectrum of a chaotic system, the space-time dynamics of some microscopic degrees of freedom, discretization of the Riemann surfaces or their moduli spaces [1]. The different ensembles of random matrices correspond to systems with particular symmetry patterns. Spectral density, spectral correlators and level spacing distribution are among the most popular characteristics within the matrix model approach.

Large N matrix models enjoy the non-perturbative phenomena - eigenvalue instantons which are suppressed as \( \exp(-N) \) [2, 3]. The partition function for some matrix ensemble reads as

\[
Z(t_2, t_3 \ldots t_n) = \int dM \exp(-\sum_k^n t_k \text{Tr}M^k)
\]  

(1.1)

where the effective potential for the eigenvalues in the integration measure generically has several extrema. In the eigenvalue matrix model the ground state is determined by the distribution of eigenvalues of \( M \) among extrema of effective potential which depends on the variables \( t_k \). If the term \( t_2 \) dominates the eigenvalues typically are collected at one extremum and the eigenvalue instanton corresponds to the traveling of the single eigenvalue from this extremum to another one. The initial symmetry like \( SU(n) \) is broken down to some subgroup if multiple eigenvalue instantons are taken into account. Such symmetry breaking effects are important at the phase transitions at some critical values of \( t_k \) in the matrix models with different matrix measures. From the physical viewpoint eigenvalue
instantons correspond to baby-universe in 2d gravity, domain walls in SYM theory or ZZ branes in Liouville theory. The review of the different manifestations of eigenvalue instantons can be found in [4, 5].

Exponential random graphs are statistical models with the partition function

\[ Z(\mu_2, \mu_3, \ldots, \mu_n) = \sum_{\text{graphs}} \exp(-\sum_k \mu_k \text{Tr}A^k) \]

where \( A \) is a graph adjacency matrix and the summation runs over some ensemble, say, over Erdős-Rényi(ER) ensemble which involves the potential \( \text{Tr}A^2 \) and is the network analogue of Gaussian matrix model. The sum over ensembles of graphs substitutes the integration over matrix ensembles in matrix models. The terms \( \mu_k \text{Tr}A^k \) in the measure are similar to \( t_k \text{Tr}M^k \) terms in the measure of matrix models and \( \mu_k \) provide chemical potentials for number of higher k-cycles in the particular realization. One can consider the dependence of partition function on the chemical potentials and look for the phase transitions caused by condensation of some motifs which are marked by the order parameters \( <\text{Tr}A^k> \neq 0 \) [6–17]. The condensation of links, nodes, triangles has been considered and these phase transitions are analogues of the familiar criticalities in the conventional matrix models. It was shown that the phase transitions are sensitive to the finite-size effects [10, 17, 18] and the details of the emerging phases are \( N \)-dependent in several cases.

The additional local constraint imposing strict degree conservation yields the additional flavor for the condensation phenomena [11, 16, 17](see also [19, 20] for some earlier observations). It is in this case the eigenvalue instantons enter the game. It turns out that degree conservation constraint amounts to the first order phase transition with formation of the multiple weakly interacting clusters which has been demonstrated for constrained ER and RRG with Hamiltonian involving \( \mu_3 \neq 0 \) [11]. The local degree conservation constraint in the graph ensemble has a matrix model counterpart as well, it means that non-singlet sector of a matrix model now matters.

The phase transition can be effectively analyzed in terms of network spectrum. In the ER model with local constraint and RRG the formation of network cluster corresponds exactly to the single eigenvalue instanton. Eigenvalue instantons upon the averaging over ensemble form the new non-perturbative soft band in the spectrum of the graph Laplacian. The similar effects take place in a spectral density of a matrix model upon the account of multiple instantons. Soft “cluster” band is separated with the gap from the perturbative part of the spectrum. The number of instantons equals to the number of clusters. Moreover, the spectrum of the perturbative band gets deformed at the phase transition and acquires the triangular shape [11] typical for scale-free graphs due to the intercluster interactions.

Following parallels with the matrix models the exponential random graphs have been also used as the model for the discrete approximation to quantum gravity in [23]. This approach based on the Ollivier graph curvature was nicknamed as combinatorial quantum gravity. The graph Ollivier curvature [21, 22] gets reduced to the Ricci curvature in the continuum limit for the large family of graph ensembles [26] including RRG therefore the Einstein-Hilbert action can be recovered. The dimension of emerging Einstein-Hilbert action \( D \) is defined by the degree \( d \) in RRG and \( \mu_4 \) upon proper rescaling plays a role.
of the gravitational coupling. It was claimed in [23, 25] that such model undergoes the second order phase transition into the dense phase at some $\mu_4$ without a cluster formation. The $d = 3$ example has been investigated in [24] and the emerging $S^1$ geometry has been identified.

Another popular application of RRG concerns its role as a toy model for the Hilbert space of interacting many-body system. The RRG mimics the realization of the Hilbert space as the Fock space. It was suggested in [38] that one-particle localization in the Fock space is related to the localization in the interacting many-body system. It was argued in [39, 40] that indeed localization (MBL) in the interacting many-body system can be mapped to the problem of one-particle localization in the Fock space with flat diagonal disorder. In [41] we have treated the one-particle problem in the Fock space without the diagonal disorder but with the structural disorder induced by chemical potential for 3-cycles. It was found that above the phase transition the states in the non-perturbative band get localized while all states in the perturbative band are delocalized. More recently RRG with diagonal disorder has been analyzed in [42–47], moreover the arguments have been presented that RRG plays the role of tricritical point in the space of deformations [47].

In this paper we investigate numerically the effects of eigenvalue instantons in the graph ensembles with degree conservation. Three graph ensembles are considered: i) RRG ensemble; ii) RRG + hard-core constraint; iii) RRG + hard-core constraint + connectedness constraint. First we consider numerically RRG perturbed by chemical potential $\mu_4$ for 4-cycles. It is found that at $\mu_4^{RRG}$ the network gets clusterized however in contrast to the case of 3-cycles all clusters are bipartite. Then we elaborate the model with the additional hard-core constraint for a possible touching of neighbor 4-cycles in RRG suggested in [23] which we denote as cRRG. The nature of the phase transition in cRRG and the dependence on initial configurations is investigated. We find the first order phase transition in cRRG and check the clear-cut hysteresis which confirms the order of phase transition for $d > 3$. A bit surprisingly it turned out that almost all emerging bipartite clusters are isolated or weakly interacting hypercubes while the second ingredient of the emerging clustered phase for all numerically available degrees is the composite bipartite closed ribbon. The number of nodes involved into the closed ribbon depends on $\mu_4$. Our finding contradicts the claim in [23–25] about the order of the phase transition for $d > 3$ and about the structure of emerging phase.

Finally we introduce the second constraint for cRRG assuming the connectedness of the graph and obtain the closed chain of the weakly connected hypercubes at $\mu_4 > \mu_4^{cRRG}$. We reproduce the result of [24] for $d = 3$ that at $\mu_4 > \mu_4^{cRRG}$ the single composite bipartite closed ribbon emerges. However for $d > 3$ we clearly demonstrate that the clustering into hypercubes exists contrary to the claim in [23–25].

The hypercube phase provides the interesting insight on the possible dual holographic picture. Indeed it was noted in [27] that the hypercube adjacency matrix exactly coincides with the interaction term in the Maldacena-Qi model of two coupled SYK models [28]. Hence for a single hypercube we deal with the strong coupling limit of the Maldacena-Qi model which has thermofield double state (TFD) as the ground state [27, 29]. On the other
hand the TFD is holographically dual to the eternal black hole \cite{30}. The eternal black hole was considered as the simple example of the "geometry from entanglement" approach \cite{31} when the dual classical geometry emerges from the entanglement of states of the boundary theory. Here we have the highly entangled Majorana dimers which correspond to the ground state of individual hypercube.

At strong coupling phase we obtain the ensemble of hypercubes which can be completely isolated or weakly interacting. In the holographic picture it fits with the recent discussion \cite{33, 34} of the holography for the ensemble of theories at multiple bulk boundaries. If the components do not interact the corresponding holographic geometry is assumed to be multiboundary non-traversable wormhole \cite{32} which becomes traversable if the interaction between the components is added. The multiple Majorana dimers were also used recently for the toy model for holographic quantum error-correcting codes \cite{36}.

We shall also make a brief discussion concerning the possible application of our findings for two more problems. In the dimensionally reduced SYM theory down to matrix quantum mechanics the clusterization of the matrices into the block diagonal form corresponds to the partial breaking of the $SU(N)$ gauge symmetry down to $SU(M)^k$ symmetry \cite{48, 52}. We shall compare our findings in RRG with this interpretation. On the other hand this partial breaking of the gauge symmetry presumably corresponds \cite{52} to the transforming of a graviton gas into small black holes. We shall also speculate on the relevance of the eigenvalue instantons for the partial deconfinement phenomena. Secondly we make some comments on the possible interpretation of the emerging new objects—hypercubes and composite bipartite ribbons in the context of Fock space picture for Hilbert space of interacting many-body system. The phase transition provides the different patterns for the fragmentation of the Hilbert space.

The paper is organized as follows. In Section 2 we present the results of numerical study of RRG perturbed by chemical potential for 4-cycles and supplemented with the different constraints. In Section 3 the arguments concerning the holographic interpretation of the strong coupling phase are presented. Section 4 is devoted to the aspects of Fock space realization of the Hilbert space of many-body system in terms of RRG. The phase transition is considered as a fragmentation of the Hilbert space. The results and the open questions are collected in Section 5.

2 Phase transitions in perturbed random regular graphs

2.1 The model description

Similar to discussion in \cite{11} suppose that we start with some network and rewire links under the condition that at each step of rewiring we try to maximize the number of 4-cycles $N_4$. Which is the equilibrium structure of the entire network? In mathematical terms this question reads as follows. We assign the chemical potential $\mu_4$ to each 4-cycle and consider the partition function

\[ Z(\mu_4) = \sum_{\{\text{states}\}} e^{-\mu_4 N_4} \]  

(2.1)
where prime in (2.1) means that the summation runs over all possible configurations of 
links ("states"), under the condition of fixed degrees \(\{v_1, ..., v_N\}\) in all network vertices.

To simulate the rewiring process, one applies the standard Metropolis algorithm with 
the following rules: i) if under the reconnection the number of 4-cycles is increasing, a 
move (rewiring) is accepted, ii) if the number of 4-cycles is decreasing by \(\Delta N_4\), or remains 
unchanged, a move is accepted with the probability \(e^{-\mu \Delta N_4}\). The Metropolis algorithm 
runs repeatedly for large set of randomly chosen pairs of links, until it converges. In [37] 
it was proven that such Metropolis algorithm converges to the Gibbs measure \(e^{\mu N_4}\) in the 
equilibrium ensemble of random undirected ER networks with fixed vertex degree or RRG.

In [11] it has been shown that given the bond formation probability, \(p\), in the initial 
graph in constrained ER graph or in RRG, the evolving network above the critical value 
of chemical potential for triangles \(\mu_3\) splits into the maximally possible number of clusters, 
\(N_{cl}\):

\[
N_{cl} = \left\lfloor \frac{N}{Np + 1} \right\rfloor \approx \left\lfloor \frac{1}{p} \right\rfloor, 
\tag{2.2}
\]

where \([x]\) means the integer part of \(x\) and the denominator \((Np + 1)\) defines the minimal 
size of formed cliques. The asymptotic limit \(\sim [p^{-1}]\) at \(N \to \infty\) in (2.2) is independent on 
the particular set of corresponding vertex degrees, \(\{v_1, ..., v_N\}\). For RRG with degree \(d\) the 
number of clusters tends to \([N/(d+1)]\). It has been shown in [11] that clustering of evolving 
constrained Erdős-Renyi network or RRG under condition of 3-cycle maximization, occurs 
as a first order phase transition where \(\mu_3\) is a control parameter.

### 2.2 Clusterization of the perturbed RRG

Consider the RRG with degree \(d\) perturbed by the \(\mu_4\) term

\[
H = \mu_4 Tr A^4
\tag{2.3}
\]

and vary the chemical potential. At some \(\mu^{RRG}_{4,cr}\) the network gets rearranged into bipartite 
phase with the fixed number of weakly interacting clusters. The corresponding adjacency 
matrix emerged upon transition is presented at Fig. 1. All bipartite clusters are almost max-
imal and have the same size. The similar phase transition takes place for the constrained 
ER network however it that case the size of bipartite clusters has nontrivial distribution.

The spectrum of the adjacency matrix \(A\) and the Laplacian matrix \(L = D - A\) where 
\(D = diag(d_1, \ldots, d_n)\) is encoded in the spectral density defined as

\[
\rho(\lambda) = \left< \sum_i \delta(\lambda - \lambda_i) \right>_{RRG}, \quad Av_i = \lambda_i v_i
\tag{2.4}
\]

where the averaging over ensemble is assumed. The unperturbed spectral density of RRG 
obeys the Kesten-McKay distribution

\[
\rho(\lambda) = \frac{\sqrt{4(d-1)-\lambda^2}}{2\pi(d^2-\lambda^2)}
\tag{2.5}
\]

For the RRG a spectral density of the graph Laplacian coincides with the shifted 
spectral density of adjacency matrix and we can use both of them as the Hamiltonian of a
Figure 1. A. The dependence of number of 4-cycles on the chemical potential $\mu_4$ for RRG of different sizes and $d = 8$; B. Ground state and its adjacency matrix at critical $\mu_4$.

Figure 2. The dependence of the spectral density of adjacency matrix on the chemical potential $\mu_4$ for RRG of $N = 256, d = 8$. 
particle propagating on the RRG. The spectral density gets modified upon transition and
acquires the following structure. The central band corresponds to a continuum spectrum.
If there would be no intercluster interaction there would be degenerate states symmetric
with respect to the central band and degeneracy of eigenvalues would correspond to the
number of eigenvalue instantons. We can interpret these modes as the bound state of the
particle localized at the cluster. However due to the intercluster interaction we get two
non-perturbative bands instead of the degenerate bound states. For each realization pair
of isolated eigenvalues corresponding to the bipartite cluster symmetrically tunnel from
the perturbative band in the opposite directions. The evolution of spectral density of the
adjacency matrix is presented at Fig.2.

We have also considered the evolution of the spectral density for the constrained ER
network. The clusterization pattern into bipartite clusters is the same with some peculiarities. In this case the sizes of the bipartite clusters are different with some size distribution. The spectral density of graph Laplacian acquires the three-band structure with more wide
non-perturbative bands.

Note that in the spectrum of the graph Laplacian half of eigenvalues corresponding
to instantons $\lambda_{i,+}$ are the soft modes while half of eigenvalues are the hard modes $\lambda_{i,-}$. All clusters are bipartite hence there is specific interaction inside each bipartite cluster
which connects different scales corresponding to eigenvalues $\lambda_{i,-}, \lambda_{i,+}$. It provides the
entanglement of the bipartite state.

The symmetry breaking pattern at the phase transition is $SO(2N) \rightarrow (SO(\frac{N}{2}) \times
SO(\frac{N}{2}))^d$. Let us emphasize that a formation of the bipartite clusters can be observed
in the real-time during the Metropolis cooling. The formation and evolution of the cluster
occurs simultaneously with the evolution of pair of isolated eigenvalues.

2.3 RRG with hard-core constraint and combinatorial quantum gravity

Let us consider now cRRG and argue that upon the phase transition the different ground
state emerges. If only hard-core constraint is imposed the ground state involves the en-
semble of non-interacting or weakly interacting hypercubes and a separate bipartite closed
ribbon. However if additional connectedness condition is imposed the ground state will be
identified as the closed chain of weakly interacting hypercubes.

The hard-core constraint was introduced in the interesting model of combinatorial
quantum gravity suggested in [23] which is based on the combinatorial graph curvature
invented by Ollivier [21]. The Ollivier curvature is quite involved for generic graph however
it can be simplified for special types of the graph ensembles. It was suggested in [23] to
consider as the simple model for combinatorial quantum gravity the ensemble of RRG with
two additional constraints. First, the bipartiteness condition is imposed and secondly it
is assumed that two squares can have only one common link which to some extent can be
considered as the analogue of the hard-core condition for extended objects. It was shown
recently [26] that for the large class of graphs the Ollivier curvature gets reduced to the
Ricci curvature in the thermodynamic limit.

Under these conditions the density of Ollivier curvature for the cRRG acquires the
simple form

\[ R_{ij} = -\frac{1}{d}[(2d - 2) - N_4(ij)] \]  (2.6)

where \( N_4(ij) \) is the number of squares supported at the (ij) edge. Then one introduces the analogue of the Ricci scalar

\[ R = \sum_i \sum_j R(ij) \]  (2.7)

which for the cRRG ensemble gets reduced to

\[ R_{cRRG} = -\frac{8}{d}\left[\frac{d(d - 1)}{2} N - N_4\right] \]  (2.8)

where \( N_4 \) is the total number of 4-cycles.

Therefore for cRRG the partition function involving Hamiltonian \( H = \mu_4^c TrA^4 \) acquires the meaning of the combinatorial version for the action of Euclidean Einstein gravity

\[ Z_{comb} = \int dg \exp(\alpha \int \sqrt{g}R) \]  (2.9)

where the integral over the metric comes from the summation over the cRRG ensemble. The chemical potential for 4-cycles defines the gravitational coupling constant upon some rescaling

\[ \alpha \propto \mu_4 \]  (2.10)

The authors of [23–25] claimed that there is the phase transition at some \( \mu_4^{cRRG} \) which has the different nature for RRG and cRRG. The phase transition in cRRG was assumed to be the second order transition without formation of clusters. For the \( d = 3 \) the emerging phase was found to enjoy \( S_1 \) topology [24].

We have investigated numerically the phase transition for cRRG for different degrees \( d \). First of all, we have found that the first order phase transition takes place at \( \mu_4^{cRRG} \) for \( d > 3 \). We have observed a set of isolated or weakly connected \( d \)-dimensional hypercubes at \( \mu = \mu_4^{cRRG} \), the number of hypercubes can be estimated as

\[ N_{\text{cube}} = \left\lfloor \frac{N}{2^d} \right\rfloor \bigg|_{N \gg 1} \]  (2.11)

Numerical results for the number of 4-cycles are presented in Fig.3, there is a explicit hysteresis typical for phase transitions of first order. Second, we observe that if there is no enough nodes to form one more hypercube and for \( \mu_4 > \mu_4^{cRRG} \) part of nodes are organized in the closed bipartite ribbon similar to one discussed in [24]. The number of the nodes in the closed ribbon depends on \( \mu_4 \) non-trivially, see Fig.3 B. The typical configurations in clusterized cRRG for different values \( d \) and \( \mu \) are presented at Fig.4. Let us emphasize that we do not impose the bipartiteness condition for the initial configurations and bipartiteness is emerging symmetry in the clusterized phase.

Next, we impose the second connectedness constraint in cRRG and simulated cRRG with this additional restriction. We have observed the phase transition for \( d = 3 \) with the bipartite ribbon as the ground state confirming the result of [24]. However, for \( d > 3 \)
**Figure 3.** A: The number of 4-cycles in dependence on the parameter $\mu_4$ in cRRG of $d = 4$ and different size; B: The portion of the nodes in the bipartite closed ribbon in dependence on the parameter $\mu_4$.

**Figure 4.** Typical subgraph configurations in the clustered phase involving hypercubes and composite bipartite strings.
there is a clear-cut first order phase transition with the formation of the clusterized ground state. It is identified as closed chain of weakly connected hypercubes (Fig. 7) and all 4-cycles belong to hypercubes. One could wonder why the clusterization in cRRG has not been seen in [23, 25]. It seems, that the parameters of their numerics did not allow more than one hypercube hence configuration approximately looks as homogeneous.

3 Interacting Thermofield Doubles and Holographic Dual

3.1 Towards the holographic dual for hypercube phase

We have argued above that at the transition point the RRG network with hard-core constraint gets disintegrated into the ensemble of non-interacting or weakly hypercubes with additional closed bipartite ribbon. If the connectedness condition is added the emerging configuration is identified as the single bipartite ribbon for $d = 3$ and the closed chain of weakly connected hypercubes for $d > 3$. In this study we are guided by the analogy between the exponential random graphs and matrix models. Hence we could question if a
kind of holographic representation of our partition function for the graph ensemble can be developed somewhat similar to the matrix model representation of JT gravity [35, 55]. In that case the (0 + 1) boundary Euclidean quantum mechanics is presented holographically by JT gravity. More precisely the discussion in [55] suggest that the bulk gravity is dual to the ensemble of boundary theories.

Before proceeding further two remarks are in order. First, we shall try to develop the holographic picture for the clusterized phase only for cRRG and cRRG with connectedness constraint. Secondly, we are guided by the idea that quantum entanglement of the boundaries can lead to the classical geometry in the bulk [31]. The first clear-cut of such situation has been developed in [30] for the eternal black hole with two boundaries. In the Euclidean version the corresponding geometry with several boundaries is provided by the multiboundary wormholes [32]. The boundary components can be entangled via the gravitational bulk. The recent discussion concerning this scenario can be found in [33, 34]. We shall have in mind this pattern of holography in what follows.

To develop holographic interpretation we should clarify what is the meaning of hypercubes and bipartite ribbons in the gravity framework. First take a look at the hypercubes. It was noted in [27] that the hypercube adjacency matrix \( A_{\text{hyper}} \) exactly coincides with the
interaction term in the Maldacena-Qi model [28] for the near $AdS_2$ gravity.

$A_{\text{hyper}} = H_{\text{int}} = i \sum_k \gamma^L_k \gamma^R_k$ \hspace{1cm} (3.1)

The mapping is going as follows. Let consider the tensor product representation for the hypercube Hamiltonian

$H_d = \sigma_0 \otimes H_{d-1} + \sigma_1 \otimes \cdots \otimes \sigma_0$, \hspace{0.5cm} H_1 = \sigma_1.$ \hspace{1cm} (3.2)

and define the $\gamma$ matrices representing Majorana fermions as

$\gamma^L_k = \sigma_1 \otimes \cdots \otimes \sigma_1 \otimes \sigma_0 \otimes \cdots \otimes \sigma_0$, $\gamma^R_k = \sigma_1 \otimes \cdots \otimes \sigma_1 \otimes \sigma_2 \otimes \sigma_0 \otimes \cdots \otimes \sigma_0,$ \hspace{1cm} (3.3)

than the Hamiltonian can be written as

$A_{\text{hyper}} = i \sum_{k=1}^d \gamma^L_k \gamma^R_k.$ \hspace{1cm} (3.4)

Since we are looking at the RRG ensemble the spectrum of hypercube adjacency matrix which reads as

$E_n = -d + 2n, n = 0 \ldots d$ \hspace{0.5cm} \text{deg}(E_n) = C_n^d$ \hspace{1cm} (3.5)

coincides with the shifted spectrum of the hypercube graph Laplacian $L = dI - A$ where $I$ is identity matrix. Therefore the one-particle Hamiltonian of a free particle on the hypercube gets mapped into the interaction term of Maldacena-Qi Hamiltonian for the Majorana fermions.

On the other hand is was found in [27, 29] that the ground state of the Maldacena-Qi model at strong coupling limit is well approximated by the TFD at $\beta = 0$ in boundary quantum mechanics of Majorana fermions

$|TFD> = \sum_n e^{-\beta E_n}|n>_L |n>_R$ \hspace{1cm} (3.6)

At large N boundary degrees of freedom in each component of TFD are degrees of freedom forming the eternal black hole in AdS [30] in Minkowski space or wormhole in the Euclidean space. If there are several entangled components the gravity dual is the multiboundary wormhole.

Now let us turn to our proposal for the gravity dual of the clusterized phase. For cRRG we have set of non-interacting or weakly interacting hypercubes. Each hypercube corresponds to the TFD of entangled $d$ Majorana fermions. If $d$ is large it is natural to assume that each TFD yields the path in the dual geometry moreover all TDF’s are entangled yielding the geometry of non-traversable multiboundary wormhole in AdS somewhat analogously to the arguments in [33] if we have non-interacting but entangled hypercubes.

If $d$ is small we still have the TFD’s of $d$ Majorana fermions forming the Majorana dimers. It is however impossible to assume that such TDF corresponds to the fragment
of the gravity dual since it has not enough degrees of freedom. On the other hand the
total number of TDF,s is large so a kind of holography can be expected nevertheless. We
can use the arguments recently suggested in the holographic representation of the error-
correcting codes [36]. It was argued in [36] that boundary Majorana dimers through their
entanglement yield the geodesics in the bulk geometry allowing its partial restoration.
However contrary to [36] here we have TFD,s for the groups of $d$ Majorana dimers.

When the connectedness constraint is added we get the closed chain of hypercubes and
therefore the closed chain of TDF,s as ground state. However now we certainly have the
interaction between TDF,s. Following arguments from [33, 34] we conjecture that the bulk
dual is the traversable multiboundary wormhole if $d$ is large enough. At small $d$ we can
apply the similar logic based on the error-correcting codes. Here we have the interaction
between the entangled groups of Majorana dimers.

Let us complete this Section with short remark concerning the topology of the emerging
hypercube phase. The isolated $n$-hypercube enjoys the hyperoctahedral symmetry group
$C_n$ which is the wreath product of $S_2$ and $S_n$ where $S_n$ is the symmetric group of degree
$n$. It has nontrivial first and second homology groups $H_1(C_n, \mathbb{Z}) = (\mathbb{Z}/2)^2, \ n \geq 2,$
$H_2(C_n, \mathbb{Z}) = (\mathbb{Z}/2)^3, \ n \geq 4.$ This allows to look for the topologically stable closed chain
of hypercubes.

3.2 D0-branes quantum mechanics and black hole formation

Matrix models provide the framework for a formation of extended objects from ensemble of
D0 branes [53]. Above we have made the proposal concerning the holographic interpretation
of the hypercube phase of perturbed cRRG. Let us make a short comment on the somewhat
analogous situation in the holographic interpretation of a matrix model when the typical
matrix acquires the block-diagonal form.

According to holography any transition in the ground state in the boundary matrix
model gets mapped into some transition in the dual bulk theory. The transitions can
be identified via the changes of the spectral density and the corresponding form of matrix
analogously to our discussion of exponential random graphs. It was suggested in the context
of the large $N$ (1 + 1) SYM theory on the circle that the distribution of the eigenvalues
of Wilson loops plays the key role. The flat distribution holographically corresponds to a
black string while the gaped distribution corresponds to a black hole [54].

Somewhat similar classification has been used in the context of the deconfinement
phase transition [48–51]. It was argued that again there are three phases - confined, par-
tially deconfined and completely deconfined in the boundary theory. The typical matrix
corresponding to the partially deconfined phase has deconfined $M \times M$ block filled densely
which presumably corresponds to the small black hole in the dual bulk while the rest
$SU(N - M)$ sector corresponds to the black hole exterior. The entropy in this phase has
intermediate form $S = \epsilon N^2$ where $\epsilon \ll 1$. The number of blocks in the typical matrix
corresponds to the number of small black holes.

Having the holographic picture in mind we can speculate on the analogy of the phases in
the deconfinement transition with the phases in the exponential random graphs. In the ER
network enriched by 3-cycles the single dense cluster gets emerged [6] which presumably
holo hugged corne ous to the small black hole. The RRG perturbed by 3-cycles develops several interacting dense clusters [11] which presumably correspond to the several interacting small black holes similarly to [50, 51].

4 RRG as the model for a Hilbert space and localization

The RRG is now the popular model for an investigation of the localization phenomena in a interacting many-body system. It models the Hilbert space of a model and the MBL in the physical space gets mapped into one-body localization at RRG following the initial arguments suggested in [38]. The Laplacian of the graph plays the role of the Hamiltonian for the propagating degree of freedom. If the wave function of an effective one-particle system in the Fock space is close to the state of the initial many-body system, then the localization in the Fock space occurs. Hence, one can identify the localized state in the Fock space with the particle in the initial many-body system. Meanwhile, if the wave function of the effective one-particle system in the Fock space is expanded over a large number of states of the many-body system, this regime is understood as a delocalized in the Fock space. Similarly to the localization in the real space, the notion of a mobility edge can be introduced in the Fock space as well.

Technically one can analyze the ergodic properties through the fractal dimensions \(D_q\), which show the spread of a state in the Fock space or via level spacing distribution. Ergodic states at infinite temperatures are spread homogeneously over the entire Fock space hence \(D_q = 1\). Instead, non-ergodic states cover only a vanishing fraction of the Fock space, \(0 < D_q < 1\). While a localization in the Fock space requires \(D_q = 0\). Hence in terms of the Fock space the MBL transition can be identified as transition from \(D_q = 1\) in the ergodic space phase to \(D_q < 1\) in the MBL phase. Different aspects of the one-body localization on RRG with diagonal disorder have been discussed in [42–45, 47]. Recently some arguments concerning the possible Kosterlitz-Thouless nature of this transition in terms of the Fock space have been developed in [62].

It was argued in [56, 57] that the so-called scars in the real space could provide the MBL phase. They were argued to be related to the peculiar fragmentation of the Fock space in the many-body system. Generically it is expected that the disorder is the source of the Hilbert space fragmentation however there are clear examples [58, 59] that the local conservation laws also can play such role. In particular it was shown in [58, 59] that the combination of the charge and dipole number conservation amounts to the fragmentation of the Fock space into the exponentially many scars supporting localized states. In this case there is no need a disorder. More formal group theory based arguments concerning the fragmentation of the Hilbert space can be found in [60, 63]. The use of the Krylov basis for the fragmentation phenomenon has been discussed in [61].

It was found in [41] that the RRG perturbed by the chemical potential for 3-cycles \(\mu_3\) gets defragmented into the fixed number of weakly coupled clusters at some critical \(\mu_{3,crit}\). The spectrum of graph Laplacian acquires the two-band structure, the number of the eigenvalues in the non-perturbative band is equal to the number of clusters and the eigenvectors in the non-perturbative band are localized. Hence we have explicit example
of the localization in the Fock space via its fragmentation. One could question about the underlying mechanism for the fragmentation in this case similar to the hidden conservation laws in other examples. The fixed degrees of the nodes in the RRG play the role of the local conservation laws. To clarify this point we have considered the constrained ER with the degree conservation constraint. The fragmentation of the network similar to the RRG takes place however if we drop off the degree conservation constraint the pure ER network does not exhibit the fragmentation phase transition. Note that the degree conservation constraint in the Fock space corresponds to the non-local constraint in the real space.

The identification of the graph responsible for the Hilbert space of particular interacting many-body system is not a simple task. The nodes correspond to the states while the links connect the states related by the resonant conditions. The cycles have the meaning of the higher resonances [66] for instance the 3-cycle discussed in [41] corresponds to the three nodes whose energies are organized in such way that the interaction provides the resonant conditions for all pairs of states. In this study we have considered the 4-cycles which correspond to the resonant conditions for four states. We have demonstrated that the increasing of the number of four-resonances yields the structural disorder in the graph upon the phase transition via the network fragmentation.

We look at the localization of the modes in the RRG and cRRG in hypercube phase similarly to [41]. Preliminary study shows that similarly to [41] the modes corresponding to the bipartite clusters in RRG are localized in agreement with the naive expectations. The pure hypercube corresponds to the integrable system hence it enjoys the localized modes. However when the interaction between the hypercubes is switched on it can be seen that there is localization in the whole spectrum. The question concerning the existence of mobility edge in this case need for the additional study.

Note that the ER network with chemical potential for 4-cycles without degree conservation constraint can be considered as well. In this case the analytical analysis is available and it perfectly fits with the numerical simulations. In this case the fragmentation of the Hilbert space does not take place and all modes are delocalized. The ER network has the intrinsic disorder in the graph Laplacian due to the degree distribution however it does not lead to localization.

We do not know exactly what physical system has the Hilbert space which we are treating as the perturbed RRG. However a few remarks are in order. First note that the perturbation by 4-cycles amounts to the emerging $Z_2$ symmetry in the Hilbert space. Secondly one could question if some physical system has the hypercube as the Hilbert space. Some indication of the relevance of the single hypercube to the Hilbert space of spin chain has been noted in [62] but this point certainly needs for further analysis.

Finally note that the Fock space perspective provides the interesting twist of the holographic picture. Now we consider the bulk holographic dual not for representation of the boundary partition function via the path integral over fields but via sum over the Hilbert space represented by some ensemble of graphs. In particular the combinatorial quantum gravity we have discussed above acquires the meaning of the effective gravity in the Hilbert space.

---

1 This result is obtained in collaboration with A. Vasyliev
space where the chemical potential for the 4-resonances plays the role of the gravitational coupling. The Ollivier curvature plays the role of the discrete Ricci curvature in the Hilbert space. The multiboundary wormhole interpretation of the hypercube phase we suggested above has the interpretation of the dual bulk geometry for the boundary Hilbert space ensemble for some theory which we do not identify.

5 Discussion

In this study we investigated numerically the non-perturbative phenomena in exponential random graphs with the degree conservation constraints. They are similar to the eigenvalue instantons in matrix models however the degree conservation constraint corresponds to the account of the non-singlet sector in matrix model context. It was argued that the degree conservation induces the first order phase transition of a network into bipartite clusters at $\mu_4 > \mu_c^4$ both for RRG and constrained ER networks. The induced network bipartiteness at strong coupling phase is the dynamical phenomenon.

The RRG with 4-cycle chemical potential has been used as the model for the combinatorial quantum gravity if the additional hard-core constraint is imposed. We have performed the detailed numerical analysis of cRRG and have found some novelties and disagreements with results claimed earlier in [23–25]. It turned out that the first order phase transition with a clear-cut hysteresis takes place at $\mu_{c}^{cRRG}$ for $d > 3$. Nearby the phase transition point the cRRG decays into the ensemble of separated non-interacting or weakly interacting hypercubes supplemented with closed bipartite ribbon. Such constituents of the clustered phase - hypercubes and bipartite ribbon, have appeared in all numerical experiments at different $d$. If we impose the additional graph connectedness condition for cRRG a structure of the clustered phase gets changed and depends on value of $d$. At $d = 3$ there is a phase transition with the formation of the single bipartite closed ribbon in agreement with [24]. However for $d > 3$ there is the first order phase transition with clear-cut hysteresis and formation of the weakly connected chain of hypercubes contrary to the claims in the early studies.

Using the relation between the hypercubes and TFD,s we have made the proposal concerning the holographic interpretation of the bipartite hypercube phase. Namely we have conjectured that the ground state of cRRG at large $d$ holographically corresponds to the multiboundary non-traversable wormholes where the number of boundaries coincides with the number of isolated hypercubes. At small $d$ when there are no enough degrees of freedom to form a wormhole we have assumed the relation with a holographic representation of the error-correcting codes in terms the Majorana dimers [36]. The multiboundary wormhole is supplemented with the bipartite closed ribbon which is related to the specific moduli spaces of the mapping of the Riemann surfaces into the sphere with three branching points [65] and presumably deals with the topological membrane. If we add the connectedness constraint for cRRG the suggested holographic dual for the closed chain of weakly interacting hypercubes presumably is the multiboundary traversable Euclidean wormhole. It would be interesting to relate this proposal with the tensor network representation of
AdS geometry [64] based on the entanglement renormalization. Certainly the holographic dual of the bipartite hypercube phase deserves a further study.

Our study demonstrates that non-perturbative phenomena in exponential random graphs are more tractable for numerical simulations than in the matrix models. This allows to visualize the eigenvalue instantons as the process of the creation of the corresponding bipartite clusters. In the context of the hypercube phase it is also possible numerically to fix $\mu_4$ and increase $N$, this procedure allows to consider the finite-size effects. Such analysis in two-star model [18] provides the clear picture for the evaporation of the single cluster. In our case the similar process of a evaporation of the hypercubes can be expected. It is natural since $N^{-1}$ is the effective coupling. Since according to our proposal the hypercube at large $d$ being the TFD state is holographically dual to the wormhole the evaporation of hypercube presumably can be related to a kind of wormhole evaporation. We hope to discuss this point elsewhere.

Treating RRG as a model for the Hilbert space of many-body system we indicated a few new patterns of the Hilbert space fragmentation induced by the higher resonances. The fragmentation of the Hilbert space is related to the MBL phase in the real space and the preliminary study indicates the one-particle localization of the cluster modes occurs indeed. We shall present the more detailed analysis of the IPR, level spacing distribution and the entanglement entropy in the hypercube phase elsewhere. It would be also interesting to consider the RRG supplemented with the fluxes which would yield the Parisi hypercube model upon fragmentation of the Hilbert space. The consideration of the SYK model on the perturbed RRG along the logic of [67] could be of some importance as well.

One more interesting development concerns the dual holographic picture for the Hilbert space in the spirit of the operator-state correspondence. The fragmentation of the Hilbert space in the hypercube phase provides the firm starting point along this line having in mind the wormhole interpretation of the hypercube ground state.

Our study also provides some suggestions concerning the partial deconfinement scenario. In the holographic context the block diagonal form of the matrix presumably corresponds to the partial deconfinement and formation of the small black holes in the bulk. The spectral density of the Wilson or Polyakov loops acquires the gaps. Our study suggests that the correspondence can be more general and some version of wormholes can be relevant. They correspond to the bipartite block diagonal matrices and the spectral density with two gaps. It would be interesting to develop these arguments further.

Finally remark that the bipartite large $N$ ensemble arises naturally in low energy QCD when the integration over instanton moduli spaces is mimicked by the matrix model with a simple potential [68]. The degree conservation condition should be implemented in this model by hand since the degree of the node is a topological invariant. Our study suggests that when the quartic term in the potential starts to dominate in the matrix measure one could expect that the instanton fluid phase gets transformed into the instanton molecular phase when each "molecule" corresponds to the bipartite cluster.
