(Received 27 February 2017; revised manuscript received 7 November 2017; published 29 November 2017)

We analyze the parametric structure of twin Higgs (TH) theories and assess the gain in fine tuning which they enable compared to extensions of the standard model with colored top partners. Estimates show that, at least in the simplest realizations of the TH idea, the separation between the mass of new colored particles and the electroweak scale is controlled by the coupling strength of the underlying UV theory, and that a parametric gain is achieved only for strongly-coupled dynamics. Motivated by this consideration we focus on one of these simple realizations, namely composite TH theories, and study how well such constructions can reproduce electroweak precision data. The most important effect of the twin states is found to be the infrared contribution to the Higgs quartic coupling, while direct corrections to electroweak observables are subleading and negligible. We perform a careful fit to the electroweak data including the leading-logarithmic corrections to the Higgs quartic up to three loops. Our analysis shows that agreement with electroweak precision tests can be achieved with only a moderate amount of tuning, in the range 5%–10%, in theories where colored states have mass of order 3–5 TeV and are thus out of reach of the LHC. For these levels of tuning, larger masses are excluded by a perturbativity bound, which makes these theories possibly discoverable, hence falsifiable, at a future 100 TeV collider.

I. INTRODUCTION

The principle of naturalness offers arguably the main motivation for exploring physics at around the weak scale. According to naturalness, the plausibility of specific parameter choices in quantum field theory must be assessed below a physical cutoff scale and considering only the known interactions of the Higgs boson, we expect the following corrections to its mass.1

\[
\delta m_H^2 = \frac{3y_t^2}{4\pi^2} \Lambda^2 - \frac{9g_2^2}{32\pi^2} \Lambda \hat{\Lambda}^2 - \frac{3g_1^2}{32\pi^2} \Lambda \hat{\Lambda}_h^2 - \frac{3\lambda_h}{8\pi^2} \Lambda_h^2 + \cdots , \quad (1.1)
\]

where each \( \Lambda \) represents the physical cutoff scale in a different sector of the theory. The above equation is simply dictated by symmetry: dilatations (dimensional analysis) determine the scale dependence and the broken shift symmetry of the Higgs field sets the coupling dependence.

Unsurprisingly, these contributions arise in any explicit UV completion of the SM, although in some cases there may be other larger ones. According to Eq. (1.1), any given (large) value of the scale of new physics can be associated with a (small) number \( \epsilon \), which characterizes the accuracy at which the different contributions to the mass must cancel among themselves, in order to reproduce the observed value \( m_h = 125 \text{ GeV} \). As the largest loop factor is due to the top Yukawa coupling, according to Eq. (1.1) the scale \( \Lambda_{NP} \) where new states must first appear is related to \( m_h^2 \) and \( \epsilon \) via

\[
\Lambda_{NP}^2 \sim \frac{4\pi^2}{3y_t^2} \times \frac{m_h^2}{\epsilon} \Rightarrow \Lambda_{NP} \sim 0.45 \sqrt{\frac{1}{\epsilon}} \text{ TeV}. \quad (1.2)
\]

The dimensionless quantity \( \epsilon \) measures how finely-tuned \( m_h^2 \) is, given \( \Lambda_{NP} \), and can therefore be regarded as a measure of the tuning. Notice that the contributions from \( g_2^2 \) and \( \lambda_h \) in Eq. (1.1) correspond to \( \Lambda_{NP} = 1.1 \text{ TeV}/\sqrt{\epsilon} \) and \( \Lambda_{NP} = 1.3 \text{ TeV}/\sqrt{\epsilon} \), respectively. Although not significantly different from the relation in the top sector, these scales would still be large enough to push new states out of direct reach of the LHC for \( \epsilon \sim 0.1 \).

Indeed, for a given \( \epsilon \), Eq. (1.2) only provides an upper bound for \( \Lambda_{NP} \); in the more fundamental UV theory
can in principle exist larger corrections to $m_R^2$ which are not captured by Eq. (1.1). In particular, in the minimal supersymmetric SM (MSSM) with high-scale mediation of the soft terms, $\delta m_R^2$ in Eq. (1.1) is logarithmically enhanced by RG evolution above the weak scale. In that case, Eq. (1.2) is modified as follows:

$$\Lambda_{NP}^2 \approx \frac{2\pi^2}{3y_t^2} \times \frac{1}{\ln \Lambda_{UV}/\Lambda_{NP}} \times \frac{m_R^2}{e}, \quad (1.3)$$

where $\Lambda_{NP}$ corresponds to the overall mass of the stops and $\Lambda_{UV} \gg \Lambda_{NP}$ is the scale of mediation of the soft terms. However, for generic composite Higgs (CH) models, as well as for supersymmetric models with low-scale mediation, Eq. (1.2) provides a fair estimate of the relation between the scale of new physics and the amount of tuning, the Higgs mass being fully generated by quantum corrections at around the weak scale. If the origin of $m_R$ is normally termed soft in the MSSM with large $\Lambda_{UV}$ [Eq. (1.3)], it should then be termed supersoft in models respecting Eq. (1.2). As is well known, and shown by Eq. (1.3), the natural expectation in the MSSM for $\Lambda_{UV} \geq 100$ TeV is $\Lambda_{NP} \approx m_{2\tau} \approx m_h$. In view of this, soft scenarios were already somewhat constrained by direct searches at LEP and Tevatron, whereas the natural range of the scale of supersoft models is only now being probed at the LHC.

Equation (1.2) sets an absolute upper bound on $\Lambda_{NP}$ for a given fine tuning $\epsilon$, but does not give any information on its nature. In particular it does not specify the quantum numbers of the new states that enter the theory at or below this scale. Indeed, the most relevant states associated with the top sector, the so-called top partners, are bosonic in standard supersymmetric models and fermionic in CH models. Nonetheless, one common feature of these standard scenarios is that the top partners carry SM quantum numbers, color in particular. They are thus copiously produced in hadronic collisions, making the LHC a good probe of these scenarios. Yet there remains the logical possibility that the states that are primarily responsible for the origin of the Higgs mass at or below $\Lambda_{NP}$ are not charged under the SM, and thus much harder to produce and detect at the LHC. The twin Higgs (TH) is probably the most interesting of the (few) ideas that take this approach [1–22]. This is primarily because the TH mechanism can, at least in principle, be implemented in a SM extension valid up to ultrahigh scales. The structure of TH models is such that the states at the threshold $\Lambda_{NP}$ in Eq. (1.2) carry quantum numbers under the gauge group of a copy, a twin, of the SM, but are neutral under the SM gauge group. These twin states, of which the twin tops are particularly relevant, are thus poorly produced at the LHC. The theory must also contain states with SM quantum numbers, but their mass $m_1$ is boosted with respect to $\Lambda_{NP}$ roughly by a factor $g_1/g_{SM}$, where $g_1$ describes the coupling strength of the new dynamics, while $g_{SM}$ represents a generic SM coupling. As discussed in the next section, depending on the structure of the model, $g_{SM}$ can be either the top Yukawa or the square root of the Higgs quartic. As a result, given the tuning $\epsilon$, the squared mass of the new colored and charged states is roughly given by

$$m_t^2 \sim \frac{4\pi^2}{3y_t^2} \times \frac{m_h^2}{\epsilon} \times \left(\frac{g_1}{g_{SM}}\right)^2, \quad (1.4)$$

For $g_1 > g_{SM}$, we could define this model as effectively hypersoft, in that, for fixed fine tuning, the gap between the SM-charged states and the weak scale is even larger than that in supersoft models. In practice the above equation implies that, for strong $g_1$, the new states are out of reach of the LHC even for mild tuning (see Sec. II A for a more precise statement). Equation (1.4) synthesizes the potential relevance of the TH mechanism, and makes it clear that the new dynamics must be rather strong for the mechanism to work. Given the hierarchy problem, it then seems almost inevitable to make the TH a composite TH (although it could also be a supersymmetric composite TH). Realizations of the TH mechanism within the paradigm of CH models and fermionic in CH models have already been proposed, both in the holographic and effective theory setups [9,13,14].

It is important to recognize that the factor that boosts the mass of the states with SM gauge quantum numbers in Eq. (1.4) is the coupling $g_1$ itself. Because of this, strong-dynamics effects in the Higgs sector, which are described in the low-energy theory by nonrenormalizable operators with coefficients proportional to powers of $g_1/m_1$, do not “decouple” when these states are made heavier, at fixed fine tuning $\epsilon$. In the standard parametrizations of the CH, $m_1/g_1$ is of the order of $f$, the decay constant of the $\sigma$-model within which the Higgs doublet emerges as a pseudo-Nambu-Goldstone boson (pNGB). Then $\xi \equiv v^2/f^2$, as well as being a measure of the fine tuning through $\epsilon = 2\xi$, also measures the relative deviation of the Higgs couplings from the SM ones, in the TH like in any CH model. Recent Higgs coupling measurements roughly constrain $\xi \lesssim 10$–20% [24], and a sensitivity of order 5% is expected in the high-luminosity phase of the LHC [25]. However Higgs loop effects in precision $Z$-pole observables measured at LEP already limit $\xi \lesssim 5\%$ [26,27]. Having to live with this few-percent tuning would somewhat undermine the motivation for the clever TH construction. In ordinary CH models this strong constraint on $\xi$ can in principle be relaxed thanks to compensating corrections to the $\tilde{T}$ parameter coming from the top partners. In the most natural models, these are proportional to $y_t^4 v^2/m_t^2$ and thus, unlike the Higgs-sector contribution, decouple when $m_t$ is

---

2The factor of two difference between the fine tuning $\epsilon$ and $\xi$ is due to the $Z_2$ symmetry of the Higgs potential in the TH models, as shown in Sec. II A [7].
increased. This makes it hard to realize such a compensatory effect in the most distinctive range of parameters for TH models, where \( m_\phi \sim 5-10 \text{ TeV} \). Alternatively one could consider including custodial-breaking couplings larger than \( y_t \) in the top-partner sector. Unfortunately these give rise to equally-enhanced contributions to the Higgs potential, which would in turn require further ad-hoc cancellations.

As already observed in the literature \([13,14]\) another important aspect of TH models is that calculable IR-dominated contributions to the Higgs quartic coupling almost saturate its observed value. Though a welcome property in principle, this sets even stronger constraints on additional UV contributions, such as those induced by extra sources of custodial breaking. In this paper we study the correlation between these effects, in order to better assess the relevance of the TH construction as a valid alternative to the SM, of the SM fields and interactions, \( g, \bar{g} \) and \( \bar{g}_L \). Section VI is devoted to a discussion of the resulting constraints on the Higgs potential, which would in turn require further ad-hoc cancellations.

The paper is organized as follows: in Sec. II we discuss the general structure and parametrics of TH models, followed by Sec. III where we discuss the more specific class of composite TH models we focus on for the purpose of our study. In Secs. IV and V we present our computations of the basic physical quantities: the Higgs potential and precision electroweak parameters \( \langle S, T, \phi_{jL,R} \rangle \). Section VI is devoted to a discussion of the resulting constraints on the model and an appraisal of the whole TH scenario. Our conclusions are presented in Sec. VII.

II. THE TWIN HIGGS SCENARIO

A. Structure and parametrics

In this section we outline the essential aspects of the TH mechanism. Up to details and variants which are not crucial for the present discussion, the TH scenario involves an exact duplicate, SM, of the SM fields and interactions, underpinned by a \( Z_2 \) symmetry. In practice this \( Z_2 \) must be explicitly broken in order to obtain a realistic phenomenology, and perhaps more importantly, a realistic cosmology \([19-21]\). However the sources of \( Z_2 \) breaking can have a structure and size that makes them irrelevant in the discussion of naturalness in electroweak symmetry breaking, which is the main goal of this section.

Our basic assumption is that the SM and its twin emerge from a more fundamental \( Z_2 \)-symmetric theory at the scale \( m_\phi \), at which new states with SM quantum numbers, color in particular, first appear. In order to get a feel for the mechanism and its parametrics, it is sufficient to focus on the most general potential for two Higgs doublets \( H \) and \( \tilde{H} \), invariant under the gauge group \( G_{\text{SM}} \times \tilde{G}_{\text{SM}} \), with \( G_{\text{SM}} = SU(3)_c \times SU(2)_L \times U(1)_Y \), as well as a \( Z_2 \):

\[
V(H, \tilde{H}) = -\frac{1}{2}m_H^2 |H|^2 + \frac{\lambda_H}{4} |H|^4 + \frac{\lambda_{\tilde{H}}}{4} |\tilde{H}|^4 + \lambda_{hH} |H|^2 |\tilde{H}|^2 + \text{H.c.}
\]  

(2.1)

Strictly speaking, the above potential does not have minima with realistic “tunable” \( \langle H \rangle \). This goal can be achieved by the simple addition of a naturally small \( Z_2 \)-breaking mass term which, while changing the vacuum expectation value, does not affect the estimates of fine tuning, and hence will be neglected for the purposes of this discussion. Like for the SM Higgs, the most general potential is accidentally invariant under a custodial \( SO(4) \times SO(4) \). Notice however that in the limit \( \lambda_h \to 0 \), the additional \( Z_2 \) enhances the custodial symmetry to \( SO(8) \), where \( H \equiv H \oplus \tilde{H} \equiv 8 \). In this exact limit, if \( \tilde{H} \) acquired an expectation value \( \langle \tilde{H} \rangle \equiv f / \sqrt{2} \), all 4 components of the ordinary Higgs \( H \) would remain exactly massless NGBs. Of course the SM and SM gauge and Yukawa couplings, along with \( \hat{\lambda}_h \), explicitly break the \( SO(8) \) symmetry that protects the Higgs. Consider however the scenario where these other couplings, which are known to be weak, can be treated as small \( SO(8) \)-breaking perturbations of a stronger \( SO(8) \)-preserving underlying dynamics, of which the quartic coupling \( \lambda_{hH} \) is a manifestation. In this situation we can reassess the relation between the SM Higgs mass, the amount of tuning and the scale \( m_\phi \) where new states charged under the SM are first encountered, treating \( \hat{\lambda}_h \) as a small perturbation of \( \lambda_{hH} \). At zeroth order, i.e., neglecting \( \hat{\lambda}_h \), we can expand around the vacuum \( \langle \tilde{H} \rangle^2 = 2m_{\tilde{H}}^2 / \lambda_{hH} \equiv f^2 / 2 \), \( \langle H \rangle = 0 \). The spectrum consists of a heavy scalar \( \sigma \), with mass \( m_\sigma = \sqrt{2m_{\tilde{H}}^2} = \sqrt{\lambda_{hH}f / \sqrt{2}} \), corresponding to the radial mode, 3 NGBs eaten by the twin gauge bosons, which get masses \( \sim gf/2 \) and the massless \( H \). When turning on \( \hat{\lambda}_h \), \( SO(8) \) is broken explicitly and \( H \) acquires a potential. At leading order in \( \lambda_{hH}/\lambda_{hH} \) expansion the result is simply given by substituting \( |\tilde{H}|^2 = f^2 / 2 - |H|^2 \) in Eq. (2.1). \(^3\)

The quartic coupling and the correction to the squared mass are then given by

\[
\lambda_h \approx \hat{\lambda}_h \delta m_{\tilde{H}}^2 \sim \hat{\lambda}_h f^2 / 8 = (\lambda_h/2\lambda_H)m_{\tilde{H}}^2.
\]  

(2.2)

\(^3\)Notice that the effective Higgs quartic receives approximately equal contributions from \( |H|^4 \) and \( |\tilde{H}|^4 \). This is a well-known and interesting property of the TH, see for instance Ref. [7].
As mentioned above, we assume that $m_H^2$ also receives an independent contribution from a $Z_2$-breaking mass term, which can be ignored in the estimates of tuning. Note that in terms of the physical masses of the Higgs, $m_H$, and of its heavy twin, $m_\sigma$, we have precisely the same numerical relation $\delta m_H^2 = (\lambda_H/2 \lambda_H) m_\sigma^2$. The amount of tuning $\epsilon$, defined as $m_H^2 / \delta m_H^2$, is given by $\epsilon = 2s^2 = 2v^2/f^2$.

Our estimate of $\delta m_H^2$ in Eq. (2.2) is based on a simplifying approximation where the $SO(8)$-breaking quartic is taken $Z_2$-symmetric. In general we could allow different couplings $\lambda_H$ and $\lambda_H^*$ for $|H|^4$ and $|H|^4$, respectively, constrained by the requirement $\lambda_H + \lambda_H^* = 2 \lambda_H$. As the estimate of $\delta m_H^2$ in Eq. (2.2) is determined by the $|H|^4$ term, it is clear that a reduction of $\lambda_H$, with $\lambda_H$ fixed, would improve the tuning, as emphasized in Ref. [22]. As discussed in Sec. IV, however, a significant fraction of the contribution to $\lambda_H$ and $\lambda_H^*$ is coming from RG evolution due to the top and twin top. According to our analysis, $\lambda_H/\lambda_H^* \sim 1.5$ in the simplest models to 3 in models where $\lambda_H$ is purely IR-dominated as in Ref. [22]. Though interesting, this gain does not change our parametric estimates.

The ratio $\lambda_H/\lambda_H^*$ is the crucial parameter in the game. Indeed it is through Eq. (2.2) that $m_H$ is sensitive to quantum corrections to the Lagrangian mass parameter $m_{H^0}$, or, equivalently, that the physical Higgs mass $m_h$ is sensitive to the physical mass of the radial mode $m_\sigma$. In particular, what matters is the correlation of $m_\sigma$ with, and its sensitivity to, $m_s$, where new states with SM quantum numbers appear. One can think of three basic scenarios for that relation, which we now illustrate, ordering them by increasing level of model-building ingenuity. Beyond these scenarios there is the option of tadpole-dominated electroweak symmetry breaking, which we shall briefly discuss at the end.

### 1. Subhypersoft scenario

The simplest option is given by models with $m_\sigma \sim m_s$. Supersymmetric TH models with medium- to high-scale soft-term mediation belong to this class [7], with $m_\sigma$ representing the soft mass of the squarks. Like in the MSSM, $m_{H^0}$, and therefore $m_\sigma$, is generated via RG evolution: two decades of running are sufficient to obtain $m_\sigma \sim m_s$. Another example is composite TH models [13,14]. In their simplest incarnation they are characterized by one overall mass scale $m_s$ and coupling $g_s$ [31], so that by construction one has $m_\sigma \sim m_s$ and $\lambda_H \sim g_s^2$. As discussed below Eq. (2.2), in both these scenarios one then expects $\delta m_H^2 \sim (\lambda_H/2 \lambda_H) m_\sigma^2$. It is interesting to compare this result to the leading top-sector contribution in Eq. (1.1). For that purpose it is worth noticing that, as discussed in Sec. IV, in TH models the RG-induced contribution to the Higgs quartic coupling $\Delta \lambda_H |_{\text{RG}} \sim (3y^2/\pi^2) \ln m_s/m_t$ (more than) saturates its experimental value $\lambda_H \sim 0.5$ for $m_s \sim 3 - 10 \text{ TeV}$.

We can thus write

$$\delta m_H^2 \sim (\lambda_H/2 \lambda_H) m_\sigma^2 \sim \frac{3y^2}{2\pi^2} \frac{1}{\lambda_H} \ln (m_s/m_t) m_t^2$$

which should be compared to the term on the right-hand side of Eq. (1.1). Accounting for the possibility of tuning we then have

$$m_s \sim 0.45 \frac{g_s}{\sqrt{2} y_s} \sqrt{\frac{1}{\ln (m_s/m_t)} \times \frac{1}{\epsilon}} \text{ TeV}. \quad (2.4)$$

Compared to Eq. (1.2), the mass of colored states is on one hand parametrically boosted by the ratio $g_s/(\sqrt{2} y_s)$, and on the other it is mildly decreased by the logarithm. The motivation for, and gain in, the ongoing work on the simplest realization of the TH idea pivot upon the above $g_s/y_s$. The basic question is how high $g_s$ can be pushed without leading to a breakdown of the effective description. One goal of this paper is to investigate to what extent one can realistically gain from this parameter in more explicit CH realizations. Applying naive dimensional analysis (NDA) one would be tempted to say that $g_s$, as big as $\sim 4\pi$ makes sense, in which case $m_s \sim 10 \text{ TeV}$ would only cost a mild $\epsilon \sim 0.1$ tuning. However such an estimate seems quantitatively too naive. For instance, by focusing on the simple toy model whose potential is given by Eq. (2.1), we can associate the upper bound on $\lambda_H \equiv g_s^2$, to the point where perturbation theory breaks down. One possible way to proceed is to consider the one loop beta function

$$\mu \frac{d \lambda_H}{d \mu} = \frac{N + 8}{32\pi^2} \lambda_H^2,$$

and to estimate the maximum value of the coupling $\lambda_H$ as that for which $\Delta \lambda_H / \lambda_H = O(1)$ through one e-folding of RG evolution. We find

$$\lambda_H = \frac{2m_\sigma^2}{f^2} \leq \frac{32\pi^2}{N + 8} \Rightarrow m_\sigma^2 \leq f \pi^2 \quad \text{for } N = 8, \quad (2.6)$$

which also gives $g_s \sim \sqrt{\lambda_H} \lesssim \sqrt{2} \pi$, corresponding to a significantly smaller maximal gain in Eq. (2.4) with respect to the NDA estimate. In Sec. III B we shall perform alternative estimates in more specific CH constructions, obtaining similar results.
It is perhaps too narrow-minded to stick rigidly to such estimates to determine the boost that \( g_s/\sqrt{2} y_t \) can give to \( m_s \). Although it is parametrically true that the stronger the coupling \( g_s \), the heavier the colored partners can be at fixed tuning, the above debate over factors of a few make it difficult to be more specific in our estimates. In any case the gain permitted by Eq. (2.4) is probably less than one might naively have hoped, making it fair to question the motivation for the TH, at least in its “subh dysperse” realization. With this reservation in mind, we continue our exploration of the TH in the belief that the connection between naturalness and LHC signatures is so crucial that it must be analyzed in all its possible guises.

Concerning in particular composite TH scenarios one last important model building issue concerns the origin of the Higgs quartic \( \lambda_h \). In generic CH it is known that the contribution to \( \lambda_h \) that arises at \( O(y_t^4) \) is too large when \( g_s \) is strong. Given that the TH mechanism demands \( g_s \) as strong as possible then composite TH models must ensure that the leading \( O(y_t^4) \) contribution is absent so that \( \lambda_h \) arises at \( O(y_t^4) \). As discussed in Ref. [13], this property is not guaranteed but it can be easily ensured provided the couplings that give rise to \( y_t \) via partial compositeness respect specific selection rules.

### 2. Hypersoft scenario

The second option corresponds to the structurally robust situation where \( m_s^2 \) is one loop factor smaller than \( m_s^2 \). This is for instance achieved if \( \mathcal{H} \) is a PNG-boson octet multiplet associated to the spontaneous breaking \( SO(9) \rightarrow SO(8) \) in a model with fundamental scale \( m_s \). Another option would be to have a supersymmetric model where supersymmetric masses of order \( m_s \) are mediated to the stops at the very scale \( m_s \), at which \( \mathcal{H} \) is massless. Of course in both cases a precise computation of \( m_s^2 \) would require the full theory. However a parametrically correct estimate can be given by considering the quadratically divergent 1-loop corrections in the low energy theory, in the same spirit of Eq. (1.1). As \( y_t \) and \( \lambda_h \) are expected to be the dominant couplings the analogue of Eqs. (1.1) and (2.2) imply

\[
\delta m_s^2 \approx \frac{\lambda_h}{2\lambda_H} \left( \frac{3y_t^2}{4\pi^2} + \frac{5\lambda_H}{16\pi^2} \right) m_s^2 = \left( \frac{y_t^2}{\lambda_H} + \frac{5}{12} \right) \frac{3\lambda_h}{8\pi^2} m_s^2.
\]  

(2.7)

Very roughly, for \( \lambda_H > y_t^2 \), top effects become subdominant and the natural value for \( m_s \) becomes controlled by \( \lambda_h \), like the term induced by the Higgs quartic in Eq. (1.1). In the absence of tuning this roughly corresponds to the technicolor limit \( m_s \sim 4\pi \nu \), while allowing for fine tuning we have

\[ m_s \approx 1.4 \times \sqrt{\frac{\nu}{\epsilon}} \text{ TeV}. \]  

(2.8)

It should be said that in this scenario there is no extra boost of \( m_s \) at fixed tuning by taking \( \lambda_H > y_t^2 \). Indeed the choice \( \lambda_H \sim y_t^2 \) is preferable as concerns electroweak precision tests (EWPT). It is well known that RG evolution in the effective theory below \( m_s \) gives rise to corrections to the \( \hat{S} \) and \( \hat{T} \) parameters as discussed in Sec. V [32]. In view of the relation \( \epsilon = 2v^2/f^2 \) this gives a direct connection between fine-tuning electroweak precision data, and the mass of the twin Higgs \( m_s \). At fixed \( v^2/f^2 \), EWPT then favor the smallest possible \( m_s = \sqrt{\lambda_H} f/\sqrt{2} \), that is the smallest \( \lambda_H \sim y_t^2 \). The most plausible spectrum in this class of models is roughly the following: the twin scalar \( \sigma \) and the twin tops appear around the same scale \( \sim y_t f/\sqrt{2} \), below the colored partners who live at \( m_s \). The presence of the somewhat light scalar \( \sigma \) is one of interesting features of this class of models.

### 3. Superhypersoft scenario

This option is a clever variant of the previous one, where below the scale \( m_s \) approximate supersymmetry survives in the Higgs sector in such a way that the leading contribution to \( \delta m^2_H \) proportional to \( \lambda_H \) is purely due to the top sector [7]. In that way Eq. (2.7) reduces to

\[
\delta m_s^2 \sim \frac{\lambda_H}{2\lambda_H} \left( \frac{3y_t^2}{4\pi^2} \right) m_s^2 = \frac{3\lambda_h}{8\pi^2} m_s^2.
\]  

(2.9)

so that by choosing \( g_s > y_t \) one can push the scale \( m_s \) further up with fixed fine tuning \( \epsilon \)

\[ m_s \approx 1.4 \times \frac{g_s}{\sqrt{2} y_t} \times \sqrt{\frac{1}{\epsilon}} \text{ TeV}. \]  

(2.10)

In principle even under the conservative assumption that \( g_s \sim \sqrt{2} \pi \) is the maximal allowed value, this scenario seemingly allows \( m_s \approx 14 \text{ TeV} \) with a mild \( \epsilon \sim 0.1 \) tuning.

It should be said that in order to realize this scenario one would need to complete \( \mathcal{H} \) into a pair of chiral superfield octets \( \mathcal{H}_a \) and \( \mathcal{H}_d \), along the lines of Ref. [7], as well as add a singlet superfield \( S \) in order to generate the Higgs quartic via the superpotential trilinear \( g_3 S \mathcal{H}_a \mathcal{H}_d \). Obviously this is a very far-fetched scenario combining all possible ideas to explain the smallness of the weak scale: supersymmetry, compositeness, and the twin Higgs mechanism.

### 4. Alternative vacuum dynamics: Tadpole induced EWSB

In all the scenarios discussed so far the tuning of the Higgs vacuum expectation value (VEV) and that of the Higgs mass coincided: \( \epsilon \), which controls the tuning of \( m_s^2 \) according to Eqs. (2.4), (2.8), and (2.10), is equal to \( 2v^2/f^2 \), which measures the tuning of the VEV. This was because the only tuning in the Higgs potential was associated with the small quadratic term, while the quartic
was assumed to be of the right size without the need for further cancellations (see, e.g., the discussion in Ref. [33]). Experimentally however, one can distinguish between the need for tuning that originates from measurements of Higgs and electroweak observables, which are controlled by $v^2/f^2$, and that coming from direct searches for top partners. Currently, with bounds on colored top partners at just around 1 TeV [34,35], but with Higgs couplings already bounded to lie within 10%-20% of their SM value [24], the only reason for tuning in all TH scenarios is to achieve a small $v^2/f^2$. It is then fair to consider options that reduce or eliminate only the tuning of $v^2/f^2$. As argued in Ref. [18], this can be achieved by modifying the $H$ scalar vacuum dynamics, and having its VEV induced instead by a tadpole mixing with an additional electroweak-breaking technicolor (TC) sector [36–38]. In order to preserve the $Z_2$ symmetry one adds two twin TC sectors, both characterized by a mass scale $m_{TC}$ and a decay constant $f_{TC} \sim m_{TC}/4\pi$ (i.e., it is parametrically convenient to assume $g_{TC} \sim 4\pi$). Below the TC scale the dynamics in the visible and twin sectors is complemented by Goldstone triplets $\pi_a$ and $\tilde{\pi}_a$ which can be embedded into doublet fields according to

$$\Sigma = f_{TC} \bar{e}^{i\beta} \sigma_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \tilde{\Sigma} = f_{TC} \bar{e}^{i\beta} \sigma_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad (2.11)$$

and are assumed to mix with $H$ and $\tilde{H}$ via the effective potential terms

$$V_{\text{tadpole}} = M^2 (H^\dagger \Sigma + \tilde{H}^\dagger \tilde{\Sigma}) + \text{H.c.} \quad (2.12)$$

Assuming $m_{TC} \ll m_H$ the $\tilde{H}$ vacuum dynamics is not significantly modified, but, for $m_{TC} > m_H$, $V_{\text{tadpole}}$ acts like a rigid tadpole term for $H$. The expectation value $\langle H \rangle$ is thus determined by balancing such a tadpole against the significantly modified, but, for vacuum dynamics, and having its VEV induced instead by a mass scale $\tilde{m}_{TC}$, the only reason for tuning in all TH scenarios is to achieve a small $v^2/f^2$. It is then is parametrically convenient to assume $g_{TC} \sim 4\pi$.

Below the TC scale the dynamics in the visible and twin sectors is complemented by Goldstone triplets $\pi_a$ and $\tilde{\pi}_a$ which can be embedded into doublet fields according to

$$\Sigma = f_{TC} \bar{e}^{i\beta} \sigma_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \tilde{\Sigma} = f_{TC} \bar{e}^{i\beta} \sigma_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad (2.11)$$

and are assumed to mix with $H$ and $\tilde{H}$ via the effective potential terms

$$V_{\text{tadpole}} = M^2 (H^\dagger \Sigma + \tilde{H}^\dagger \tilde{\Sigma}) + \text{H.c.} \quad (2.12)$$

Assuming $m_{TC} \ll m_H$ the $\tilde{H}$ vacuum dynamics is not significantly modified, but, for $m_{TC} > m_H$, $V_{\text{tadpole}}$ acts like a rigid tadpole term for $H$. The expectation value $\langle H \rangle$ is thus determined by balancing such a tadpole against the gauge-invariant $|H|^2$ mass term; the latter will then roughly coincide with $m_H^2$. In order for this to work, by Eq. (2.2) the $SO(8)$-breaking quartic $\lambda_h$ should be negative, resulting in $v \sim (M^2/m_H^2) f_{TC}$. It is easy to convince oneself that the corrections to Higgs couplings are $O(f_{TC}^2/v^2)$; present bounds can then be satisfied for $f_{TC} \sim v/\sqrt{10} \approx 80$ GeV. In turn, the value of $v/f$ is controlled by $f$ and can thus be naturally small. The TC scale is roughly $m_{TC} \sim 4\pi f_{TC} \sim 600–800$ GeV, while the noneaten pNGB $\pi$ in Eq. (2.11) have a mass $m_{\pi}^2 \sim M^2/v f_{TC} \sim m_H^2(v/f_{TC})^2 \sim 400$ GeV. The latter value, although rather low, is probably large enough to satisfy constraints from direct searches. In our opinion, what may be more problematic are EWPT, in view of the effects from the TC sector, which shares some of the vices of ordinary TC. The IR contributions to $\tilde{S}$ and $\tilde{T}$, associated with the splitting $m_{\tilde{w}} < m_{TC}$, are here smaller than the analogues of ordinary technicolor (there associated with the splitting $m_w < m_{TC}$). However the UV contribution to $\tilde{S}$ is parametrically the same as in ordinary TC, in particular it is enhanced at large $N_{TC}$. Even at $N_{TC} = 2$, staying within the allowed $(\tilde{S}, \tilde{T})$ ellipse still requires a correlated contribution from $\Delta \tilde{T}$, which in principle should also be counted as tuning. In spite of this, models with tadpole-induced EWSB represent a clever variant where, technically, the dynamics of EWSB does not currently appear tuned. A thorough analysis of the constraints is certainly warranted.

### III. THE COMPOSITE TWIN HIGGS

In this section and in the remainder of the paper, we will focus on the CH realization of the TH, which belongs to the subhypersoft class of models. In this simple and well-motivated context we shall discuss EWPT, fine tuning, and structural consistency of the model.

Our basic structural assumption is that at a generic UV scale $\Lambda_{UV} \gg m_\pi$, our theory can be decomposed into two sectors: a strongly-interacting composite sector and a weakly-interacting elementary sector. The composite sector is assumed to be endowed with the global symmetry $G = SO(8) \times U(1)_X \times Z_2$ and to be approximately scale-(conformal) invariant down to the scale $m_\pi$, at which it develops a mass gap. We assume the overall interaction strength at the resonance mass scale $m_\pi$ to be roughly described by one parameter $g_\pi$ [31]. The large separation of mass scales $\Lambda_{UV} \gg m_\pi$ is assumed to arise naturally, in that the occurrence of the mass gap $m_\pi$ is controlled by either a marginally relevant deformation, or by a relevant deformation whose smallness is controlled by some global symmetry. At the scale $m_\pi$, $SO(8) \times U(1)_X \times Z_2$ is spontaneously broken to the subgroup $H = SO(7) \times U(1)_X$, giving rise to seven NGBs in the 7 of $SO(7)$ with decay constant $f \sim m_\pi/g_\pi$. The subgroup $U(1)_X$ does not participate to the spontaneous breaking, but its presence is needed to reproduce the hypercharges of the SM fermions, similarly to CH models. The elementary sector consists in turn of two separate weakly interacting sectors: one containing the visible SM fermions and gauge bosons, corresponding to the SM gauge group $G_{SM} = SU(3)_c \times SU(2)_L \times U(1)_Y$; the other containing the twin SM with the same fermion content and a SM gauge group $G_{SM} = SU(3)_c \times SU(2)_L$. The external $Z_2$ symmetry, or twin parity, interchanges these two copies. For simplicity, and following [13], we choose not to introduce a mirror hypercharge field. This is our only source of explicit twin-parity breaking, and affects neither our discussion of fine tuning, nor that of precision electroweak measurements.

The elementary and composite sectors are coupled according to the paradigm of partial compositeness [23]. The elementary EW gauge bosons couple to the strong dynamics as a result of the weak gauging of the $SU(2)_L \times U(1)_Y \times SU(2)_L$ subgroup of the global $SO(8) \times U(1)_X$. A linear mixing with the global conserved currents is thus induced:
\[ L^V_{\text{mix}} \supset g_1 W^\mu_\mu f_\mu^a + g_1 B_\mu f_\mu^a + \tilde{g}_2 \tilde{W}^\mu_\mu f_\mu^a, \quad (3.1) \]

where \( g_{1,2} \) denote the SM and twin weak gauge couplings, \( f_\mu^a \equiv f_R^\mu + f_L^\mu \) and \( f_\mu^\rho \) are the currents associated respectively to the \( SU(2)_L, SU(2)_R \) and \( U(1)_X \) generators. The elementary fermions mix analogously with various operators transforming as linear representations of \( SO(8) \) that are generated in the far UV by the strongly interacting dynamics. The mixing Lagrangian takes the schematic form:

\[ L^F_{\text{mix}} \supset \tilde{q}_L^a \Delta_{aa} O_R^a + \tilde{t}_R^A \Theta_A O_L^A + \bar{q}_L^a \tilde{\Delta}_{aa} \tilde{O}_R^a + \tilde{t}_R^A \tilde{\Theta}_A \tilde{O}_L^A + \text{H.c.}, \quad (3.2) \]

where, following, e.g., Ref. [39], we introduced spurions \( \Delta_{aa}, \tilde{\Delta}_{aa}, \Theta_A, \tilde{\Theta}_A \) in order to uplift the elementary fields to linear representations of \( SO(8) \), and match the quantum numbers of the composite operators. The left-handed mixings \( \Delta_{aa}, \tilde{\Delta}_{aa} \) necessarily break \( SO(8) \) since \( q_L \) only partially fills a multiplet of \( SO(8) \). The right-handed mixings, instead, may or may not break \( SO(8) \). The breaking of \( SO(8) \) gives rise to a potential for the NGBs at one loop and the physical Higgs is turned into a pNGB. We conclude by noticing that \( g_{1,2} \) and \( \tilde{g}_2 \) correspond to quasimarginal couplings which start off weak in the UV, and remain weak down to \( m_2 \). The fermion mixings could be either relevant or marginal, and it is possible that some may correspond to interactions that grow as strong as \( g_1 \) at the IR scale \( m_c \). In particular, as is well known, there is some advantage as regards tuning in considering the right mixings \( \Theta_A \) and \( \tilde{\Theta}_A \) to be strong. In that case one may even imagine the IR scale to be precisely generated by the corresponding deformation of the fixed point. While this latter option may be interesting from a top-down perspective, it would play no appreciable role in our low-energy phenomenological discussion.

**A. A simplified model**

In order to proceed we now consider a specific realization of the composite TH and introduce a concrete simplified effective Lagrangian description of its dynamics. Our model captures the most important features of this class of theories, like the pNGB nature of the Higgs field, and provides at the same time a simple framework for the interactions between the elementary fields and the composite states, vectors and fermions. We make use of this effective model as an example of a specific scenario in which we can compute EW observables, and study the feasibility of the TH idea as a new paradigm for physics at the EW scale.

We write down an effective Lagrangian for the composite TH model using the Callan-Coleman-Wess-Zumino (CCWZ) construction [41,42], and generalizing the simpler case of a two-site model developed in Ref. [13]. According to the CCWZ technique, a Lagrangian invariant under the global \( SO(8) \) group can be written following the rules of a local \( SO(7) \) symmetry. The basic building blocks are the Goldstone matrix \( \Sigma \), which encodes the seven NGBs, \( \Pi \), present in the theory, and the operators \( d_\mu (\Pi) \) and \( E_\mu (\Pi) \) resulting from the Maurer-Cartan form constructed with the Goldstone matrix. An external \( U(1)_X \) group is also added to the global invariance in order to reproduce the correct fermion hypercharges [13]. The CCWZ approach is reviewed and applied to the \( SO(8)/SO(7) \) coset in Appendix A.

Before proceeding, we would like to recall the simplified model philosophy of Ref. [43], which we essentially employ. In a generic composite theory, the mass scale \( m_7 \) would control both the cutoff of the low energy \( \sigma \)-model and the mass of the resonances. In that case no effective Lagrangian method is expected to be applicable to describe the resonances. So, in order to produce a manageable effective Lagrangian we thus consider a Lagrangian for resonances that can, at least in principle, be made lighter that \( m_7 \). One more structured way to proceed could be to consider a deconstructed extra-dimension where the mass of the lightest resonances, corresponding to the inverse compactification length, is parametrically separated from the 5D cut-off, interpreted as \( m_7 \). Here we do not go that far and simply consider a set of resonances that happen to be a bit lighter than \( m_7 \). We do so to give a structural dignity to our effective Lagrangian, though at the end, for our numerical analysis, we just take the resonances a factor of 2 below \( m_7 \). We believe that is a fair procedure given our purpose of estimating the parametric consistency of the general TH scenario.

We start our analysis of the effective Lagrangian with the bosonic sector. Together with the elementary SM gauge bosons, the \( W \)'s and \( B \), we introduce the twin partners \( \tilde{W} \) to gauge the \( SU(2)_L \) group. As representative of the composite dynamics, we restrict our interest to the heavy spin-1 resonances transforming under the adjoint of \( SO(7) \) and to a vector singlet. We therefore introduce a set of vectors \( \rho^a_\mu \) which form a \( 21 \) of \( SO(7) \) and the gauge vector associated with the external \( U(1)_X \), which we call \( \rho^X_\mu \). The Lagrangian for the bosonic sector can be written as

\[ \mathcal{L}_{\text{bosonic}} = \mathcal{L}_\pi + \mathcal{L}_\text{comp}^V + \mathcal{L}_\text{elem}^V + \mathcal{L}_\text{mix}^V. \quad (3.3) \]

The first term describes the elementary gauge bosons masses and the NGBs dynamics and is given by

\[ \mathcal{L}_\pi = \frac{f^2}{4} \text{Tr} [d_\mu d^\mu]. \quad (3.4) \]

The second term, \( \mathcal{L}_\text{comp}^V \), is a purely composite term, generated at the scale \( m_7 \) after confinement; it reduces to the kinetic terms for the \( \rho \) vectors, namely:
where \( \rho_{\mu}^{\mu} = \partial_{\mu} \rho_{\mu} - \partial_{\mu} \rho_{\mu} - f_{abc} \rho_{\mu}^{\nu} \rho_{\mu}^{\rho} \), \( \rho_{\mu}^{X} = \partial_{\mu} \rho_{\mu}^{X} - \partial_{\mu} \rho_{\mu}^{X} \), and \( \rho_{\mu} \) and \( \rho_{\mu}^{X} \) are the coupling strengths for the composite spin-1 bosons. The third term in Eq. (3.3), \( \mathcal{L}_{\text{comp}}^{V} \), is a purely elementary interaction, produced at the scale \( \Lambda_{\text{UV}} \) where the elementary fields are formally introduced. Also this Lagrangian can contain only the kinetic terms for the elementary fields:

\[
\mathcal{L}_{\text{comp}}^{V} = - \frac{1}{4g_{1}^{2}} B_{\mu} B^{\mu} - \frac{1}{4g_{3}^{2}} W_{\mu} W^{\mu} - \frac{1}{4g_{2}^{2}} \tilde{W}_{\mu} \tilde{W}^{\mu},
\]

where \( g_{1}, g_{2}, \) and \( g_{3} \) denote the weak gauge couplings. The last term in the Lagrangian (3.3), \( \mathcal{L}_{\text{mix}}^{V} \), is a mixing term between the elementary and composite sectors originating from partial compositeness. We have:

\[
\mathcal{L}_{\text{mix}}^{V} = \frac{M_{0}^{2}}{2g_{1}^{2}} (\text{Tr}[\rho_{\mu}^{\nu} T_{a}^{31} - E_{\mu}])^{2} + \frac{M_{0}^{2}}{2g_{3}^{2}} (\rho_{\mu}^{X} - B_{\mu})^{2},
\]

where \( T_{a}^{31} \) are the \( SO(8) \) generators in the adjoint of \( SO(7) \) (see Appendix A).

We now introduce the Lagrangian for the fermionic sector. This depends on the choice of quantum numbers for the composite operators in Eq. (3.2). The minimal option is to choose \( O_{R} \) and \( \tilde{O}_{R} \) to be in the fundamental representation of \( SO(8) \), whereas the operators \( O_{L} \) and \( \tilde{O}_{L} \) are singlets of the global group. Therefore, the elementary SM doublet and its twin must be embedded into fundamental representations of \( SO(8) \), whereas the \( t_{R} \) and \( \bar{t}_{R} \) are complete singlets under the global \( SO(8) \) invariance. This choice is particularly useful to generalize our discussion to the case of a fully-composite right-handed top. From the low-energy perspective, the linear mixing between composite operators and elementary fields translates into a linear coupling between the latter and a layer of fermionic resonances excited from the vacuum by the operators in the fundamental and singlet representations of the global group. Decomposing the \( 8 \) of \( SO(8) \) as \( 8 = 7 + 1 \) under \( SO(7) \), we introduce a set of fermionic resonances filling a complete fundamental representation of \( SO(7) \) and another set consisting of just one singlet. We denote with \( \Psi_{7} \) the fermionic resonances in the septuplet and with \( \Psi_{1} \) the singlet, both charged under \( SU(3)_{c} \). Together with them, we must introduce analogous composite states charged under \( SU(3)_{c} \); we use the corresponding notation \( \tilde{\Psi}_{7} \) and \( \tilde{\Psi}_{1} \). We refer to Ref. [13] for the complete expression of \( \Psi_{7} \) and \( \tilde{\Psi}_{7} \) in terms of the constituent fermions.

The fermionic effective Lagrangian is split into three parts, which have the same meaning as the analogous distinctions we made for the bosonic sector of the theory:

\[
\mathcal{L}_{\text{fermion}} = \mathcal{L}_{\text{comp}}^{F} + \mathcal{L}_{\text{elem}}^{F} + \mathcal{L}_{\text{mix}}^{F}.
\]

The fully composite term is given by:

\[
\mathcal{L}_{\text{comp}}^{F} = \tilde{\Psi}_{7}(i\partial_{\mu} - M_{\tilde{\Psi}})\Psi_{7} + \tilde{\Psi}_{1}(i\partial_{\mu} - M_{\tilde{\Psi}})\Psi_{1} + \tilde{\Psi}_{7}(i\partial_{\mu} - m_{\tilde{\Psi}})\Psi_{7} + \tilde{\Psi}_{1}(i\partial_{\mu} - m_{\tilde{\Psi}})\Psi_{1} + (ic_{L}\tilde{\Psi}_{7}^{\dagger}d_{\Psi_{L}} + ic_{R}\tilde{\Psi}_{7}^{\dagger}d_{\Psi_{R}} + ic_{L}\tilde{\Psi}_{1}^{\dagger}d_{\Psi_{L}} + ic_{R}\tilde{\Psi}_{1}^{\dagger}d_{\Psi_{R}} + \text{H.c.}),
\]

The final term in our classification is the elementary/composite mixing that we write again following the prescription of partial compositeness. With our choice of quantum numbers for the composite operators, the spurions in Eq. (3.2) can be matched to dimensionless couplings according to:

\[
\Delta_{AA} = \begin{pmatrix} 0 & 0 & i\gamma_{L} & -\gamma_{L} & 0 & 0 \\ i\gamma_{L} & \gamma_{L} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ \end{pmatrix}, \quad \Theta_{A} = \gamma_{R},
\]

and

\[
\tilde{\Delta}_{AA} = \begin{pmatrix} 0 & 0 & i\gamma_{L} & -\gamma_{L} & 0 & 0 \\ i\gamma_{L} & \gamma_{L} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ \end{pmatrix}, \quad \tilde{\Theta}_{A} = \tilde{\gamma}_{R}.
\]
where we have introduced the elementary/composite mixing parameters $y_L$, $y_R$ and their twin counterparts. These dimensionless $y$’s control the strength of the interaction between the elementary and composite resonance fields, according to the Lagrangian:

$$L_{\text{max}}^F = f\left(\tilde{q}_L^a \Delta_a \Sigma_A \Psi_L^i + \tilde{q}_R^a \Delta_a \Sigma_A \Psi_1^i + y_R \bar{t}_R \Psi_1^i + \text{H.c.}\right) + f\left(\tilde{q}_L^a \Delta_a \Sigma_A \Psi_L^i + \tilde{q}_R^a \Delta_a \Sigma_A \Psi_1^i + \bar{y}_R \bar{t}_R \Psi_1^i + \text{H.c.}\right).$$

(3.13)

Depending on the UV boundary condition and the relevance or marginality of the operators appearing in $\mathcal{L}_{\text{comp}}^V$, we have:

$$\mathcal{L}_{\text{comp}}^V = \sum_{i=L,R} \left[ \alpha_i \bar{\Psi}_i \left( \phi - \vec{E} \right) \Psi_i + \alpha_1 \bar{\Psi}_i \left( \phi^X - \vec{P} \right) \Psi_i + \alpha_1 \bar{\Psi}_i \left( \phi^Y - \vec{P} \right) \Psi_i + \bar{\alpha}_1 \Psi_i \left( \phi^X - \vec{P} \right) \Psi_i + \bar{\alpha}_1 \Psi_i \left( \phi^Y - \vec{P} \right) \Psi_i \right],$$

(3.14)

Alternatively, the limit set by perturbativity on the UV interaction strength may also be estimated in the effective theory described by the nonlinear $\sigma$-model by determining the energy scale at which tree-level scattering amplitudes become nonperturbative. For concreteness, we considered the following two types of scattering processes: $\pi\pi \to \pi\pi$ and $\pi\pi \to \psi\psi$, where $\pi$ are the NGBs and $\psi = \{\Psi_1, \Psi_2\}$ denotes a composite fermion transforming in the fundamental of $SO(7)$. Other processes can (and should) be considered, with the actual bound being given by the strongest of the constraints obtained in this way.

Requiring that the process $\pi\pi \to \pi\pi$ stay perturbative up the cutoff scale $m_*$ gives the bound

$$\frac{M_H}{f} \sim \frac{M_{\psi}}{f} \lesssim \frac{m_*}{f} \lesssim \frac{4\pi}{\sqrt{N-2}} \approx 5.1,$$

(3.15)

where the second inequality is valid in a generic $SO(\mathcal{N})/SO(\mathcal{N}-1)$ nonlinear $\sigma$-model, and we have set $N = 8$ in the last step. More details on how this result was obtained can be found in Appendix G. Equation (3.15) in fact corresponds to a limit on the interaction strength of the UV theory, given that the couplings among fermion and vector resonances are of order $M_{\psi}/f$ and $M_{\phi}/f$, respectively. Perturbativity of the scattering amplitude for $\pi\pi \to \psi\psi$ instead gives (see Appendix G for details)

$$\frac{M_H}{f} \sim \frac{M_{\psi}}{f} \lesssim \frac{m_*}{f} < \frac{\sqrt{12\sqrt{2}\pi}}{\sqrt{N_f}} \approx \frac{4\pi}{\sqrt{N_f}},$$

(3.16)

where $N_f$ is the multiplicity of composite fermions (including the number of colors and families). Our simplified model with one family of composite fermions has $N_f = 6$, which gives a limit similar to Eq. (3.15):
A model with three families of composite quarks and leptons has instead $N_f = 24$, from which follows the stronger bound $M_{W}/f \lesssim 2.6$.

As a third alternative, one could analyze when 1-loop corrections to a given observable become of the same order as its tree-level value. We applied this criterion to our simplified model by considering the $\hat{S}$ parameter, the new physics contribution to which includes a tree-level correction from heavy vectors given by Eq. (5.6), and a one-loop correction due to heavy fermions, which can be found in Appendix E. By requiring that the one-loop term be smaller than the tree-level correction, we obtain a bound on the strong coupling constant $g_{\rho}$. As an illustration, we consider the two-site model limit $c_{L} = c_{R} = 0$ and $M_{\rho} = g_{\rho}f/\sqrt{2}$ and keep the dominant UV contribution to $\hat{S}$ in Eq. (E7) which is logarithmically sensitive to the cutoff. By setting $m_{s} = 2M_{W}$, we find:

$$\frac{\Delta \hat{S}_{\text{1-loop}}}{\Delta \hat{S}_{\text{tree}}} < 1 \Rightarrow \frac{M_{\rho}}{f} < \frac{g_{\rho}}{\sqrt{2}} \frac{\pi}{\sqrt{2} \log 2} = 2.7.$$  \hspace{1cm} (3.17)

The perturbative limits obtained from Eqs. (3.15), (3.16), and (3.17) are comparable to that on $\lambda_{H}$ derived in Sec. II A 1. As already discussed there, one could take any of these results as indicative of the maximal interaction strength in the underlying UV dynamics, though none of them should be considered as a sharp exclusion condition. In our analysis of EW observables we will make use of Eq. (3.15) with $N_{f} = 8$ and of Eq. (3.16) with $N_{f} = 24$ to highlight the regions of parameter space where our perturbative calculation is less reliable. We use both limits as a measure of the intrinsic uncertainty which is inevitably associated with this type of estimation.

### IV. HIGGS EFFECTIVE POTENTIAL

As anticipated in the general discussion of Sec. II A, a potential for the Higgs boson is generated at the scale $m_{s}$ by loops of heavy states through the $SO(8)$-breaking couplings of the elementary fields to the strong sector. Once written in terms of the Higgs boson $h$ (where $H^{\dagger}H = f^{2} \sin^{2}(h/f)/2$, $H^{\dagger}H = f^{2} \cos^{2}(h/f)/2$), at 1-loop this UV threshold contribution has the form [13]:

$$V(m_{s}) = \frac{3}{32\pi^{2}} \left[ 1 + \left( \frac{g^{2}_{\rho}L_{1} + (y_{t}^{2} - y_{b}^{2})g^{2}_{\rho}L_{2}}{1} \right) \sin^{2}\frac{h}{f} \right] + \frac{3 y_{t}^{2}}{64 \pi^{2}} F_{1} \left( \sin^{4}\frac{h}{f} + \cos^{4}\frac{h}{f} \right).$$  \hspace{1cm} (4.1)

where $g_{\rho} = M_{W}/f$, $L_{1}$, $L_{2}$, $F_{1}$ are $O(1)$ dimensionless functions of the masses and couplings of the theory and the explicit expression of the function $F_{1}$ is reported in Eq. (C1) of Appendix C. The first term in the above equation originates from $Z_{2}$-breaking effects. The second term, generated by loops of fermions, is $Z_{2}$ symmetric and explicitly violates the $SO(8)$ invariance; it thus corresponds to the (UV part of the) last term of Eq. (2.1). Upon electroweak symmetry breaking, Eq. (4.1) contributes to the physical Higgs mass an amount equal to

$$\delta m_{h}^{2}|_{\text{UV}} = \frac{3 y_{t}^{4}}{4 \pi^{2}} f^{2} \xi (1 - \xi),$$  \hspace{1cm} (4.2)

where $\xi$ controls the degree of vacuum misalignment:

$$\xi \equiv \sin^{2}\frac{h}{f} = \frac{v^{2}}{f^{2}}.$$  \hspace{1cm} (4.3)

Below the scale $m_{s}$ an important contribution to the potential arises from loops of light states, in particular from the top quark and from its twin. The bulk of this IR contribution is captured by the RG evolution of the Higgs potential from the scale $m_{s}$ down to the electroweak scale. As noted in previous studies (see, e.g., Ref. [13]), for sufficiently large $m_{s}$ this IR effect dominates over the UV threshold correction and can reproduce the experimental Higgs mass almost entirely. An analogous IR correction to the Higgs quartic arises in SUSY theories with large stop masses, from loops of top quarks. The distinctive feature of any TH scenario, including our model, is the additional twin top contribution.

The Higgs effective action, including the leading $O(\xi)$ corrections associated with operators of dimension 6, was computed at 1-loop in Ref. [13]; the resulting IR contribution to $m_{h}^{2}$ was found to be

$$\delta m_{h}^{2}|_{\text{IR}} = \frac{3 y_{t}^{4}}{8 \pi^{2}} f^{2} \xi (1 - \xi) \left( \log \frac{m_{t}^{2}}{m_{s}^{2}} + \log \frac{m_{t}^{2}}{m_{t}^{2}} \right),$$  \hspace{1cm} (4.4)

where $y_{t}$ denotes the top Yukawa coupling. The two single-log terms in parentheses correspond to the IR contributions to the effective Higgs quartic $\lambda_{h}$ from the top quark and twin top respectively. Leading-logarithmic corrections of the form $(a \log)^{n}$, arising at higher loops have however an important numerical impact. For example, $(a \log)^{2}$ corrections generated by 2-loop diagrams (mostly due to the running of the top and twin top Yukawa couplings, that are induced by respectively QCD and twin QCD) are expected to give a $\sim 30\%$ reduction in the Higgs mass for $m_{s} = 5$ TeV.

We have computed the IR contribution to the Higgs mass in a combined expansion in $\xi$ and $(a \log)$. We have included the LO electroweak contribution, all terms up to NLO in $a_{t}$

---

7. Subleading $Z_{2}$-breaking terms have been neglected for simplicity. The complete expressions are given in Ref. [13].

8. Here $\alpha = g^{2}_{SM}/4 \pi$, with $g_{SM}$ being any large SM coupling, i.e., $g_{s}$ and $y_{t}$.
and $\alpha_S$, and some contributions, expected to be leading for not too large $m_*$, at NNLO in $\alpha_S$. We report the details in Appendix C.

The value of $(\delta m^2_{\text{IR}})^{1/2}$ is shown in Fig. 1 as a function of $m_*$ for $\xi = 0.1$. The upper and lower curves represent respectively the LO and NLO calculation in our combined $(\xi, \alpha \log)$ expansion. Numerically, the naive expectation is confirmed, as the NLO correction decreases $(\delta m^2_{\text{IR}})^{1/2}$ by $\sim 35\%$ for $m_* = 5$ TeV. The dotted curve, indicated as NNLO*, includes NNLO contributions of order $\alpha_2 \xi^2 \log$, $\alpha_3 \xi^3 \log^2$, and $\alpha_3^2 \xi \log^3$ (see Appendix C). Additional contributions of order $\alpha_2^2 \xi \log^2$, $\alpha_2 \alpha_3 \log^3$ and $\alpha_3^3 \log^3$ are not included. An attempt to include these contributions has been made in Ref. [46]. However, the calculation presented there misses some additional contributions from the twin GB and does not represent the full NNLO calculation. The picture that we get from our NNLO* calculation and the incomplete result of Ref. [46], is that the NNLO* gives an overestimate of the IR contribution to the Higgs mass as the aforementioned neglected effects are expected to give a reduction. Given the lack of a complete NNLO calculation, we estimate our uncertainty on the IR contribution to the Higgs mass as the green shaded region lying between the LO and NLO results in Fig. 1. In order to choose, within this uncertainty, a value that is as close as possible to the full NNLO result, in the rest of the paper we take as input value for the IR correction to the Higgs mass the average of the LO and NLO results, corresponding to the solid black line in the figure.

The plot of Fig. 1 illustrates one of the characteristic features of TH models: the IR contribution to the Higgs mass largely accounts for its experimental value and is completely predicted by the theory in terms of the low-energy particle content (SM plus twin states). In particular, considering the aforementioned input value and choosing as a benchmark values $m_*=5$ TeV and $\xi=0.1$, we find that the contributions of the SM and twin light degrees of freedom account for around 50\% and 40\% of the Higgs mass squared, respectively, so that almost the entire experimental value of the Higgs mass can be due only to the IR degrees of freedom. Threshold effects arising at the UV matching scale, on the other hand, are model dependent but give a subleading correction. An accurate prediction of the Higgs mass and an assessment of the plausibility of the model thus requires a precise determination of its IR contribution. Indeed the difference between the IR contribution of Fig. 1 and the measured value $m_h=125$ GeV must be accounted for by the UV threshold contribution in Eq. (4.2); for our previous benchmark choice of $m_*$, about 12\% of the Higgs mass should be generated by the UV physics. This translates into a generic constraint on the size of $y_t$, a parameter upon which electroweak precision observables (EWPO) crucially depend, thus creating a nontrivial correlation between the Higgs mass, EWPO and naturalness.

V. ELECTROWEAK PRECISION OBSERVABLES

In this section we compute the contribution of the new states described by our simplified model to the EWPO. Although it neglects the effects of the heavier resonances, our calculation is expected to give a fair assessment of the size of the corrections due to the full strong dynamics, and in particular to reproduce the correlations among different observables.

It is well known that, under the assumption of quark and lepton universality, short-distance corrections to the electroweak observables due to heavy new physics can be expressed in terms of four parameters, $\hat{S}$, $\hat{T}$, $W$, $Y$, defined in Ref. [47] (see also Ref. [48] for an equivalent analysis) as a generalization of the parametrization introduced by Peskin and Takeuchi in Refs. [49,50]. Two additional parameters, $\delta g_{Lb}$ and $\delta g_{Rb}$, can be added to account for the modified couplings of the $Z$ boson to left- and right-handed bottom quarks respectively. A naive estimate shows that in CH theories, including our TH model, $W$ and $Y$ are subdominant in an expansion in the weak couplings [31] and can thus be neglected. The small coupling of the right-handed bottom quark to the strong

\[ L_{\text{eff}} \supset \frac{g_2}{2c_W} Z_{\rho} \bar{b}_{\rho} b \left( (g_{Lb}^\text{SM} + \delta g_{Lb})(1 - \gamma_5) + (g_{Rb}^\text{SM} + \delta g_{Rb})(1 + \gamma_5) \right) b + \cdots \] (5.1)

where the dots stand for higher-derivative terms and $g_{Lb}^\text{SM} = -1/2 + \frac{s_W^2}{3}$, $g_{Rb}^\text{SM} = \frac{s_W^2}{3}$. 

---

\[ \xi = 0.1 \]

**FIG. 1.** IR contribution to the Higgs mass as a function of the scale $m_*$ for $\xi = 0.1$. The dot-dashed (upper) and dashed (lower) curves denote the LO and NLO result in a combined perturbative expansion in $(\alpha \log)$ and $\xi$. The dotted curve contains the pure QCD part of the NNLO correction (see Appendix C for details). The shaded region represents the uncertainty in our estimate. The central value of this band, given by the solid black line and computed as the average of the LO and NLO results, is the value that we use as our numerical estimate throughout the paper.
dynamics makes also $\delta g_{Rb}$ small and negligible in our model. We thus focus on $S$, $\tilde{T}$, and $\delta g_{Lb}$, and compute them by including effects from the exchange of vector and fermion resonances, and from Higgs compositeness.

We work at the 1-loop level and at leading order in the electroweak couplings and perform an expansion in inverse powers of the new physics scale. In this limit, the twin states do not affect the EWPO as a consequence of their being neutral under the SM gauge group. Deviations from the SM predictions arise only from heavy states with SM quantum numbers and are parametrically the same as in ordinary CH models with singlet $t_R$. This can be easily shown by means of naive dimensional analysis and symmetries as follows. Twin tops interact with the SM fields only through higher-dimensional operators. The operators relevant for the EWPO are those involving either a SM current or a derivative of the hypercharge field strength:

$$O_{Bi} = \frac{g'}{m_W^2} \partial^\mu B_{\mu\nu} t^\nu \tilde{t}, \quad O_{q1} = \frac{1}{v} \tilde{q}_L \gamma_\mu q_L t^\mu \tilde{t},$$

$$O_{Hi} = \frac{i}{v} H^\dagger D_\mu \tilde{H} t^\mu \tilde{t},$$  \hspace{1cm} (5.2)

where $\tilde{t}$ indicates either a right- or left-handed twin top. The first two operators of Eq. (5.2) are generated at the scale $m_t$ by the tree-level exchange of the $\rho_X$. Their coefficients (in a basis with canonical kinetic terms) are respectively of order $(m_W^2/m_t^2)(\tilde{y}/g_s)^2$ and $(\tilde{y}_L^2 v^2/m_t^2) \times (\tilde{y}/g_s)^2$, where $\tilde{y}$ equals either $\tilde{y}_L$ or $\tilde{y}_R$ depending on the chirality of $\tilde{t}$. The third operator breaks custodial isospin and the only way it can be generated is via the exchange of weakly coupled elementary fields at loop level. Given that the contribution to EWPO is further suppressed by $1/\tilde{t}$ loops, the third operator can affect EWPO only at, at least, two loops and is thus clearly negligible. By closing the $\tilde{t}$ loops the first two operators can give rise to effects that are schematically of the form $BB$, $B\bar{q}q$, or $(\bar{q}q)^2$. The formally quadratically divergent piece of the loop integral renormalizes the corresponding dimension-6 operators. For instance the second structure gives

$$\mathcal{C} \frac{g'}{16\pi} \frac{\tilde{y}_L^2 v^2}{m_t^2} \left( \frac{\tilde{y}}{g_s} \right)^4 \partial_\mu B^{\mu\nu} \tilde{q}_L \gamma_\mu q_L$$  \hspace{1cm} (5.3)

with $\mathcal{C}$ an $O(1)$ coefficient which depends on the details of the physics at the scale $m_t$. Using the equations of motion for $B$, the above operator gives rise to a correction to the $Zbb$ vertex of relative size $\delta g_{Rb}$. Notice that $O_{Bi}$ can be rewritten in terms of the other two operators by using the equations of motion, but it is still useful to consider it in our discussion.

The leading contribution to the $\hat{S}$ parameter arises at tree level from the exchange of spin-1 resonances. Since only the $(3,1)$ and $(1,3)$ components of the spin-1 multiplet contribute, its expression is the same as in $SO(5)/SO(4)$ composite-Higgs theories:

$$\Delta \hat{S}_p = \frac{g_{3/2}^2}{2 g_{1/2}^2} \bar{g}_s.$$  \hspace{1cm} (5.5)

In our numerical analysis presented in Sec. VI we use the two-site model relation $M_p = g_{1/2}/\sqrt{2}$ to rewrite

$$\Delta \hat{S}_p = \frac{m_W^2}{M_p^2}.$$  \hspace{1cm} (5.6)

The 1-loop contribution from loops of spin-1 and fermion resonances is subdominant (by a factor $g_{3/2}^2/16\pi^2$) and will be neglected for simplicity in the following. Nevertheless, we explicitly computed the fermionic contribution (see Appendix E) to monitor the validity of the perturbative expansion and estimate the limit of strong coupling in our model (a discussion on this aspect was given in Sec. III B). An additional threshold correction to $\hat{S}$, naively of the same order as Eq. (5.6), arises from the exchange of cutoff modes

$$O_{Hi} \sim \frac{g'}{m_W^2} \frac{\tilde{y}_L^2 v^2}{m_t^2} \left( \frac{\tilde{y}}{g_s} \right)^4$$  \hspace{1cm} (5.4)

which, even assuming $\tilde{y} \sim g_s$, is $O((g'/g_s)^2)$ suppressed with respect to the leading visible sector effect we discuss below. Aside the quadratically divergent piece there is also a logarithmic divergent piece whose overall coefficient is calculable. The result is further suppressed with respect to the above contribution by a factor $(m_t^2/m_r^2) \ln(m_t^2/m_r^2)$.

An additional contribution could in principle come from loops of the extra three “twin” NGBs contained in the coset $SO(8)/SO(7)$. Simple inspection however shows that there is no corresponding 1-loop diagram contributing to the EWPO. In the end we conclude that the effect of twin loops is negligible.

Since the effects from the twin sector can be neglected, the corrections to $\hat{S}$, $\hat{T}$, and $\delta g_{Lb}$ are parametrically the same as in ordinary CH models. We now give a concise review of the contributions to each of these quantities, distinguishing between the threshold correction generated at the scale $m_t$ and the contribution arising from the RG evolution down to the electroweak scale. For recent analyses of the EWPO in the context of $SO(5)/SO(4)$ CH models see for example Refs. [29,30,45].

A. $\hat{S}$ parameter

The leading contribution to the $\hat{S}$ parameter arises at tree level from the exchange of spin-1 resonances. Since only the $(3,1)$ and $(1,3)$ components of the spin-1 multiplet contribute, its expression is the same as in $SO(5)/SO(4)$ composite-Higgs theories

$$\Delta \hat{S}_p = \frac{g_{3/2}^2}{2 g_{1/2}^2} \bar{g}_s.$$  \hspace{1cm} (5.5)

In our numerical analysis presented in Sec. VI we use the two-site model relation $M_p = g_{1/2}/\sqrt{2}$ to rewrite

$$\Delta \hat{S}_p = \frac{m_W^2}{M_p^2}.$$  \hspace{1cm} (5.6)

The 1-loop contribution from loops of spin-1 and fermion resonances is subdominant (by a factor $g_{3/2}^2/16\pi^2$) and will be neglected for simplicity in the following. Nevertheless, we explicitly computed the fermionic contribution (see Appendix E) to monitor the validity of the perturbative expansion and estimate the limit of strong coupling in our model (a discussion on this aspect was given in Sec. III B). An additional threshold correction to $\hat{S}$, naively of the same order as Eq. (5.6), arises from the exchange of cutoff modes
The total correction to the \( \hat{S} \) parameter in our model is \( \Delta \hat{S} = \Delta \hat{S}_p + \Delta \hat{S}_b \), with the two contributions given by Eqs. (5.6) and (5.7).

**B. \( \hat{T} \) parameter**

Tree-level contributions to the \( \hat{T} \) parameter are forbidden in our model by the \( SO(3) \) custodial symmetry preserved by the strong dynamics, and can only arise via loops involving the elementary states. A non-vanishing effect arises at the 1-loop level corresponding to a violation of custodial isospin by two units. The leading contribution comes from loops of fermions and is proportional to \( y_L^2 \), given that the spurionic transformation rule of \( y_L \) is that of a doublet, while \( y_R \) is a singlet. We find:

\[
\Delta \hat{T}_\psi = a_{UV} N_c \frac{y_L^2 y_R^2 v^2}{16 \pi^2 M^2_\psi} + a_{IR} N_c \frac{y_L^2 y_R^2 v^2}{16 \pi^2 M^2_\psi} \log \frac{M^2_\psi}{m^2_\psi},
\]

where \( a_{UV,IR} \) are \( O(1) \) coefficients whose values are reported in Appendix E and we have defined \( M_1 = \sqrt{M_3^2 + y_R^2 f^2} \). The result is finite and does not depend on the cutoff scale \( m_\psi \). The first term corresponds to the UV threshold correction generated at the scale \( \mu = M_1 \sim M_\psi \). The second term instead encodes the IR running from the threshold scale down to low energy, due to loops of top quarks. In the effective theory below \( M_1 \) it corresponds to the RG evolution of the dimension-6 operator

\[
O_T = \frac{1}{2 v^2} (H^\dagger D^\mu H)^2
\]

due to insertions of the current-current operators of Eq. (5.11). In particular, \( \Delta \hat{T} = \tilde{c}_T (m_T) \tilde{\xi} \) and one has \( \gamma_{T,H} = -\gamma_{T,Hq} = \gamma_{T,Hq} = 0 \). Notice that the size of the second contribution with respect to the first is \( O(\langle y_L^2 \rangle^2 \log (M^2_3/m_3^2)) \); for \( y_L \sim y_R \), that is for fully composite \( t_R \), the IR dominated contribution is formally logarithmically enhanced and dominant.

Further contributions to \( \hat{T} \) come from loops of spin-1 resonances, the exchange of cutoff modes and Higgs compositeness. The latter is due to the modified couplings of the composite Higgs to vector bosons and reads [32]:

\[
\Delta \hat{T}_h = - \frac{3 y_L^2}{64 \pi^2} \xi \log \frac{m_3^2}{m_T^2}.
\]

In the effective theory it corresponds to the running of \( O_T \) due to the insertion of the operator \( O_H \) in a loop with hypercharge. The contribution is of the form of Eq. (5.10) with \( \gamma_{T,H} = \gamma_{T,Hq} = 3 y_L^2 / 2 \pi^2 \). The exchange of spin-1 resonances gives a UV threshold correction which is also proportional to \( y_L^2 \) (as a spurion, the hypercharge coupling transforms as an isospin triplet), but without any log enhancement. It is
thus subleading compared to Eq. (5.14) and we will neglect it for simplicity (see Ref. [45] for the corresponding computation in the context of $SO(5)/SO(4)$ models). Finally, we also omit the effect of the cutoff modes because it is incalculable, although naively this is of the same order as the contribution from states included in our simplified model. Our result is thus subject to an $O(1)$ uncertainty.

The total contribution to the $\hat{T}$ parameter in our model is therefore $\Delta \hat{T} = \Delta \hat{T}_h + \Delta \hat{T}_\Psi$ with the two contributions given by Eqs. (5.12) and (5.14).

C. $\delta g_{Lb}$

In the limit of vanishing transferred momentum, tree-level corrections to $\delta g_{Lb}$ are forbidden by the $P_{LR}$ parity of the strong dynamics that exchanges $SU(2)_L$ with $SU(2)_R$ in the visible $SO(4)$ and $SU(2)_L$ with $SU(2)_R$ in the twin $SO(4)$ (see Appendix A for details). This is a simple extension of the $P_{LR}$ symmetry of CH models which protects the $Zb\bar{b}$ coupling from large corrections [52]. In our case $P_{LR}$ is an element of the unbroken $SO(7)$ and keeps the vacuum unchanged. It is thus an exact invariance of the strong dynamics, differently from $SU(5)/SO(4)$ models where it is accidental at tree level corrections to $\delta g_{Lb}$ results from diagrams where the spin-1 resonances circulate in the loop. For simplicity we will not include such effect in our analysis (see Ref. [30] for the corresponding computation in the context of $SO(5)/SO(4)$ models). It is however easy to show that there is no possible diagram with $\rho_X$ circulating in the loop as a consequence of its quantum numbers, while the corresponding contribution from vector resonances in the adjoint of $SO(7)$ is nonvanishing in this case.

The second term in Eq. (5.17) accounts for the IR running down to the electroweak scale. In the effective theory below $M_t$ one has $\delta g_{Lb} = -\langle \bar{c}_{Hq}(m_Z) + \bar{c}_{Hq}(m_Z) \rangle /2$, hence the IR correction arises from the evolution of the operators $O_{Hq}$ and $O_{Hq}$ due to loops of top quarks. In this case the operators that contribute to the running via their 1-loop insertion are those of Eq. (5.10) as well as the following four-quark operators [53]:

$$O_{LR} = \langle \bar{q}_L \gamma^\mu q_L \rangle (\bar{t}_R \gamma^\mu t_R), \quad O_{LL} = \langle \bar{q}_L \gamma^\mu q_L \rangle (\bar{q}_L \gamma^\mu q_L), \quad O_{LL} = \langle \bar{q}_L \gamma^\mu q_L \rangle (\bar{q}_L \gamma^\mu q_L).$$

(5.18)

In fact, the operators contributing at $O(y^2 \Lambda^2)$ to Eq. (5.10) are only those generated at $O(y^2 \Lambda^2)$ at the matching scale; these are $O_{Ht}$, the linear combination $O_{Hq} - O_{Hq}$ (even under $P_{LR}$), and $O_{LR}$ (generated via the exchange of $\rho_X$). Notice finally that the relative size of the IR and UV contributions to $\delta g_{Lb}$ is $O(y_t / y_L)^2 \log (M^2_t / m^2_t)$ precisely like in the case of $\Delta \hat{T}_\Psi$.

It is interesting that in our model the fermionic corrections to $\delta g_{Lb}$ and $\hat{T}$ are parametrically of the same order and their signs tend to be correlated. It is for example well known that a heavy fermion with the quantum numbers of $SO(5)/SO(4)$ heavy fermions (the corresponding diagrams are those of Figs. 4 and 5) and reads

$$\langle \delta g_{Lb} \rangle_{\Omega} = \frac{\gamma^2}{16\pi^2} N_c \gamma^2 \mu M_{\Psi} \frac{b_{UV} + c_{UV} \log (m^2_t / M^2_{\Psi})}{M_{\Psi}}$$

(5.17)

The expressions of the $O(1)$ coefficients $b_{UV,LR}$ and $c_{UV}$ are reported in Appendix E. The first term is logarithmically divergent and encodes the UV threshold correction at the matching scale. The divergence comes, in particular, from diagrams where the fermion loop is connected to the $b$-quark current through the exchange of a spin-1 resonance [29]. A simple operator analysis shows that the threshold contribution from the vector resonances in the adjoint of $SO(7)$ identically vanishes in our model (see Appendix D for details). An additional UV threshold contribution to $\delta g_{Lb}$ arises from diagrams where the spin-1 resonances circulate in the loop. For simplicity we will not include such effect in our analysis (see Ref. [30] for the corresponding computation in the context of $SO(5)/SO(4)$ models). It is however easy to show that there is no possible diagram with $\rho_X$ circulating in the loop as a consequence of its quantum numbers, while the corresponding contribution from vector resonances in the adjoint of $SO(7)$ is nonvanishing in this case.

In this limit one has $\Delta \hat{T}_\Psi = 3(\delta g_{Lb})_{\Psi}$. However, the existence of a similar sign correlation in the limit of a light $(2,2)$ has been pointed out in the context of $SO(5)/SO(4)$ CH models, see Ref. [29].
subleading. The sign correlation can instead be broken if $\rho_X$ contributes significantly to $\delta g_{Lb}$ [in particular, $(\delta g_{Lb})_\Psi$ can be negative for $a_{Lb} = -a_{Rb}$]. The importance of the above considerations lies in the fact that EW precision data prefer a positive $\tilde{T}$ and a negative $\delta g_{Lb}$. Situations when both quantities have the same sign are thus experimentally disfavored.

Considering that no additional correction to $\delta g_{Lb}$ arises from Higgs compositeness, and that we neglect as before the in calculable effect due to cutoff states, the total contribution in our model is $\delta g_{Lb} = (\delta g_{Lb})_{\text{tree}} + (\delta g_{Lb})_{\Psi}$, with the two contributions given by eqs. (5.15) and (5.17).

VI. RESULTS AND DISCUSSION

We are now ready to translate the prediction for the Higgs mass and the EWPO into bounds on the parameter space of our simplified model and for the composite TH in general. We are interested in quantifying the degree of fine tuning that our construction suffers when requiring the Higgs mass and the EWPO into bounds on the parameter space of our simplified model and for the composite TH in $\chi^2$-parameter space. The importance of the above considerations lies in the fact that EW precision data prefer a positive $\tilde{T}$ and a negative $\delta g_{Lb}$. Situations when both quantities have the same sign are thus experimentally disfavored.

Notice indeed that ($a = 1, c = 0$) and ($a = 0, c = 1/\sqrt{2}$) correspond to specific limits at weak coupling, namely the two-site model and the linear sigma model respectively. This suggests that their natural range is $O(1)$.
95% confidence level (CL), see Appendix F for details. Solid black contours denote the regions for which \( a_{LL} = -a_{LR} = 1 \), while dashed contours surround the regions obtained with \( a_{LL} = a_{LR} = 1 \). The areas in blue are theoretically inaccessible. The lower left region in dark blue, in particular, corresponds to \( M_\Psi/f \equiv g_\Psi < y_L \). The upper dark- and light-blue regions correspond instead to points violating the perturbative limits on \( g_\Psi \) given by Eq. (3.15) with \( N = 8 \), and Eq. (3.16) with \( N_f = 24 \), respectively (see Sec. III B for a discussion). The difference between these two regions can be taken as an indication of the uncertainty associated with the perturbative bound.\(^{16}\)

In the left panel of Fig. 2 the allowed (lighter yellow) region extends up to \( \xi = 0.2 \) for masses \( M_\Psi \) in the 2–3 TeV range. Such large values of \( \xi \) are possible in this case because the fermionic contribution to \( \Delta \tilde{T}_\Psi \) turns out to be sufficiently large and positive to compensate for both the negative \( \Delta \tilde{T}_h \) in Eq. (5.14) and the positive \( \Delta \tilde{S}_p \) and \( \Delta \tilde{S}_h \) in Eqs. (5.6), (5.7). For larger \( M_\Psi \) the fermionic contribution \( \Delta \tilde{T}_\Psi \) becomes too small and this compensation no longer occurs. In this case, however, the strongest bound comes from the perturbativity limit (blue region), which makes points with large \( M_\Psi \) at fixed \( \xi \) theoretically inaccessible. Notice that large values of \( \xi \) become excluded if one considers the choice \( a_{LL} = a_{LR} = 1 \) leading to the dashed contour. The large difference between the solid and dashed curves (i.e. lighter and darker yellow regions) depends on

\(^{16}\)Notice that because of our choice \( m_s = 2M_\Psi \), the scale \( m_s \) lies a factor of 2 above the perturbative cutoff. This is compatible with the semiquantitative nature of our estimates. As we stated previously we insisted in keeping \( m_s = 2M_\Psi \) because it implies a more generic contribution to electroweak precision observables.

The sign correlation between \( \Delta \tilde{T}_\Psi \) and \( \delta g_{Lb} \). In the case of the solid line, the signs are anticorrelated (e.g., positive \( \Delta \tilde{T}_\Psi \) and negative \( \delta g_{Lb} \)), allowing for the compensation effect by \( \Delta \tilde{T}_\Psi \). In the case of the dashed line, instead, the signs of the two parameters are correlated (both positive), so that when \( \Delta \tilde{T}_\Psi \) is large, \( \delta g_{Lb} \) is also large and positive. This makes it more difficult to pass the \( \chi^2 \) test, since data prefer a negative \( \delta g_{Lb} \).

In the right panel of Fig. 2, obtained with \( F_1 = 1 \), the allowed yellow region shrinks because the larger value of \( F_1 \) implies a smaller \( y_L \) hence a smaller \( \Delta \tilde{T}_\Psi \). In this case the \( \chi^2 \) test is passed only for \( \xi \leq 0.06 \), and the difference between the solid and dashed lines is small since the large and positive \( \Delta \tilde{S} \) always dominates the fit. Masses \( M_\Psi \) larger than \( \sim 5 \) TeV are excluded by the perturbative bound, unless one considers smaller values of \( \xi \).

The results of Fig. 2 can change significantly if the parameter \( c \) is allowed to be different from zero. In particular, as one can verify from our formulas in Appendix E, positive values of \( c \) increase \( \Delta \tilde{T} \) and as a result the allowed regions in Fig. 2 shift to the right toward larger values of \( M_\Psi \). In this case the perturbative bound excludes a large portion of the region passing the \( \chi^2 \) test. The effect of varying \( c \) is illustrated in Fig. 3, which shows the 95% CL allowed regions in the plane \( (c, \alpha) \) for \( F_1 = 0.3 \) (left panel) and \( F_1 = 1 \) (right panel). In both panels we have set \( \alpha = a_{LL} = -a_{LR} \) (ensuring positive \( \Delta \tilde{T}_\Psi \) and negative \( \delta g_{Lb} \)). The yellow, orange, and red regions correspond, respectively, to \( \xi = 0.05 \), \( \xi = 0.1 \), and \( \xi = 0.15 \), with the masses of the resonances fixed at their perturbative upper bound \( M_\rho = M_\Psi = 4\pi f / \sqrt{N} - 2 \) (which for \( N = 8 \) gives \( \sim 6/4/3.2 \) TeV). Note that
increasing $F_1$ (reducing $y_L$) shifts the allowed region toward positive values of $c$, since as mentioned above, smaller $y_L$ requires a larger positive $c$ to get a large enough $\Delta T_\Psi$. Obviously, larger values of $\xi$ correspond to smaller allowed regions, as is clear from Fig. 2. Finally, notice that the vertically symmetric structure of the allowed regions is due to the quadratic dependence of $\delta g_{Lb}$ on $\alpha$. From these plots, one can see that for resonances conceivably out of direct reach of the LHC and for $\xi \sim 0.1$, corresponding to about 20% tuning of the Higgs mass, both $\alpha$ and $c$ are allowed to span a good fraction of their expected $O(1)$ range. No dramatic extra tuning in these parameters seems therefore necessary to meet the constraints of EWPT. In particular, considering the plot for $F_1 = 1$ (right panel), one notices that the bulk of the allowed region is at positive $c$. For instance by choosing $c \sim 0.2$–0.5 the plot in the $(\xi, M_\Psi)$ plane for $F_1 = 1$ becomes quite similar to the one at the left of Fig. 3 valid for $F_1 = 0.3$: there exists a “peak” centered at $M_\Psi \sim 2$–4 TeV and extending up to $\xi \sim 0.2$. The specific choice $c = 0$ is thus particularly restrictive for $F_1 = 1$ (right panel of Fig. 2), but this restriction is lifted for positive $c$. Overall we conclude that for $\xi \sim 0.1$ and for resonances just beyond the LHC reach, the correct value of the Higgs quartic can be obtained and EWPT passed with only a mild additional tuning associated with a sign correlation $\alpha_{4L} = -\alpha_{4R}$, and a correlation between $c$ and $F_1$ (e.g. $c > 0$ for $F_1 = 1$). These correlations allow the various contributions to $\hat{T}$ and $\delta g_{Lb}$ to compensate for each other, achieving agreement with EWPT. If forced to quantify the tuning inherent in these effects, we could estimate it to be around $1/4 = (1/2) \times (1/2)$, given about $1/2$ of the plausible choices for both $\alpha_i$ and $c_i$ are allowed.

**VII. SUMMARY**

In this paper we tried to assess how plausible a scenario yielding no new particles at the LHC can be obtained using the TH construction. We distinguished three possible classes of models: the subhypersoft, the hypersoft and the superhypersoft, with increasing degree of technical complexity and decreasing (technical) fine tuning. We then focused on the CH incarnation of the simplest option, the subhypersoft scenario, where the boost factor for the mass of colored partners [Eq. (2.4)] at fixed tuning is roughly given by

$$\frac{g_t}{\sqrt{2} y_t} \times \frac{1}{\sqrt{\ln(m_t/m_t)}},$$

(7.1)

Here the gain derives entirely from the relative coupling strength $g_t/\sqrt{2} y_t$, making the marriage of twinning and compositeness practically obligatory. We attempted a more precise estimate of the upper limit on $g_t/\sqrt{2} y_t$, as compared with previous studies (e.g. Ref. [13]). We found by independent but consistent estimates, that the bound ranges from $\sim 3$ in a toy sigma model [Eq. (2.6)] to $\sim 5$ in a simplified CH model [Eq. (3.15)], with both limits somewhat below the NDA estimate of $4 \pi \sim 12$. Consequently for a mild tuning $c \sim 0.1$ the upper bound on the mass of the resonances with SM quantum numbers is closer to the 3–5 TeV range than it is to 10 TeV. This gain, despite...
being less spectacular than naively expected, is still sufficient to push these states out of direct reach of the LHC, provided we resort to full strong coupling. In practice this implies no real computational advantage from considering holographic realizations of composite TH constructions: since the boost factor is controlled by the KK coupling, the 5D description breaks down in precisely the most interesting regime, where the KK coupling is strong. In this situation computations based on an explicit 5D construction, such as the ones studied in Refs. [9,16] for instance, are no better than numerical estimates made in our simplified model. Indeed we have checked that EWPT can be satisfied in a sizable portion of the parameter space, given some interplay among the various contributions. In particular the IR corrections to $\hat{T}$ and $\hat{S}$ are enhanced by $\ln(m_s/m_h)$, and for $\xi > 0.1$ the compensating contribution to $\hat{T}$, which decreases like $1/m_s^2$, is necessary. Given that perturbativity limits $m_s$ to be below 5 TeV for $\xi > 0.1$ (see the upper blue exclusion region in Fig. 2) this compensation in EWPT can still take place at the price of a moderate extra tuning. For $\xi$ of order a few percent on the other hand, EWPT would be passed without any additional tuning, while the masses of SM-charged resonances would be pushed up to the 10 TeV range, where nothing less than a 100 TeV collider would be required to discover them, and that barely so [58,59].

Although EWPT work similarly in the CH and composite TH frameworks, the two are crucially different when it comes to contributions to the Higgs quartic. In the CH these are enhanced when $g_s$, i.e. $m_{\sigma}/f$, is strong and, as discussed for instance in Ref. [33], in order to avoid additional tuning of the Higgs quartic $g_s$ cannot be too large. According to the study in Refs. [60–63] the corresponding upper bound on the mass of the colored top partners in CH reads roughly $m_\tau/f \lesssim 1.5$; this should be compared to the upper bound $m_\tau/f \lesssim 5$ from strong coupling we found in Eq. (3.15). The Higgs quartic protection afforded by the TH mechanism allows us to take $m_\tau/f$ as large as possible, allowing the colored partners to be heavier at fixed $f$, hence at fixed fine tuning $\xi$. In the end the gain is about a factor of $5/1.5 \sim 3$, not impressive, but sufficient to place the colored partners outside of LHC reach for a mild tuning $\xi \sim 0.1$.

Finally, we comment on the classes of models not covered in this paper: the hypersoft and superhypersoft scenarios. The latter requires combining supersymmetry and compositeness with the TH mechanism, which, while logically possible, does not correspond to any existing construction. Such a construction would need to be rather ingenious, and we currently do not feel compelled to provide it, given the already rather epicyclic nature of the TH scenario. The simpler hypersoft scenario, though also clever, can by contrast be implemented in a straightforward manner, via, e.g., a tumbling $SO(9) \rightarrow SO(8) \rightarrow SO(7)$ pattern of symmetry breaking. The advantage of this approach is that it allows us to remain within the weakly-coupled domain, due to the presence of a relatively light twin Higgs scalar mode $\sigma$, whose mass can be parametrically close to that of the twin tops, $\sim y_{\tau} f$ (around 1 TeV for $\xi \sim 0.1$). As well as giving rise to distinctive experimental signatures due to mixing with the SM Higgs [64], the mass of the light $\sigma$ acts as a UV cutoff for the IR contributions to $\hat{S}$ and $\hat{T}$ in Eqs. (5.7) and (5.14) [12]. For sufficiently light $\sigma$ then, less or no interplay between the various contributions is required in order to pass EWPT. Together with calculability, this property may well single out the hypersoft scenario as the most plausible TH construction.

ACKNOWLEDGMENTS

APPENDIX A: $SO(8)$ GENERATORS AND CCWZ VARIABLES

In this Appendix we define the generators of the $SO(8)$ algebra and describe the $SO(8)/SO(7)$ symmetry-breaking pattern, introducing the CCWZ variables for our model. We refer the reader to Refs. [41,42] for a detailed analysis of this procedure and we closely follow the notation of Ref. [13].

We start by listing the twenty-eight generators of $SO(8)$ and decomposing them into irreducible representations of the unbroken subgroup $SO(7)$: $28 = 7 \oplus 21$. They can be compactly written as:

$$ (T_{ij})_{kl} = \frac{i}{\sqrt{2}}(\delta_{ik}\delta_{jl} - \delta_{il}\delta_{jk}). $$

with $i,j,k,l = 1, \ldots, 8$. We choose to align the vacuum expectation value responsible for the spontaneous breaking of $SO(8)$ to $SO(7)$ along the 8th component: $\phi_0 = (0, 0, 0, 0, 0, 0, 1)'$. With this choice, the broken and unbroken generators, transforming, respectively, in the $7$ and $21$ of $SO(7)$, are
\begin{align}
(T_{\mu})_{\tau\rho} &= \frac{i}{\sqrt{2}} (\delta_{\mu\rho} \delta_{\nu\tau} - \delta_{\mu\tau} \delta_{\nu\rho}), \\
(T_{\mu})_{\tau\rho}^{21} &= \frac{i}{\sqrt{2}} (\delta_{\mu\rho} \delta_{\nu\tau} - \delta_{\mu\tau} \delta_{\nu\rho}),
\end{align}

where \( \alpha, \beta = 1, \ldots, 7 \) and \( \gamma, \rho = 1, \ldots, 8 \). It is useful to identify the subgroups \( SO(4) \sim SU(2)_L \times SU(2)_R \) and \( \tilde{SO}(4) \sim SU(2)_L \times SU(2)_R \) of \( SO(8) \); they are generated by:

\begin{align}
(T_L)^a &= \begin{pmatrix} t_L^a & 0 \\ 0 & 0 \end{pmatrix}, \\
(T_R)^a &= \begin{pmatrix} t_R^a & 0 \\ 0 & 0 \end{pmatrix}, \\
(t_L)^a &= \begin{pmatrix} 0 & 0 \\ 0 & t_L^a \end{pmatrix}, \\
(\bar{t}_L)^a &= \begin{pmatrix} 0 & t_L^a \\ 0 & 0 \end{pmatrix},
\end{align}

where \( t_L^a \) and \( t_R^a \) are \( 4 \times 4 \) matrices defined as

\begin{align}
(t_L^a)_{ij} &= -\frac{i}{2} \left[ 1 - i e^{\alpha \rho} (\delta_i^\alpha \delta_j^\rho - \delta_i^\rho \delta_j^\alpha) \right]
\end{align}

with \( \alpha = 1, 2, 3 \) and \( i, j = 1, \ldots, 4 \). The elementary SM and twin vector bosons gauge, respectively, a subgroup \( SU(2)_L \times U(1)_Y \) of \( SO(4) \), with \( U(1)_Y \equiv U(1)_{E_8} \), and the subgroup \( SU(2)_L \) inside \( SO(4) \). This choice corresponds to having zero vacuum misalignment at tree level.

The spontaneous breaking of \( SO(8) \) to \( SO(7) \) delivers seven NGBs, that we collect in the vector \( \Pi = (\pi_2, x_1, -x_3, x_4, \tilde{x}_2, \tilde{x}_1, -\tilde{x}_3) \). The first four transform as a fundamental of \( SO(4) \) and form the Higgs doublet; the remaining three are singlets of \( SO(4) \) and are thus neutral under the SM gauge group. All together they can be arranged in the Goldstone matrix

\begin{align}
\Sigma(\Pi) &= e^{i(\Pi^a T^a)} \\
&= \begin{pmatrix}
\frac{\im}{\sqrt{2}} & \frac{\Pi}{\sqrt{2}} (1 - \cos \left( \frac{\sqrt{N} T^a}{f} \right)) & \frac{\Pi}{\sqrt{2}} \sin \left( \frac{\sqrt{N} T^a}{f} \right) \\
-\frac{\Pi}{\sqrt{2}} \sin \left( \frac{\sqrt{N} T^a}{f} \right) & \cos \left( \frac{\sqrt{N} T^a}{f} \right)
\end{pmatrix}.
\end{align}

The latter transforms nonlinearly under the action of an \( SO(8) \) group element \( g \), according to the standard relation:

\begin{align}
\Sigma(\Pi) \rightarrow g \cdot \Sigma(\Pi) \cdot h^\dagger(\Pi, g),
\end{align}

where \( h(\Pi, g) \in SO(7) \) depends on \( g \) and \( \Pi(x) \). We identify the Higgs boson with the NGB along the generator \( T_L^1 \); in the unitary gauge, all the remaining NGBs are nonpropagating fields and the \( \Pi \) vector becomes

\begin{align}
\Pi|_{\text{unitary gauge}} = (0, \ldots, x_4 = \langle h \rangle + h(x), \ldots, 0).
\end{align}

where \( \xi = \sin^2(\langle h \rangle / f) = v^2 / f^2 \). In this case the \( \Sigma \) matrix simplifies to:

\begin{align}
\Sigma(\Pi)|_{\text{unitary gauge}} &= e^{i(\Pi^a T^a)} \\
&= \begin{pmatrix}
\frac{\im}{\sqrt{2}} & 0 & 0 & 0 \\
0 & \cos \frac{\Pi}{f} & 0 & \sin \frac{\Pi}{f} \\
0 & 0 & \frac{\im}{\sqrt{2}} & 0 \\
0 & -\sin \frac{\Pi}{f} & 0 & \cos \frac{\Pi}{f}
\end{pmatrix}.
\end{align}

Given the above symmetry breaking pattern, it is possible to define a LR parity,

\begin{align}
P_{LR} = \text{diag}(-1, -1, -1, +1, -1, -1, +1),
\end{align}

which exchanges \( SU(2)_L \) with \( SU(2)_R \) inside \( SO(4) \) and \( SU(2)_L \) with \( SU(2)_R \) inside \( \tilde{SO}(4) \). The corresponding action on the fields is such that \( x_4 \) is even, while all the other NGBs are odd. As already noticed in Sec. \( \text{V C} \), \( P_{LR} \) is an element of both \( SO(8) \) and \( SO(7) \), which means that it is an exact symmetry of the strong dynamics and acts linearly on the physical spectrum of fields.

The CCWZ variables \( d_\mu \) and \( E_\mu \) are defined as usual through the Maurer-Cartan form,

\begin{align}
\Sigma'(\Pi) D_\mu \Sigma(\Pi) \equiv i d_\mu(\Pi) T_\mu^a + i E_\mu(\Pi) T_\mu^{21},
\end{align}

as the components along the broken and unbroken generators of \( SO(8) \) respectively. The derivative \( D_\mu \) is covariant with respect to the external SM and twin gauge fields:

\begin{align}
D_\mu = \partial_\mu - i A^A_\mu T^A, \quad \text{with} \\
A^A_\mu T^A &= g_2 W_\mu^a (T_L^a)^\mu + g_1 B_\mu (T_R)^3 + g_2 \tilde{W}_\mu^a (\bar{T}_L)^a.
\end{align}

Under the action of a global element \( g \in SO(8) \), \( d_\mu \) and \( E_\mu \) transform with the rules of a local \( SO(7) \) transformation:

\begin{align}
d_\mu \rightarrow d_\mu g h(\Pi, g), \\
E_\mu \rightarrow E_\mu g (E_\mu - i \partial_\mu) h(\Pi, g).
\end{align}

It is straightforward to derive the explicit expressions of \( d_\mu \) and \( E_\mu \) from the Maurer-Cartan relation in Eq. (A10). They are however lengthy and not very illuminating, so we do not report them here. We can easily obtain the mass spectrum of the gauge sector of our theory from the NGB kinetic term;
in the unitary gauge and after rotating to the mass eigenstate basis, we find:

\[
\mathcal{L}_\text{mass} = \frac{f^2}{4} (d^\mu d^\nu \partial \xi^\mu \partial \bar{\psi}^\nu + (g^2 + g_s^2) \frac{3}{8} f^2 \xi Z^\mu Z_\mu \\
+ \frac{g^2}{8} f^2 (1 - \xi) \sum_{i=1}^3 (\bar{W}_i^i)^2. \tag{A13}
\]

**APPENDIX B: MASS MATRICES AND SPECTRUM**

In this Appendix, we briefly discuss the mass matrices of the different charged sectors in the composite TH model and the related particle spectrum. We refer to Ref. [13] for the expressions of the \( \Psi_7 \) and \( \bar{\Psi}_7 \) multiplets in terms of their component heavy fermions.

We start by considering the fields that do not have the right quantum numbers to mix with the elementary SM and twin quarks and whose mass is therefore independent of the mixing parameters \( y_{L,R} \) and \( \bar{y}_{L,R} \). These are the composite fermions \( X_{5/3}, D_1 \) and \( D_{-1} \), with charges \( 5/3, 1 \) and \( -1 \) respectively; their mass is exactly given by the Lagrangian parameters \( M_\psi \) (for the first one), and \( \tilde{M}_\psi \) (for the last two).

The remaining sectors have charge \(-1/3, 0, \) and \( 2/3 \) and because of the elementary/composite mixing the associated mass matrices are in general nondiagonal and must be diagonalized by a proper field rotation. The simplest case is the \((-1/3)\)-charged sector, containing the bottom quark and the heavy \( B \) field; the mass matrix in the \( \{b, B\} \) basis is

\[
M_{-1/3} = \begin{pmatrix}
0 & fy_L \\
\bar{y}_L & -\tilde{M}_\psi
\end{pmatrix}. \tag{B1}
\]

After rotation, we find a massless bottom quark (it has no mass since we are not including the \( b_R \) in the model), and a massive \( B \) particle with \( m_B^2 = \tilde{M}_\psi^2 + f_Y^2 f^2 \).

As regards the sector of charge \( 2/3 \), it contains seven different particles: the top quark, the toplike heavy states \( T \) and \( X_{2/3} \) and four composite fermions that do not participate in the SM weak interactions, \( S_{2/3}^1 \), \( S_{2/3}^2 \), \( S_{2/3}^3 \), \( S_{2/3}^4 \). In the \( \{t, T, X_{2/3}, S_{2/3}^1, S_{2/3}^2, S_{2/3}^3, S_{2/3}^4\} \) basis, the mass matrix is given by:

\[
M_{2/3} = \begin{pmatrix}
0 & \frac{1}{2} fy_L (\sqrt{1 - \xi} + 1) & -\frac{1}{2} fy_L (\sqrt{1 - \xi} - 1) & \frac{f y_L \sqrt{2}}{2} & 0 & 0 \\
0 & -\tilde{M}_\psi & 0 & 0 & 0 & 0 \\
0 & 0 & -\tilde{M}_\psi & 0 & 0 & 0 \\
f y_R & 0 & 0 & -\tilde{M}_\psi \times \mathbb{I}_3 & 0 \\
f y_R & 0 & 0 & 0 & -M_S
\end{pmatrix}. \tag{B2}
\]

The states \( S_{2/3}^1, S_{2/3}^2, S_{2/3}^3 \) completely decouple from the elementary sector and do not mix with the top quark. Their mass is therefore exactly given by the Lagrangian parameter \( M_\psi \). The remaining \( 4 \times 4 \) matrix is in general too complicated to be analytically diagonalized, but one can easily find the spectrum in perturbation theory by expanding \( M_{2/3} \) for \( \xi \ll 1 \), which is in general a phenomenologically viable limit. The leading order expression for the masses is then:

\[
m_t^2 = f_Y^2 y_L^2 y_R^2 f^2 \xi + O(\xi^2),
\]

\[
m_{X_{2/3}}^2 = M_\psi^2,
\]

\[
m_T^2 = M_\psi^2 + y_L^2 f^2 \left(1 - \frac{\xi}{2}\right) + O(\xi^2),
\]

\[
m_{S_{2/3}^3}^2 = M_S^2 + y_R^2 f^2 + \frac{y_L^2 f^2 M_\psi^2}{2(M_S^2 + y_R^2 f^2)} \xi + O(\xi^2). \tag{B3}
\]

The \( X_{2/3} \) fermion can be also decoupled and its mass is exactly equal to \( M_\psi \). On the contrary, the other three particles mix with each other and their mass gets corrected after EWSB (as expected, the top mass is generated for nonzero values of \( \xi \)).

Finally, we analyze the neutral sector of our model. It comprises eight fields, the twin top and bottom quarks, and six of the composite fermions contained in the \( \bar{\Psi}_7 \) multiplet. Working in the field basis \( \{t, \bar{b}, \bar{D}_0^l, \bar{D}_0^r, \bar{U}_0^l, \ldots, \bar{U}_0^l\} \), the mass matrix reads:
After diagonalization, we find one massless eigenvalue corresponding to the twin bottom quark (it does not acquire mass since we are not introducing the \( \tilde{b}_R \) field). Four of the neutral heavy fermions completely decouple and acquire the following masses

\[
m_{U_0}^2 = m_{U_0}^2 = m_{D_0}^2 = \tilde{M}_q, \quad m_{U_0}^2 = \tilde{M}_q^2 + \tilde{y}_R^2 f^2. \tag{B5}
\]

The elementary/composite mixing induces instead corrections to the masses of the remaining neutral particles; at leading order in \( \xi \) we find:

\[
m_i^2 = \frac{f^4}{2} \frac{\tilde{y}_L^2 \tilde{y}_R^2}{M_S^2 + \tilde{y}_R^2 f^2} (1 - \xi) + O(\xi^2),
\]

\[
m_{D_0}^2 = \tilde{M}_q^2 + \frac{1}{2} \tilde{y}_L^2 f^2 (1 + \xi) + O(\xi^2),
\]

\[
m_{U_0}^2 = \tilde{M}_q^2 + \tilde{y}_R^2 f^2 + \frac{\tilde{y}_L^2 f^2 \tilde{M}_q^2}{2(M_S^2 + \tilde{y}_R^2 f^2)} (1 - \xi) + O(\xi^2). \tag{B6}
\]

We conclude by noticing that the masses of the particles in different charged sectors are not unrelated to each other, but must be connected according to the action of the twin symmetry. In particular, it is obvious that the two singlets \( S_{2/3}^1 \) and \( U_0^4 \) form an exact twin pair, as it is the case for each SM quark and the corresponding twin partner. The remaining pairs can be easily found from the spectrum and correspond to the implementation of the twin symmetry in the composite sector as defined in [13].

**APPENDIX C: RG IMPROVEMENT OF THE HIGGS EFFECTIVE POTENTIAL**

In this Appendix we describe the computation of the Higgs effective potential and its RG improvement. First of all, the UV threshold correction can be computed with a standard Coleman-Weinberg (CW) procedure, from which we can easily derive the function \( F_t \) of Eq. (4.2).

We find:

\[
F_t = -\frac{1}{4} \left[ 1 + \frac{\hat{M}_q^4}{(\hat{M}_q^2 + \hat{y}_R^2 f^2)^2} \frac{\hat{M}_q^2 + \hat{y}_R^2 f^2}{\hat{M}_q^2 - \hat{y}_R^2 f^2} \log \frac{m_0^2}{\hat{M}_q^2} \right. \\
+ \frac{\hat{M}_q^2 (\hat{M}_q^2 + \hat{y}_R^2 f^2) + \hat{y}_R^2 f^2 \hat{M}_q^2}{(\hat{M}_q^2 + \hat{y}_R^2 f^2)(\hat{M}_q^2 - \hat{y}_R^2 f^2)} \log \frac{m_0^2}{\hat{M}_q^2 + \hat{y}_R^2 f^2} \right]. \tag{C1}
\]

The IR contribution to the Higgs mass can be organized using a joint expansion in \( \xi \) and \( (\alpha_i, \log) \), where \( \alpha_i = g_i^2 / (4\pi) \) for couplings \( g_i \). Schematically:

\[
\delta m_i^2|_{IR} = m_i^2 \frac{\alpha_i}{4\pi} \left[ a_1 + b_1 \xi + b_2 \frac{\alpha_i}{4\pi} t + b_3 \frac{\alpha_i}{4\pi} t + c_1 \xi^2 + c_2 \xi + c_3 \frac{\alpha_i}{4\pi} t + c_4 \right. \\
+ c_5 \frac{\alpha_i}{4\pi} t + c_6 \frac{\alpha_i}{4\pi} t^2 + c_7 \frac{\alpha_i}{4\pi} t^2 \left] - a_2 m_w^2 \frac{\alpha_{EW}}{4\pi} t + \text{twin}. \tag{C2}
\]
where $t = \log \frac{m^2}{m_t^2}$ and all the couplings are evaluated at the scale $m_t$. Here $a_i$, $b_i$, $c_i$ are the $O(1)$ coefficients of the LO, NLO, and NNLO terms respectively. The twin contribution is obtained by substituting all $a_i$, $a_i$, $b_i$, $c_i$ with the corresponding tilded quantities and $t$ with $\tilde{t} = \log \frac{m^2}{m_t^2}$.

The calculation of the LO and NLO terms is straightforward and all these contributions are included in our calculation. The NNLO terms indicated in blue are also simple to evaluate, and are included in our final result, indicated as NNLO*. The calculation of the remaining NNLO terms is more complicated, since it involves the running of several higher dimensional operators involving both the SM and twin fields. An attempt to compute the full potential at NNLO has been presented in Ref. [46]. However, while that result includes the contribution of the SM Goldstone bosons, additional contributions induced by the twin Goldstones, which are expected to arise at NNLO, are not included. Since the full calculation at NNLO is beyond the scope of this paper, we limit ourselves to only include the colored contributions in Eq. (C2). Comparing with Ref. [46] suggests that our NNLO* result gives an overestimate of the IR Higgs mass; that this is the case at large $m_t$ is also evident from Fig. 1. For this reason we consider the NNLO* curve only as an indication of the importance of the NNLO correction, and use as final input for our numerical analysis the average of the LO and NLO results as described in Sec. IV.

We present now a procedure for computing the aforementioned contributions to the Higgs mass based on the approach of Ref. [46]. The RG improvement of the Higgs effective potential can be obtained by solving the one-loop $\beta$-function of the vacuum energy in the background of the Higgs field. The fermion contribution to the vacuum energy is given by

$$\frac{dV_f(h_c,t)}{dt} = \frac{N_c}{16\pi^2} [M_1(h_c,t)^4 + M_1(h_c,t)^4], \quad (C3)$$

whereas the leading gauge contribution is given by

$$V_g(h_c,t) = \frac{3}{16\pi^2} [2M_W(h_c)^2 + M_Z(h_c)^2 + 3M_W(h_c)^2]t. \quad (C4)$$

In order to compute the improved potential to NNLO* accuracy, we must input the gauge boson masses at tree-level and the renormalized top and twin top masses with leading-log accuracy in the corresponding Yukawa couplings and with next-to-leading-log accuracy in the strong gauge couplings. After solving Eq. (C3) for the effective potential, one must properly account for the Higgs wave function renormalization before expanding around the minimum of the potential in order to compute the physical Higgs mass. We fill in the salient details below.

On integrating out the heavy degrees of freedom, the composite twin Higgs model at the scale $m_t$ can be represented by an effective Lagrangian that is invariant under a global $SU(3)_c \times SU(2)_L \times U(1)_Y$ symmetry, identified with the gauge group of the SM, as well as an additional $SU(3)_c \times SU(2)_{L+R} \times SU(3)_c$ is the gauged twin color and $SU(2)_{L+R}$ is a global twin custodial group, broken only by fermion interactions, under which the twin gauge bosons ($W$) and Goldstone bosons (GBs) transform as triplets. We work in the gaugeless limit $g = g' = g = 0$, since we are only interesting in capturing the leading contributions to the Higgs potential that parametrically depend on $y_t$, $\tilde{y}_t$, $g_S$, and $\tilde{g}_S$.

The relevant light degrees of freedom are the SM fermion doublet, $Q_L$, and singlet, $t_R$, and their twin counterparts $\tilde{t}_L$ and $\tilde{t}_R$, the gluons and their twins; the Higgs doublet (including the massless GBs) and the twin GBs. For economy of notation we define a twin Higgs doublet in analogy with the SM one,

$$\tilde{H} = \frac{1}{\sqrt{2}} \left( \sqrt{\frac{\sqrt{2} g}{\tilde{h} + i \tilde{\pi}}} \right), \quad \text{with} \quad \tilde{h} = f \sqrt{1 - \frac{2H^2 + \tilde{\pi}^2}{f^2}}, \quad (C5)$$

making explicit the dependence on the twin Higgs which is integrated out at tree-level, thus realizing the $SO(8)$ symmetry nonlinearly.

Since the background field calculation at leading-log order requires corrections to the fermion masses and Higgs wave function at only one loop, we can neglect in the effective Lagrangian at the scale $m_t$, any operator that has vanishing coefficients at tree level. We also omit all operators that cannot be predicted solely in terms of the low-energy parameters of the theory ($y_t$ and $\tilde{y}_t$) and $f$, including products of Higgs and fermion currents that arise from integrating out composite fermions.\footnote{In any case, these do not contribute to the effective potential at this order.}

We make the following field redefinition:

$$f \sin \frac{\Pi}{f} \rightarrow \Pi', \quad \text{for} \quad |\Pi| = \sqrt{2H^2 + \tilde{\pi}^2} \quad (C6)$$

which allows the effective Lagrangian, containing a pure scalar sector $L_S$ and a fermionic sector $L_F$, to be expressed in an especially compact form. The relevant operators in each sector are given below:

$$L_S = \mathcal{D}_\mu H^\dagger \mathcal{D}^\mu H + \frac{1}{2} \partial_\mu \tilde{\pi} \partial^\mu \tilde{\pi} + c_{H} \mathcal{O}_H + c_{H3} \mathcal{O}_{H_H H} + c_{H2} \mathcal{O}_{H_H H}$$

$$+ 2d_H \frac{H^\dagger H}{f^2} \mathcal{O}_H, \quad (C7)$$
Yukawa couplings are defined at tree-level as
\[ y_L(m_s) = \frac{y_L y_R f}{\sqrt{m_S^2 + y_R^2 t^2}} \quad \text{and} \quad \tilde{y}_L(m_s) = \frac{y_L y_R f}{\sqrt{m_S^2 + y_R^2 t^2}}, \]

where
\[
O_H = \partial_{\mu}(H^+ H)\partial^\mu(H^+ H),
O_H^* = \partial_{\mu}\bar{\pi}^2\partial^\mu\pi^2,
O_{H\tilde{H}} = \partial_{\mu}(H^+ H)\partial^\mu\bar{\pi}^2. \tag{C9}
\]

We have defined a twin fermion doublet \( \tilde{Q}_L = (\tilde{t}_L, \tilde{b}_L)^T \), transforming under the twin-sector symmetries, and the Yukawa couplings are defined at tree-level as
\[ y_L(m_s) = \frac{y_L y_R f}{\sqrt{M_S^2 + y_R^2 t^2}} \quad \text{and} \quad \tilde{y}_L(m_s) = \frac{y_L y_R f}{\sqrt{M_S^2 + y_R^2 t^2}}. \tag{C10} \]

The Wilson coefficients at the scale \( m_s \) have the boundary values:
\[ c_H(m_s) = c_{\tilde{H}}(m_s) = c_\mu(m_s) = d_H(m_s) = 1, \tag{C11} \]

while the \( Z_2 \) symmetry enforces
\[ y_i(m_s) = \tilde{y}_i(m_s) \quad \text{and} \quad \alpha_i(m_s) = \tilde{\alpha}_i(m_s). \tag{C12} \]

We now expand the effective Lagrangian in the background of the Higgs field \( h = h_c + \hat{h} \) to obtain:
\[ \mathcal{L}_S = Z_\psi(h_c) \left( \frac{1}{2} \partial_\mu \pi^0 \partial^\mu \pi^0 + \partial_\mu \pi^+ \partial^\mu \pi^- \right) + \frac{1}{2} Z_{\tilde{H}}(h_c) \partial_\mu \bar{\pi} \partial^\mu \bar{\pi}, \tag{C13} \]

where we defined
\[ Z_\psi(h_c) = 1, \quad Z_{\tilde{H}}(h_c) = 1 + c_H \frac{h_c^2}{f^2} + d_H \frac{h_c^4}{f^4}, \tag{C14} \]

and
\[ Z_{\tilde{H}}(h_c) = 1, \quad Z_{\tilde{H}}(h_c) = 1 + c_H \frac{h_c^2}{f^2} + d_H \frac{h_c^4}{f^4}, \tag{C14} \]

We can now compute the running masses of the top and twin top in the background:
\[ M_t(h_c, t) \approx m_t(h_c) \left[ 1 + \frac{g_5^2}{4\pi^2} - \frac{3y_t(h_c)^2}{4(4\pi)^2} \right], \tag{C17a} \]
\[ M_{\tilde{t}}(h_c, t) \approx m_{\tilde{t}}(h_c) \left[ 1 + \frac{g_5^2}{4\pi^2} - \frac{3\tilde{y}_t(h_c)^2}{4(4\pi)^2} \right], \tag{C17b} \]

with \( t = \log(m_s^2/\mu^2) \). The values of the parameters in the Higgs background are simply read off from the effective Lagrangian at the scale \( m_s \). Notice that in the background, only \( y_i \) and \( \tilde{y}_i \) are scale-dependent, while \( h_c \) is “frozen”; hence the running of the quark mass is identical to that of the corresponding Yukawa coupling.
We can now substitute Eqs. (C17) into the RG equation (C3), integrate the result and expand at the required order in $h_c/f$ to get

\[
V_f(h_c, t)^{\text{IR}} = \frac{N_c}{64\pi^2} \left\{ y^2_i h^4_c + \tilde{y}^2_4 f^4 \left( 1 - \frac{h^2_c}{f^2} \right)^2 \right\} t + \frac{y^2_i h^4_c}{2} \left( \frac{\tilde{g}^2_3}{\pi^2} - \frac{3 \tilde{g}^2_2}{\pi^2} - \frac{3 \tilde{g}^2_1}{\pi^2} \right) t^2
\]

\[+ \frac{23}{96\pi^2} \left[ \tilde{g}^2_3 y^2_i h^4_c + \tilde{g}^2_2 \tilde{y}^2_4 f^4 \left( 1 - \frac{h^2_c}{f^2} \right)^2 \right] t^3
\]

\[+ \frac{\tilde{y}^2_4 f^4}{32\pi^2} \left( 1 - \frac{h^2_c}{f^2} \right)^2 \left[ 16 \tilde{g}^2_3 - 3 \tilde{g}^2_2 \left( 1 - (1 + c_H) \frac{h^2_c}{f^2} \right) \right] t^4. \tag{C18}
\]

This is the improved effective potential written in terms of parameters computed at the scale $m$. We can now treat $h_c$ as a quantum field, fluctuating around its minimum $h_c = h + \langle h \rangle$. We then have to take into account that the potential (C18) has been computed in a noncanonical basis for $h_c$, where its kinetic term coefficient, including only the leading logarithmic running, is

\[
Z_{h_c}(t) = 1 + \frac{3 y^2_i}{(4\pi)^2} t. \tag{C19}
\]

Notice that only the top contributes to the one-loop running of the $h_c$ wave function, since the twin top only couples quadratically to $h_c$, giving rise to a one-loop contribution that is not logarithmically divergent. After normalizing $h_c$ using Eq. (C19), including a $Z_2$ breaking mass term necessary to achieve a viable minimum and minimizing the potential, $h_c$ acquires a vacuum expectation value $h_c = h + \langle h \rangle$. This makes the wave function of $h$ (the Higgs field in the minimum) noncanonical again, due to the presence of $c_H$:

\[
Z_h(\langle h \rangle) = 1 + c_H \frac{\langle h \rangle^2}{f^2}. \tag{C20}
\]

After normalizing $h$ taking into account also this last effect, and including the LO gauge contribution, the desired contribution to the Higgs mass reads:

\[
\delta m^2_h|_{\text{IR}} = \frac{3 y^2_i}{8\pi^2} \left\{ (y^2_i t + \tilde{y}^2_4 t^2)(1 - c_H \xi + (c^2_H - d_H) \xi^2) - \frac{1}{16} \left[ (3 g^4_2 + 2 g^2_3 g^2_2 + g^4_2) t + 3 \tilde{g}^2_2 \right] \right\}
\]

\[+ \frac{1}{32\pi} \left[ 16 y^2_i g^2_3 t^2 + 16 \tilde{y}^2_4 \tilde{g}^2_2 t^2 \right] (1 - c_H \xi)
\]

\[+ \frac{1}{32\pi} \left[ -15 y^2_i t^2 - 12 \tilde{y}^2_4 \tilde{g}^2_2 t^2 + 3 \tilde{g}^2_2 (1 + c_H) \right]
\]

\[+ \frac{23}{96\pi^2} \left( y^2_i \tilde{g}^2_3 t + y^2_4 \tilde{g}^2_2 t^3 \right), \tag{C21}
\]

where we have highlighted the various contributions present in Eq. (C2) with the corresponding colors and set $t = \log m^2_\tau/m^2_t$, $\tilde{t} = \log m^2_\tau/m^2_t$. The Higgs vev has been defined by fixing the W mass according to

\[
m^2_W = \frac{g^2 \langle h \rangle^2}{4}, \quad \Rightarrow \langle h \rangle^2 = v^2 = \frac{1}{\sqrt{2} G_F} = 246 \text{ GeV}. \tag{C22}
\]

A numerical determination of the IR contribution $\delta m^2_h|_{\text{IR}}$ can be obtained by making use of the experimental value of the top quark mass to fix $y_i(m_t)$ and $\tilde{y}_i(m_t)$. In fact, the 1-loop RG equation for $y_i$ is decoupled from the twin sector at the order we are interested in and can be easily solved. Including only the orders required to match our calculation of the Higgs mass squared in Eq. (C21) we get:

\[
y_i(m_\tau) = y_i(m_t) = y_i(m_t) \left[ 1 - \frac{(g_s(m_t))^2}{4\pi^2} - \frac{9 y_i(m_t)^2}{64\pi^2} \right] \log \frac{m^2_\tau}{m^2_t} + \frac{22 g_s(m_t)^4}{(4\pi)^4} \log \frac{m^2_\tau}{m^2_t}\right]
\]

\[
gs(m_\tau) = \tilde{g}_S(m_\tau) = g_s(m_t) \left[ 1 - \frac{2 g_s(m_t)^2}{32\pi^2} \log \frac{m^2_\tau}{m^2_t} \right]. \tag{C23}
\]
which fixes $y_i(m_s)$ in terms of $y_i(m_t)$. As an input to our numerical analysis we use the PDG combination for the top quark pole mass $m_t = 173.21 \pm 0.51 \pm 0.71$ GeV [57]. This is converted into the top Yukawa coupling in the \( \overline{\text{MS}} \) scheme $y_t^{\overline{\text{MS}}}(m_t) = 0.936 \pm 0.005$ by making use of Eq. (62) of Ref. [65]. We then use $y_t(m_t) = y_t^{\overline{\text{MS}}}(m_t)$. For the strong interaction, we run the parameter measured at the scale of the Z boson mass, $g_S(m_Z) \sim 1.22$, to the scale $m_t$ to obtain $g_S(m_t)$.

APPENDIX D: OPERATOR ANALYSIS OF THE HEAVY-VECTOR CONTRIBUTION TO $\delta g_{Lb}$

In this Appendix we discuss the UV threshold contribution to $\delta g_{Lb}$ generated by the tree-level exchange of the composite vectors $\rho$ [adjoint of SO(7)] and $\rho^X$ [singlet of SO(7)] at zero transferred momentum. This effect arises at leading order from diagrams with a loop of heavy fermions, as in Fig. 5. Our simple effective operator analysis will show that the contribution of the $\rho$ identically vanishes, in agreement with the explicit calculation in the simplified model.

An adjoint of SO(7) decomposes under the custodial $SU(2)_L \times SU(2)_R$ as:

$$21 = (3, 1) + (1, 3) + 3 \times (2, 2) + 3 \times (1, 1).$$  (D1)

The first two representations contain the vector resonances that are typically predicted by ordinary CH models, namely $\rho_L$ and $\rho_R$. They mix at tree-level with the Z boson and in general contribute to $\delta g_{Lb}$. The remaining resonances do not have the right quantum numbers to both mix with the Z boson and couple to the left-handed bottom quark due to isospin conservation. As a result, only the components $\rho_L$ and $\rho_R$ inside the 21 can give a contribution to $\delta g_{Lb}$ at the 1-loop level.

In order to analyze such effects, we make use of an operator approach. We classify the operators that can be generated at the scale $m_t$ by integrating out the composite states, focusing on those which can modify the Z$b\bar{b}$ vertex at zero transferred momentum. In general, since an exact $P_{LR}$ invariance implies vanishing contribution to $g_{Lb}$ at zero transferred momentum, any $\delta g_{Lb}$ must be generated proportional to some spurionic coupling breaking this symmetry. In our model, the only coupling breaking $P_{LR}$ in the fermion sector is $\chi_L$, and a non-vanishing $\delta g_{Lb}$ arises at order $y_t^4$. The effective operators can be constructed using the CCWZ formalism in terms of the covariant spurion

$$\chi_L = \Sigma^i \Delta^i \Delta \Sigma,$$  (D2)

where $\Delta$ is defined in Eq. (3.11). By construction $\chi_L$ is a Hermitian complex matrix. Under the action of an element $g \in SO(8)$, it transforms as a $21_a + 27_h + 7 + 1 + 1$ of $SO(7)$ (where the 7 is complex), and its formal transformation rule is

$$\chi_L \rightarrow h(\Pi, g)\chi_L h^\dagger(\Pi, g), \quad h \in SO(7).$$  (D3)

As a second ingredient to build the effective operators, we uplift the elementary doublet $q_L$ into a $7 + 1$ representation of SO(7) by dressing it with NGBs:

$$Q_L = (\Sigma^i \Delta^i q_L).$$  (D4)

We will denote with $Q_L^{(7)}$ and $Q_L^{(1)}$ respectively the septuplet and singlet components of $Q_L$. Since $Q_L^{(1)}$ does not contain $b_L$ (it depends only on $t_L$), only $Q_L^{(7)}$ is of interest for the present analysis. Under a SO(8) transformation

$$Q_L^{(7)} \rightarrow h(\Pi, g)Q_L^{(7)}.$$  (D5)

The effective operators contributing to $\delta g_{Lb}$ can be thus constructed in terms of $\chi_L$, $d_L$, and $Q_L^{(7)}$. We find that the exchange of $\rho^X$ in the diagram of Fig. 5 can generate two independent operators,

$$O_{21} = \tilde{Q}_L^{(7)} \gamma^\mu T^a Q_L^{(7)} \text{Tr}(d_{L\chi_L} T^a),$$
$$O_{21}' = \tilde{Q}_L^{(7)} \gamma^\mu Q_L^{(7)}(d_{L\chi_L})_{88},$$  (D6)

where $T^a$ is an SO(8) generator in the adjoint of SO(7); the exchange of $\rho^X$ gives rise to other two:

$$O_1 = \tilde{Q}_L^{(7)} \gamma^\mu Q_L^{(7)} \text{Tr}(d_{L\chi_L}), \quad O_1' = \tilde{Q}_L^{(7)} \gamma^\mu Q_L^{(7)}(d_{L\chi_L})_{88}.$$  (D7)

Simple inspection reveals that only the septuplet component of $\chi_L$ contributes in the above equations. One can easily check that the operators of Eq. (D6) give a vanishing contribution to $\delta g_{Lb}$. In particular, the terms generated by the exchange of the $(2, 2)$ and $(1, 1)$ components of the $\rho$ give (as expected) an identically vanishing contribution. Those arising from $\rho_L$ and $\rho_R$ [obtained by setting $T^a$ in Eq. (D6) equal to respectively one of the $(3, 1)$ and $(1, 3)$ generators] give instead an equal and opposite correction to $g_{Lb}$. This is in agreement with the results of a direct calculation in the simplified model, from which one finds

\[ \text{Additional structures constructed in terms of } d_L \text{ and } \chi_L \text{ can be rewritten in terms of those appearing in Eqs. (D6) and (D7), hence they do not generate new linearly independent operators. Notice that } \text{Tr}(d_{L\chi_L} T^a) \propto f^{abc} d_{L\chi_L}^{(7)c}, (d_{L\chi_L})_{88} \propto f^{abc} d_{L\chi_L}^{(7)c}, (d_{L\chi_L})_{88} = -d_{L\chi_L}^{(7)c}, \text{Tr}(d_{L\chi_L}) = -d_{L\chi_L}^{(7)c} + d_{L\chi_L}^{(7)c}, \text{ where } d_{L\chi_L}^{(7)c} \text{ denotes the component of } \chi_L \text{ transforming as a (complex) fundamental of SO(7). A similar classification in the context of SO(5)/SO(4) models in Ref. [29] found only one operator, corresponding to the linear combination } O_1' - O_1. \]
that the contributions from $\rho_L$ and $\rho_R$ cancel each other. Finally, a nonvanishing $\delta g_{Lb}$ arises from the operators of Eq. (D7) generated by the exchange of $\rho^8$. Upon expanding in powers of the Higgs doublet, $O_4$ and $O'_4$ both match the dimension-6 operator $O_{Hq}$ of Eq. (5.11) and differ only by higher-order terms.

**APPENDIX E: EXPLICIT FORMULAS FOR THE EWPO**

In this Appendix we report the results of our calculation of the electroweak precision observables, in particular we collect here the explicit expression of the coefficients $a_{UV}^{\text{IR}}$, $a_{IR}$ of Eq. (5.12) and $b_{UV}$, $c_{UV}$, $b_{IR}$ of Eq. (5.17).

Let us start considering the $T$ parameter. For convenience, we split the UV contribution into two parts, redefining $a_{UV}$ as:

$$a_{UV} = a_{UV}^{\text{Fin}} + a_{UV}^{\text{Log}} \log \left( \frac{M_{\text{UV}}^2}{M_{\text{SM}}^2 + f_{Y_R}^2} \right).$$  

(E1)

The coefficients $a_{UV}^{\text{Fin}}$ and $a_{UV}^{\text{Log}}$ are obtained through a straightforward calculation, but their expressions are complicated functions of the Lagrangian parameters. We thus show them only in the limit $c_L = c_R \equiv c$ and $M_{\psi} = M_{S} \equiv M$, for simplicity. For $a_{IR}$ we give instead the complete expression. We find:

$$a_{UV}^{\text{Fin}} = \frac{1}{12} \left( -\frac{12M^4}{f^4y_R^4} + \frac{6f^2M^2y_R^2}{(f^2y_R^2 + M^2)^2} + \frac{9M^6}{(f^2y_R^2 + M^2)^4} \right) - \frac{8}{y_R^2} \left( -5y_R^8 + 2f^8M^2y_R^6 + 7f^4M^4y_R^4 + 12f^2M^6y_R^2 + 4M^8 \right) \sqrt{2f^5y_R^8(f^2y_R^2 + M^2)^2}$$

$$+ \frac{c^2(f^2y_R^2 + 2M^2)^2(3f^2y_R^2 - 5M^2)}{2f^5y_R^8(f^2y_R^2 + M^2)^2} + \frac{c^4}{2f^5y_R^8(f^2y_R^2 + M^2)^2} \\

a_{UV}^{\text{Log}} = \frac{f^5y_R^6 - f^4M^2y_R^4 - f^2M^4y_R^2 - 2M^6}{2f^5y_R^8}$$

$$+ \sqrt{2}c \left( 2f^5y_R^6 - 3f^4M^2y_R^4 + 3f^2M^4y_R^2 + 2M^6 \right) \frac{c^2(f^2M^4y_R^2 - 10M^6)}{f^5y_R^8}$$

$$a_{IR} = \frac{1}{2} + \frac{M_{\psi}^2M_{\rho}}{2(M_{\rho}^2 + f^2y_R^2)} + \sqrt{2} \left( \frac{c_LM_{\psi}^2 + 2c_Rf^2y_R^2}{M_{\rho}^2 + f^2y_R^2} \right)$$

(E2)

The derivation of $\delta g_{Lb}$ at 1-loop level is more involved and requires the computation of a series of diagrams. As explained in the text, we focus on those featuring a loop of fermions and NGBs (see Fig. 4), and that one with a loop of fermion and the tree-level exchange of a heavy vector (see Fig. 5). The coefficients $c_{UV}$ is generated only by the latter diagram; we find:

$$c_{UV} = \alpha_{4L}(\alpha_{4R} + \alpha_{2R})(1 + \frac{\sqrt{2}c_R}{f^2M_{\rho}^2\sqrt{2}M_{\rho}^2 + 2M_{\rho}^2 + y_R^2f^2})$$

(E3)

We remind the reader that in our numerical analysis we use $M_{\rho}^2/(g_{\rho}^0f^2) = 1$, see footnote 5. We redefine the other two coefficients as

![Diagrams](image-url)

**FIG. 4.** Diagrams with a loop of fermions and NGBs contributing to the $Z\bar{b}_Lb_L$ vertex. Here $f^i$ indicates any fermion (both heavy and light) in our simplified model; $\pi^\pm$ are the charged NGBs.
where $\delta_{\text{IR}}$, $\delta_{\text{IR}}^{\text{Fin}}$, and $\delta_{\text{IR}}^{\text{Log}}$ are generated by the diagrams in Fig. 4 only, whereas $\delta_{\text{UV}}$, $\delta_{\text{UV}}^{\text{Fin}}$, and $\delta_{\text{UV}}^{\text{Log}}$ parametrize the correction due to the tree-level exchange of a heavy spin-1 singlet in Fig. 5. As before, we report the expression of the IR corrections for simplicity; in the case of the coefficients with a bar, generated by the diagram of Fig. 5, we further set $\alpha_{1L} = \alpha_{1R}$ and $\alpha_{2L} = \alpha_{2R}$. We find:

$$
\begin{align*}
\delta_{\text{IR}}^{\text{Fin}} &= -\frac{2f^6\gamma_R^0 - 4f^4M^2\gamma^2_R - 4f^2M^4\gamma^2_R + M^6}{12(f^2\gamma_R^2 + M^2)^2} - \frac{c(f^6\gamma_R^0 + 4f^4M^2\gamma^2_R - 2f^2M^4\gamma^2_R + M^6)}{6\sqrt{2}f^2\gamma_R^2(f^2\gamma_R^2 + M^2)^2}, \\
\delta_{\text{IR}}^{\text{Log}} &= \frac{1}{6} - \frac{M^2}{6f^2\gamma_R^2} - \frac{c^2M^4}{3\sqrt{2}f^2\gamma_R^2} - \frac{c^2M^2}{3f^2\gamma_R^2} - \frac{c(-f^4\gamma_R^0 + 2f^2M^2\gamma_R^2 + M^4)}{6\sqrt{2}f^4\gamma_R^2}, \\
\delta_{\text{UV}}^{\text{Fin}} &= \frac{f^2M^2\alpha_{1L}\alpha_{1R}g_{\rho}(f^4\gamma_R^0(\alpha_{1L} + 2\alpha_{1R}) + f^2M^2\gamma_R^2(3\alpha_{1L} + 8\alpha_{1R}) + 2M^4(\alpha_{1L} + \alpha_{1R})))}{4M^4_{\rho}(f^2\gamma_L^2 + M^2)(f^2\gamma_R^2 + M^2)^2} \\
&+ \frac{c^2M^2\alpha_{1L}\alpha_{1R}g_{\rho}(2\alpha_{1L} + \alpha_{1R}) + 2M^2\alpha_{1L})}{\sqrt{2}M^2_{\rho}(f^2\gamma_L^2 + M^2)(f^2\gamma_R^2 + M^2)^2}, \\
\delta_{\text{UV}}^{\text{Log}} &= \frac{c^2M^2\alpha_{1L}\alpha_{1R}g_{\rho}(\alpha_{1L} - \alpha_{1R})}{\sqrt{2}M^2_{\rho}(f^2\gamma_L^2 + M^2)^2} + \frac{f^4M^2\alpha_{1L}\alpha_{1R}g_{\rho}^2}{2M^2_{\rho}(f^2\gamma_L^2 + M^2)^2}.
\end{align*}
$$

(E5)

For the IR coefficients we give instead the full expressions. We find:

$$
\begin{align*}
\delta_{\text{IR}} &= \frac{1}{6} + \frac{M^2_{\rho}M^2_{2}}{6(M^2_{\rho} + f^2\gamma_R^2)^2} + \sqrt{2} \frac{c_{L}M^2_{\rho}M^2_{\eta}}{3(M^2_{2} + f^2\gamma_R^2)} + \sqrt{2} \frac{c_{R}f^2\gamma_R^2}{12(M^2_{2} + f^2\gamma_R^2)}, \\
\delta_{\text{IR}} &= \alpha_{1L}\alpha_{1R}g_{\rho}^2 \frac{f^4M^2\gamma_R^2}{M^2_{2}2(f^2\gamma_L^2 + M^2)(f^2\gamma_R^2 + M^2)^2}.
\end{align*}
$$

(E6)

Notice that the IR corrections $\alpha_{L}$ and $\alpha_{R}$ are related to each other and parametrize the running of the effective coefficients $\tilde{c}_{Hq}$, $\tilde{c}'_{Hq}$, and $\tilde{c}_{Ht}$, as explained in the main text.

Finally, we report the contribution to $\tilde{S}$ generated in our simplified model by loops of heavy fermions. We do not include this correction in our electroweak fit, because in the perturbative region of the parameter space it is subdominant with respect to the tree-level shift of Eq. (5.6). Rather, we use this computation as an additional way to estimate the perturbativity bound, as discussed in Sec. III B. Analogously to what we did for $\tilde{T}$ and $\delta_{gLb}$, we parametrize the fermionic contribution to $\tilde{S}$ as:

$$
\Delta \tilde{S}_{\eta} = \frac{g^2}{8\pi^2} \xi \left[ \left( 1 - c_L^2 - c_R^2 \right) \log \frac{m^2_{\eta}}{M^2_{\eta}} + \left( 1 - c_L^2 - c_R^2 \right) \log \frac{m^2_{\eta}}{M^2_{\eta}} \right] \\
+ \frac{g^2}{16\pi^2} \xi \left[ \delta_{\text{UV}}^{\text{Fin}} + \delta_{\text{UV}}^{\text{Log}} \log \left( \frac{M^2_{\eta}}{M^2_{2} + f^2\gamma_R^2} \right) + \frac{3}{12} \xi \log \left( \frac{\tilde{M}^2_{\eta}}{M^2_{2} + f^2\gamma_R^2} \right) \right] \\
+ \frac{g^2}{16\pi^2} \xi \delta_{\text{IR}} \frac{\gamma_R^2 f^2}{M^2_{\eta}} \log \frac{M^2_{\eta}}{m^2_{\eta}}.
$$

(E7)
Terms in the first line are logarithmically sensitive to the UV cutoff, the second line contains the UV threshold corrections, while the IR running appears in the third line. The UV thresholds include a contribution from the twin composites $\Psi_7$ and $\Psi_1$, parametrized by $\tilde{s}_{UV}^{\text{Fin}}$ and $\tilde{s}_{UV}^{\text{Log}}$. At leading order in $y_L$, by virtue of the twin parity invariance of the strong sector, such a contribution can be obtained from that of $\Psi_7$ and $\Psi_1$ (i.e. from $s_{UV}^{\text{Fin}}$ and $s_{UV}^{\text{Log}}$) by simply interchanging the tilded quantities with the untilded ones. Higher orders in $y_L$ break this symmetry and generate different corrections in the two sectors. We performed the computation of the UV coefficients for $\Delta s_{IR}$ derived up to order $y_L^2$.

\[
s_{\text{UV}}^{\text{Fin}} = \frac{1}{2} - \frac{6c_L c_R M_S M_{\Psi}(f^2 y_R^2 + M_S^2 + M_{\Psi}^2)}{(f^2 y_R^2 + M_S^2 - M_{\Psi}^2)^2} + \frac{(c_L^2 + c_R^2)}{6} \left( \frac{24 M_S^2 M_{\Psi}^2}{(f^2 y_R^2 + M_S^2 - M_{\Psi}^2)^2} - 7 \right),
\]

\[
s_{\text{UV}}^{\text{Log}} = \frac{2(M_S^2 + f^2 y_R^2)}{(M_S^2 - M_{\Psi}^2 + f^2 y_R^2)^2} \left[ 6c_L c_R M_S M_{\Psi} + c_R^2 M_S^2 (f^2 y_R^2 + M_S^2 - M_{\Psi}^2) + c_L^2 (f^2 y_R^2 + M_S^2 - M_{\Psi}^2) \right],
\]

\[
s_{\text{IR}} = \frac{M_S^2 M_{\Psi}^2 - f^2 y_R^2 (f^2 y_R^2 + M_S^2)}{6M_{\Psi}^2 (f^2 y_R^2 + M_S^2)^2} - \frac{2}{3M_{\Psi}^2 (f^2 y_R^2 + M_S^2)} - \frac{c_L}{3} \sqrt{2M_S (M_{\Psi}^2 - f^2 y_R^2)}.
\]

(E8)

**APPENDIX F: THE EW FIT**

For our analysis of the electroweak observables we make use of the fit to the parameters $\epsilon_{1,2,3,6}^{\text{SM}}$ [66–68] performed in Ref. [69] (see also Ref. [26]). The central values there obtained for the shifts $\Delta \epsilon_i \equiv \epsilon_i - \epsilon_i^{\text{SM}}$ and the corresponding correlation matrix are

\[
\begin{align*}
\Delta \epsilon_1 &= 0.0007 \pm 0.0010 \\
\Delta \epsilon_2 &= -0.0001 \pm 0.0009 \\
\Delta \epsilon_3 &= 0.0006 \pm 0.0009 \\
\Delta \epsilon_6 &= 0.0003 \pm 0.0013
\end{align*}
\]

\[
\rho = \begin{pmatrix}
1 & 0.8 & 0.86 & -0.33 \\
0.8 & 1 & 0.51 & -0.32 \\
0.86 & 0.51 & 1 & -0.22 \\
-0.33 & -0.32 & -0.22 & 1
\end{pmatrix}.
\]

(F1)

We can directly relate $\Delta \epsilon_1$ to $\Delta \tilde{T}$ and $\Delta \epsilon_3$ to $\Delta \tilde{S}$ by using the results of Refs. [45,47], and furthermore $\Delta \epsilon_6 = -2 \delta_{\{6\}}$. We set $\Delta \epsilon_2 = 0$ in our study, since its effect is subdominant in our model as well as in CH models [47]. We thus make use of Eq. (F1) to perform a $\chi^2$ test of the compatibility of our predictions with the experimental constraints. The $\chi^2$ function is defined as usual:

\[
\chi^2 = \sum_{ij} (\Delta \epsilon_i - \mu_i)((\sigma^2)_{ij}^{-1} (\Delta \epsilon_j - \mu_j)), \quad (\sigma^2)_{ij} = \sigma_i \rho_{ij} \sigma_j,
\]

(F2)

where $\mu_i$ and $\sigma_i$ denote respectively the mean values and the standard deviations of Eq. (F1), while $\Delta \epsilon_i$ indicates the theoretical prediction for each EW observable computed in terms of the Lagrangian parameters. After deriving the $\chi^2$, we perform a fit by scanning over the points in our parameter space keeping only those for which $\Delta \chi^2 \equiv \chi^2 - \chi^2_{\text{min}} < 7.82$, the latter condition corresponding to the 95% confidence level with 3 degrees of freedom. Using this procedure, we convert the experimental constraints into bounds over the plane $(M_{\Psi}, \xi)$.

**APPENDIX G: ESTIMATES OF THE PERTURBIVITY BOUND**

This Appendix contains details on the derivation of the perturbative limits discussed in Sec. III B. As explained there, we consider the processes $\pi^a \pi^b \rightarrow \pi^a \pi^b$ and $\pi^a \pi^b \rightarrow \bar{\psi} \psi d^d$, where $\psi = \{\Psi_7, \Psi_1\}$ and all indices transform under the fundamental representation of the unbroken $SO(7)$. In order to better monitor how the results depend on the multiplicity of NGBs and fermions, we perform the calculation for a generic $SO(N)/SO(N - 1)$ coset with $N_f$ composite fermions $\psi$ in the fundamental of $SO(N - 1)$. Taking $N = 8$ and $N_f = 2 \times 3 = 6$ thus reproduces the simplified model of Sec. III A.

The perturbative limits are obtained by first expressing the scattering amplitudes in terms of components with definite $SO(N - 1)$ quantum numbers. In the case of $SO(7)$ the product of two fundamentals decomposes as $7 \otimes 7 = 1 \oplus 21_a \oplus 27_s$, where the indices $a$ and $s$ label respectively the antisymmetric and symmetric two-index representations. A completely analogous

\[095036-28\]
decomposition holds in the general case of $SO(N)/SO(N - 1)$,\footnote{One has $N \otimes N = 1 \oplus [N(N - 1)/2]_e \oplus [N(N + 1)/2 - 1]_o$.} but for simplicity we will use the $SO(7)$ notation in the following to label the various components. The leading tree-level contributions to the scattering amplitudes arise from the contact interaction generated by the expansion of the NGB kinetic term of Eq. (3.4) and from the NGB-fermion interactions of Eq. (3.9). The structure of the corresponding vertices implies that the four-NGB amplitude has components in all three irreducible representations of $SO(N - 1)$ and contains all partial waves. The amplitude with two NGBs and two fermions, instead, has only the antisymmetric component of $SO(N - 1)$ and starts with the $p$-wave. At energies much larger than all masses the amplitudes read
\[
\mathcal{M}(\pi^a \pi^b \rightarrow \pi^c \pi^d) = \frac{s}{f^2} \delta^{ab} \delta^{cd} + \frac{t}{f^2} \delta^{ac} \delta^{bd} + \frac{u}{f^2} \delta^{ad} \delta^{bc},
\]
\[
\mathcal{M}(\pi^a \pi^b \rightarrow \bar{\Psi}^c_{\ell_L} \Psi^d_{\ell_L}) = \frac{s}{2f^2} \sin \theta (\delta^{ac} \delta^{bd} - \delta^{ad} \delta^{bc}),
\]
\[
\mathcal{M}(\pi^a \pi^b \rightarrow \bar{\Psi}^c_{\ell_R} \Psi^d_{\ell_R}) = \frac{s}{2f^2} \sin \theta (\delta^{ac} \delta^{bd} - \delta^{ad} \delta^{bc}).
\]

(G1)

They decompose into irreducible representations of $SO(N - 1)$ as follows:
\[
\mathcal{M}(\pi^a \pi^b \rightarrow \bar{\Psi}^c_{\ell_L} \Psi^d_{\ell_L}) = \frac{s}{f^2} \sin \theta,
\]
\[
\mathcal{M}(\pi^a \pi^b \rightarrow \bar{\Psi}^c_{\ell_R} \Psi^d_{\ell_R}) = \frac{s}{f^2} \sin \theta.
\]

(G2)

Performing a partial wave decomposition we get
\[
\mathcal{M}^{(r)} = \sum_{\lambda_i, \lambda_f} M^{(r)}_{\lambda_i, \lambda_f} = 16 \pi k^{(i)} k^{(f)} \sum_{j=0}^{\infty} a^{(r)}_j (2j + 1) \times \sum_{\lambda_i, \lambda_f} D^j_{\lambda_i, \lambda_f} (\theta),
\]

(G3)

where $\lambda_i, \lambda_f$ are the initial and final state total helicities, and $k^{(i)}(k^{(f)})$ is equal to either 1 or $\sqrt{2}$ depending on whether the two particles in the initial (final) state are distinguishable or identical respectively. In the above equation $\mathcal{M}^{(r)}$ should be considered as a matrix acting on the space of different channels. The coefficients $a^{(r)}_j$ are given by
\[
a^{(r)}_j = \frac{1}{32 \pi k^{(i)} k^{(f)}} \int_0^\pi d \theta \sum_{\lambda_i, \lambda_f} D^j_{\lambda_i, \lambda_f} (\theta) \mathcal{M}^{(r)}_{\lambda_i, \lambda_f}.
\]

(G4)

and act as matrices on the space of (elastic and inelastic) channels with total angular momentum $j$ and $SO(N - 1)$ irreducible representations $r$. They can be rewritten as a function of the scattering phase as
\[
a^{(r)}_j = \frac{e^{2i \delta^{(r)}_j}}{2l} - i \delta^{(r)}_j.
\]

(G5)

Our NDA estimate of the perturbativity bound is derived by requiring this phase to be smaller than maximal:
\[
|\delta^{(r)}_j| < \frac{\pi}{2} \Rightarrow |a^{(r)}_j| < \frac{\pi}{2}
\]

(G6)

Let us consider first the case $r = 1$, corresponding to the amplitude singlet of $SO(N - 1)$. The only contribution comes from the four-NGB channel. Since the helicities of the initial and final states are all zeros, in this particular case the Wigner functions $D^1_{\lambda_i, \lambda_f} (\theta)$ reduce to the Legendre polynomials:
\[
a^{(1)}_j = \frac{1}{64 \pi} \int_0^\pi d \theta P^1_j (\cos \theta) \mathcal{M}^{(1)}.
\]

(G7)

The first and strongest perturbativity constraint comes from the $s$-wave amplitude, which corresponds to $j = 0$. We find:
\[
a^{(1)}_0 = \frac{N - 2}{32 \pi} \frac{s}{f^2},
\]

(G8)

where $N = 8$ in our case. From Eqs. (G6) and (G8), one obtains the constraint of Eq. (3.15).

We analyze now the constraint from the scattering in the antisymmetric representation, $r = 21$. In this case, both the NGB and the fermion channels contribute; the process $\pi \pi \rightarrow \pi \pi$ is however independent of the fermion and Goldstone multiplicities and can be neglected in the limit of $N$ and $N_f$. The process involving fermions is a function of $N_f$ and generates a perturbative limit which is comparable and complementary to the previous one. We have:
\[ a_j^{(2)} = \sum_{\delta_j = \pm 1} \frac{1}{32\pi} \int_0^\pi d\theta D_{0j,\delta_j}(\theta) M_{0j,\delta_j}^{(2)}. \quad \text{(G9)} \]

As anticipated, this equation vanishes for \( j = 0 \), so that the strongest constraint is now derived for \( p \)-wave scattering, with \( j = 1 \). We have

\[ a_1^{(2)} = \frac{N_f s}{24\sqrt{2\pi f^2}}. \quad \text{(G10)} \]

From Eqs. \( \text{(G6)} \) and \( \text{(G10)} \) follows the constraint of Eq. \( (3.16) \).
