ABSTRACT

The objective of this study was to evaluate the occurrence of anti-Leptospira spp. antibodies in female buffalo in the state of Pernambuco. A total of 123 female buffalo blood samples were collected from five properties distributed in the state of Pernambuco. The microscopic agglutination test was used to study anti-Leptospira spp. antibodies. The occurrence of anti-Leptospira spp. antibodies was 28.5% (35/123; CI 20.7–37.3%) and on different properties, the occurrence ranged from 28.6% to 80.0%, with 100% of the properties showing animals with positive results. The serovars of the serogroup Sejroe with a higher incidence were Hardjoprajitino (CTG strain, 49.1%) and Hardjo (Prajtino genotype, 43.2%), followed by serogroup Grippotyphosa with the Grippotyphosa serovar (3.9%), serogroup Pomona with the Pomona serovar (1.9%), and the Icterohaemorrhagiae serovar Copenhageni (1.9%). This was the first record of the occurrence of anti-Leptospira spp. antibodies in female buffalo in the state of Pernambuco. Control measures are necessary to prevent health and economic losses, given that the agent involved affects animal reproduction, triggering drops in conception rates or even clinical cases of abortion.

Introduction

Leptospirosis is an anthropozoonosis of wide geographic distribution that occurs in rural and urban areas and is caused by pathogenic bacteria belonging to the Spirochaetales order, Leptospiraceae family, and Leptospira genus. In tropical and subtropical countries, it shows a high prevalence as a consequence of the temperature and humidity conditions that favor the persistence of the bacteria in the environment. In cattle raising, leptospirosis is an important cause of production drops associated with reproductive issues. In infected pregnant females, the bacteria can cross the placenta at any stage of the pregnancy, causing embryonic losses, abortions, stillbirths, or debilitated births. However, estrus repetition is a characteristic that can be observed for many months.

In Brazil, many studies on the prevalence of different Leptospira spp. serovars in buffalo have been conducted, permitting an understanding of the disease’s epidemiology, which reflects the ecological relationship between humans and chronically infected mammalian reservoirs. In the state of São Paulo, Vasconcellos et al. isolated Leptospira santarosai from buffalos of Vale do Ribeira, whereas Favero et al. found 43.7% positives in 879 serum samples with a higher frequency of the serovars Hardjo (43.3%) and Wolfii (32.5%). In the state of Pará, Silva et al., researching agglutinins of anti-Leptospira, verified a 67.7% positivity rate in 127 analyzed serum samples, of which 15.7% were reactive to serovar Hardjo. Viana et al., in the state of Amazonas, obtained 80.0% positives (164/205) with a higher frequency of serogroup Autumnalis variant autumalis and serogroup Sejroe and varieties Hardjo and Wolfii.

The epidemiological importance of leptospirosis in buffalo must be considered: infected animals may act as sources of infection for other animals raised on the same property as well as for people who manage them because as carriers, buffalo eliminate the agent into the environment, mainly through urine. Among the main risk factors involving leptospirosis in buffalo are their access to diverse ecosystems and their habit of bathing in rivers, creeks, and flooded areas.

Owing the lack of data on this disease in the northeast region of the country and the economic losses related to leptospirosis in buffalo, the objective of this study was to determine the occurrence of anti-Leptospira spp. antibodies in buffalo originating from herds in the state of Pernambuco, Brazil.

Methodology

Study area

A transversal study design was carried out through convenience sampling, not probabilities, in five counties distributed in the state of Pernambuco, Brazil. The properties were chosen for convenience, including the counties of Quipapá (5 animals), Ribeirão (42 animals), Canhotinho (21 animals), Agrestina (5 animals), and ÁguaPreta (50 animals).

Sampling

In total, 123 blood samples were collected from female buffalo of reproductive age, with or without a history of reproductive problems, raised on a semi-intensive or extensive regimen, and with no history of vaccination for leptospirosis.

Sample collection

Blood samples were obtained by venipuncture of the coccygeal vein using Vacutainer® disposable 25 × 0.8 mm needles and sterilized 5-mL Vacutainer® tubes. Afterward, the samples were packed into isothermal boxes containing recyclable ice and forwarded to the laboratory where they were centrifuged at 900 × g for 10 min. After this procedure, the samples were filled in polypropylene tubes, properly identified, and stored in a freezer at −20 °C until processing.

Serum analysis

For the study of anti-Leptospira spp. antibodies, the microscopic agglutination test (MAT) was used. Samples considered positive were those with titrations equal to or higher than 100. When agglutinations occurred between different serovars with the same titration, both serovars were considered reactive, and in cases of different titrations, the serovar with the higher titration prevailed. Titrations of the seropositive samples were carried out by employing a dilution of 1:100 to 1:3200, employing the serogroups for herbivores, available at the Serviço de Diagnóstico de Zoonoses (SDZ) UNESP Botucatu – São Paulo (Table 1).

The occurrence of anti-Leptospira spp. antibodies was verified in 28.5% (35/123; CI 20.7–37.3%) of the samples analyzed in Pernambuco. When the occurrence of antibodies in buffaloes on different properties was analyzed, a range of 29.0–80.0% was observed with at least one positive animal per serovar. The geographical distribution of positive buffaloes is shown in Fig. 1 and Table 2.

Among the positive samples, 14 (40.0%) reacted to more than serovar. The serovars of serogroup Sejroe with higher occurrences were Hardjo (strain CTG – 49.1%) and Hardjo (genotype Prajtino – 43.2%), followed by serogroup Grippotyphosa with the serovar Grippotyphosa (3.9%), serogroup Pomona (1.9%), and Icterohaemorrhagiae serovar...

| **Total** | 100 | 51 |

Copenhageni (1.9%) (Table 3). These serovars showed titrations varying from 100 to 800 (Table 4).

No significant difference was observed for the variable history of abortion (p = 0.405) associated with MAT; however, a higher occurrence of 31% of seropositive animals was observed in the properties with a history of abortion.

**Discussion**

This is the first study of serological reaction by Leptospira serogroup Sejroe (CTG and Prajtin) in female buffalo in the state of Pernambuco, Brazil. Results are similar to those found for the occurrence of anti-Leptospira spp. antibodies in buffalo formerly reported in the country by Brasil et al. in Paraíba with 27.9% of seropositive animals; however, some serogroups found by those authors were distinct from the ones observed in this study, for example Bratislava (11.0%) and Canicola (5.9%). Silva et al. investigated the occurrence of anti-Leptospira spp. antibodies in buffalo in the state of Pará and identified 67.7% of animals as seropositive, highlighting serovar Hardjo genotype Prajtko, showing the importance of this serovar to the species.

Among the herds of the studied municipalities, Ribeirão was the one that presented a greater variety of serogroups, Grippotyphosa, Sejroe (CTG and Prajtn), Pomona and Icterohaemorrhagiae (Copenhageni), suggesting the contact of the buffaloes with wild animals and of production that function as reservoirs for these serovars.

Despite the low occurrence of the serogroup Grippotyphossa serovar Grippotyphosa, the latter presented a reagent sample with an 800 titer. According to OIE, the occurrence of any serovar with titers between 100 and 200 may indicate infection or vaccine antibody residue, however higher titers may disease production of a carrier that can eliminate the agent in the urine in the stage of leptospirosis that contaminates the environment, acting as a source of infection for other animals and humans. It is noteworthy that the animals sampled in this study had no history of vaccination and therefore the high titration indicates recent infection, and the positive animals are considered sources of infection.

Differences found between the results obtained in the present study and those reported by Carvalho et al. (p<0.001) (70.58%), Langoni et al. (87.70%), Silva et al. (p<0.0003) (67.70%), and Viana et al. (p<0.05) (80.00%) on the occurrence of anti-Leptospira spp. antibodies in buffalo may be partially attributed to the quantity of types and serogroups utilized in serological studies.
screening and possible environmental differences related to the studied region, such as the hygienic/sanitary practices adopted in the management of the herd; the level and type of exposure to other domestic, wild, and synanthropic animals; and also rodents that participate in the epidemiological chain of leptospirosis. Otherwise, a comparison between the results obtained in different studies is difficult to analyze, because the MAT technique may vary among laboratories according to their collection of antigens.

This study found a higher occurrence of serogroup Sejroe with serovar Hardjo (Prajtino and CTG). The strain CTG was isolated for the first time in samples from cattle in Brazil by Moreira, being typified in the Royal Tropical Institute, Amsterdam, Holanda. Since 1991, many studies in Brazil have highlighted the importance of serogroup Sejroe in bovine leptospirosis, including the serovar of this serogroup in the antigen panel. According to those authors, a high prevalence of infection has been demonstrated in the herd (75%) and individuals (44.2%) with a predominance of serovars of the serogroup Sejroe (80.3%). Infection in buffalo by this serogroup may be associated with their proximity to bovines, because on 80.0% (4/5) of the properties studied, bovines were present.

The elevated occurrences of seropositive female buffalo for serogroup Sejroe serovar Hardjo (CTG and Prajitino) showed the importance of that species in the epidemiology for leptospirosis involving those serovars, because these animals may act as carriers and contribute to environmental contamination through urine elimination, acting in this way as a source of infection of other animals and humans. The presence of seropositive animals may assure the persistence of this serogroup in the herds, besides causing an economic impact, generating reproductive disturbances as well as hemolytic cases.

Like bovines, buffaloes suffer abortions associated with infection by Leptospira spp. It is known that serovars of the serogroup Sejroe, the Hardjo and its strains and genotypes are described as causes of abortion in that species. Regarding the abortion history, no significant association was observed in this study. However, it was verified that the property with a history of miscarriages (20%, 1/5) presented buffaloes infected the different serogroups (Grippotyphosa; Icterohaemorrhagiae; Pomona; Sejroe) which may indicate the participation of Leptospira spp. as agent responsible for reproductive disturbances in this herd.

In the literature, there are few seroepidemiological studies in buffalo. Therefore, it is necessary to execute other studies by using isolation and molecular techniques to investigate the importance of this serogroup as a cause of abortion in buffalo. Pinto et al. reinforce the necessity of studies in different countries and a greater standardization of the diagnosis of Leptospira spp. infection.

**Conclusion**

This is the first record of the occurrence of anti-Leptospira-specific antibodies against the serogroup Sejroe, serovar Hardjo (CTG and Prajitino) in buffalo in the state of Pernambuco, Brazil. Control measures are necessary to prevent sanitary and economical losses, because the agent involved affects animal reproduction and poses hazards to public health.
